when the insulin is resuspended. Sometimes, there are no visible changes, but the insulin appears to lose its effect, with the usual dosages failing to lower blood glucose. Particularly in hot countries, insulin is best stored in a refrigerator; if one is not available, insulin can be protected by a damp flannel or a porous clay pot containing some water or wet sand, placed in a cool part of the room. Even these measures may be unnecessary, as most insulin preparations can survive being kept at 25°C or more for up to 6 months, and will retain most of their biologic activity [109].

### **Food and drink**

When traveling abroad, it is essential to know the basic form of carbohydrate that is eaten locally, and useful to learn to judge quantities of foods such as pasta or rice. Items selected from local menus can be supplemented with bread, biscuits or fruit. Sugar-free drinks are difficult to obtain in many countries but bottled water is safe and usually available.

Quick-acting carbohydrate to treat hypoglycemia should always be carried and stored appropriately: dextrose tablets may disintegrate or set hard in hot and humid climates unless wrapped in silver foil or stored in a suitable container, while the temperature-dependence of chocolate is well known. Cartons of fruit juice cannot be reused once opened; a plastic bottle with a screw top is preferable. Sealed packets of powdered glucose may be the best option for hot damp climates.

Traveling companions should carry a supply of quick-acting carbohydrate (and glucagon) for emergency use, and should know how to test the patient's blood glucose and how to treat hypoglycemia.

### **Intercurrent illness**

Any intercurrent infection should be treated promptly and appropriately, with adequate replacement of fluids and carbohydrate in the form of drinks if possible. Insulin therapy must never be discontinued and dosage may have to be increased, and blood glucose should be checked every 3–4 hours, with testing for urinary ketones is possible. The “sick-day” rules described in Chapter 27 should be followed.

### **Recreational activities**

The impact of physical exercise and sport on diabetes is discussed in Chapter 23. Patients need advice about strenuous and unaccustomed exercise during holidays, such as beach sports or prolonged and vigorous dancing. Swimming alone should be avoided. The risks of alcohol and recreational drugs have been described above.

---

## **Leaving home**

As a child with diabetes grows up, inevitably parental input to the day-to-day management of diabetes is reduced with increasing autonomy of the adolescent. In teenage years this is often manifest by a deterioration in glycaemic control (Chapter 52). Even in

adolescence, parents or guardians still have a very important role with the provision of regular meals and in the recognition and treatment of hypoglycemia, particularly at night. Therefore, the eventual move away from the parental home can pose problems, especially if the individual with T1DM is living alone and if they move to another town. Social isolation may exist until new friends are made and access to alcohol and recreational drugs may increase, with the attendant risks that have been highlighted. Sexual activity may commence or increase, introducing issues of sexual health and pregnancy, and novel forms of exercise may be more readily available. On leaving the parental home, individuals often become removed from the familiar support of the health care professionals in their local diabetes centre and initially do not have the similar contact and immediate access to advice from doctors and nurses about diabetes – precisely at a time it may be most needed. It is a disturbing fact that “living alone” was associated with a more than fourfold increase risk of mortality from acute metabolic complications of diabetes in the Diabetes UK Cohort Study [98].

### **Students with diabetes**

Particular emphasis has been placed on the welfare of students with T1DM who have left home to attend university or college. In part, this has been because of high-profile instances where individuals with T1DM have died shortly after commencing university [110]. Several surveys have suggested that students do find diabetes more difficult to manage, although this does not necessarily translate into a rise in glycated hemoglobin concentrations [111–116]. Barriers to diabetes control include fear of hypoglycemia, diet, irregular schedules, lack of parental involvement, limited finances, recreational drugs and alcohol. There is a natural desire for students with diabetes not to appear different from their peers and this may lead them to assign a lower priority to diabetes management than they would normally and to undertake potentially high risk activities.

Diabetes services need to be responsive to the needs of adolescents and young adults who are leaving home. Such individuals are often poorly informed about the inherent risks associated with, for example, alcohol and drugs [95,116] and these and other needs may not be addressed in the context of a routine diabetes consultation [115]. Before the individual leaves home, a formal re-education program should be offered in which alcohol, drugs, exercise, sex and sick-day management are discussed [117]. Individuals leaving home need to think about their mealtimes; it can be difficult for someone living alone to motivate themselves to prepare substantial meals and many adolescents have limited cooking skills. Regular meals are provided in university halls of residence, but the nature and content of the food, particularly the carbohydrate content, may not be ideal. Students should be advised to monitor blood glucose levels frequently during examination periods. Many students report that studying and undertaking examinations can cause marked fluctuations in glucose levels – this may partly be associated with stress or varying carbohydrate intake. Both acute hypoglycemia and hyperglycemia

impair cognitive function and can cause mood changes and may affect examination performance adversely. Therefore, students should try to optimise glucose control during examinations and ensure that a supply of rapid-acting carbohydrate is available during an examination.

Many students may prefer to remain under the care of their “home” diabetes team, but it is important that they know how to contact local specialist diabetes services in the university town for advice or assistance. Medical practitioners in university health services have a duty to ensure that students with diabetes are offered regular diabetes follow-up. The student should be encouraged to confide at an early stage with a reliable friend or colleague about their diabetes and the potential problems that may arise [117]. This may cause embarrassment talking to recent acquaintances about having diabetes. University authorities have a pastoral responsibility for students with diabetes [111].

## Monitoring Diabetes

**Andrew J. Farmer**

Department of Primary Health Care, University of Oxford, Oxford, UK

### Keypoints

- Glycated hemoglobin (HbA<sub>1c</sub>) levels will increasingly be presented using the International Federation of Clinical Chemistry standard expressed as mmol/mol of unglycated hemoglobin. The equivalent of the current HbA<sub>1c</sub> levels of 6.5% and 7.5% are 48 mmol/mol and 59 mmol/mol.
- For patients with type 1 diabetes (T1DM), blood glucose control should be monitored with measurement of HbA<sub>1c</sub> every 2–6 months depending on the level and stability of blood glucose control and change in therapy.
- Patients with T1DM should be encouraged to self-monitor blood glucose with capillary blood glucose meters. With treatment regimens intended to produce intensive glycemic control testing should be frequent (e.g. four or more times a day).
- For patients with type 2 diabetes (T2DM), blood glucose control should be monitored using high precision methods for measurement of HbA<sub>1c</sub> every 2–6 months depending on the level and stability of blood glucose control and change in therapy.
- For non-insulin-treated patients with T2DM, self-monitoring of blood glucose is unlikely to be cost-effective for well-controlled patients and should therefore only be used when training and support is available and a clear purpose for use identified.

### Why monitor?

*“The overall goal of diabetes management is to achieve as near normal physiological or ideal values as possible, without detriment to quality of life and, for glucose control in particular, without causing significant hypoglycemia” [1].*

Diabetes is a disorder of glucose homeostasis. It currently affects 285 million people worldwide and is expected to affect 435 million by 2039 [2]. For people without diabetes, glucose levels are maintained in the range of 4–6 mmol/L (80–110 mg/dL). When blood glucose levels increase as a result of glycogen conversion or eating carbohydrate-containing food, insulin is released restoring homeostasis through hepatic conversion of glucose to glycogen, and uptake of glucose into muscle and fat cells. Conversely, if blood glucose levels fall too low as a result of exercise or lack of food, glucagon is released causing hepatic conversion of glycogen to glucose.

People with type 1 diabetes mellitus (T1DM) lack the normal homeostatic mechanism to control levels of blood glucose, while people with type 2 diabetes mellitus (T2DM) have an impaired

or absent response. In addition to insulin, which is the most important of the regulatory mechanisms, growth hormone, thyroxine and catecholamines are also important counter-regulatory hormones and lead to increases in blood glucose levels. The aim of monitoring glycemic control is to diagnose the nature of any impairment of homeostatic mechanisms, allow patients to understand the nature of their disorder, determine optimum times for initiating therapeutic intervention; and guide the day-to-day adjustment of management regimens.

Glycated hemoglobin (HbA<sub>1c</sub>) and blood glucose are the two most frequently used measures of glycemia in current practice. Glycated hemoglobin provides information about overall control of glucose levels in the previous 6–8 weeks allowing assessment of the need for therapy and therapeutic response with minimal within-person variation in measurement. Blood glucose concentrations provide information about the day-to-day level of control, variation in control and response to therapeutic intervention. Measurement and interpretation of blood glucose, however, may be difficult because of potentially wide within-person variations in measures other than when fasting. Prospective observational and intervention studies have confirmed that HbA<sub>1c</sub> levels are related to long-term disease outcomes [3,4]. Both HbA<sub>1c</sub> and blood glucose therefore, along with a number of other tests, including measurement of urinary glucose for those who do not intend to aim for intensive glucose control, remain an option for helping to identify poor glycemic control and to facilitate the adjustment of therapy to achieve optimal glucose levels.

Figure 25.1 The Amadori reaction.

## Tests and their characteristics

### Glycated hemoglobin

Quality controlled HbA<sub>1c</sub> measurement has a central role in the management of diabetes. Its pivotal role derives from its use in reports of the major outcome studies [5,6]; HbA<sub>1c</sub> levels can be directly related to the risk of development of diabetic complications. Major national guidelines address this area and make recommendations about its use [5,7].

Hemoglobin reacts spontaneously with glucose to form glycated derivatives in a non-enzymatic manner. The process occurs slowly, with the extent of glycation determined by the concentration of glucose in blood. Human hemoglobin A undergoes such glycation to form HbA<sub>1c</sub> from a reaction between the  $\beta$ -chain of hemoglobin A0 and glucose (Figure 25.1). Other compounds result from similar reactions on the  $\alpha$  and  $\beta$  chains of hemoglobin and these can be measured as the total glycated hemoglobin.

Until the measurement of different glycated derivatives in the late 1990s, the difficulties of obtaining a common reference standard and the costs of the test made comparisons between laboratories difficult and availability limited. Many of these problems have been overcome, and the most common measured component, HbA<sub>1c</sub>, is now widely accepted as a standard measurement of glycemic control.

Glycated hemoglobin can be affected by the presence of hemoglobin variants and uremia, but specific assays (e.g. high perform-

**Table 25.1** Conditions that can affect the measurement of glycated hemoglobin.

Iron deficiency anemia
Hemoglobinopathies
Polycythemia
Blood transfusion
Hemolysis (hemolytic anemia)
Uremia caused by renal failure
High levels of vitamin C

ance liquid chromatography rather than immunochemistry or affinity chromatography methods) can be used to obtain an accurate result. Vitamin C, hemolytic and iron deficiency anemia can also give abnormal results. Laboratories still differ in whether a result from a heterozygous patient with variant hemoglobin is reported as non-comparable to the Diabetes Control and Complications Trial/UK Prospective Diabetes Study (DCCT/UKPDS) standard, or whether it is not reported at all. Other conditions in which there is a rapid turnover of erythrocytes (e.g. polycythemia, anemia or blood transfusion) can also give inaccurate results (Table 25.1).

Glycated hemoglobin serves as a retrospective indicator of the average glucose concentration over the previous 6–8 weeks. Approximately 50% of the variance in HbA<sub>1c</sub> is determined by

the average blood glucose concentration over the previous month, 25% by the concentration over 30–60 days, and the remaining 25% by the concentration from 60 to 120 days.

### Alignment of assays for HbA<sub>1c</sub>

#### *New International Federation of Clinical Chemistry standard*

Soon after glycosylated hemoglobin measurements were adopted into routine use, it became clear that there were significant differences between results from differing laboratories. The differences arose because of the range of assays used and lack of agreement over a common reference standard. With the publication of DCCT [5] in 1993 a number of countries developed national programs to standardize measurement, which included external quality assurance schemes to ensure that measurements between laboratories could be compared [8]. With the development of more advanced assays it became possible to propose a new reference method based on assaying a specific component of HbA<sub>1c</sub> (the β-N-terminal hexapeptide).

Despite these efforts to standardize HbA<sub>1c</sub> there are over 30 different methods in use for measurement. Manufacturers provide calibration factors for individual machines, and there is a global network of laboratories that maintain and monitor the relationship between the different standards.

The new reference standard, agreed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) was not initially viewed with enthusiasm because it would have lowered the reference range of HbA<sub>1c</sub> by 1.5–2.0 percentage points, thus leading to confusion among both clinicians and patients and a potential deterioration in population glycemic control. A shift to the new reporting strategies, however, offers the opportunity for a global agreement about the requirements for manufacturers to supply equipment that can be standardized.

In Europe the new standard will be introduced to ensure laboratory and clinical practice is traceable to the IFCC reference method using units expressed as *mmol per mol* of unglycosylated hemoglobin. In addition, all results will be presented with both the DCCT aligned and the IFCC standard until at least June 2011. Thus, when HbA<sub>1c</sub> results (DCCT aligned) are expressed as percent hemoglobin the equation deriving the relationship is:

$$\text{IFCC-HbA}_{1c} \text{ (mmol/mol)} = [\text{DCCT-HbA}_{1c} \text{ (\%)} - 2.15] \times 10.929$$

The conversion of integer HbA<sub>1c</sub> (%) values to new units has an easy-to-remember numerical relationship known as “Kilpatrick’s kludge” [9]. For example, for an HbA<sub>1c</sub> of 7% subtract 2 = 5, and then subtract a further 2 = 3. Thus, a HbA<sub>1c</sub> of 7% becomes 53 mmol/mol. For non-integer values the use of the formula or reference tables is required. The equivalent of the current HbA<sub>1c</sub> targets of 6.5% and 7.5% are 48 mmol/mol and 59 mmol/mol in the new units (Table 25.2).

For both patients and clinicians, a shift to the new standard will reduce potential confusion between blood glucose levels and HbA<sub>1c</sub> measurements. With current reference ranges it is relatively easy for confusion between a blood glucose value given in mmol/L to a value of a similar order to the HbA<sub>1c</sub> (%) level but having different implications for clinical decision-making.

**Table 25.2** IFCC aligned values for HbA<sub>1c</sub>.

Current DCCT aligned HbA <sub>1c</sub> (%)	IFCC HbA <sub>1c</sub> (mmol/mol)
4.0	20
5.0	31
6.0	42
6.5	48
7.0	53
7.5	59
8.0	64
9.0	75
10.0	86

$$\text{IFCC-HbA}_{1c} \text{ (mmol/mol)} = [\text{DCCT-HbA}_{1c} \text{ (\%)} - 2.15] \times 10.929$$

Nevertheless, a considerable education initiative is needed to inform both patients and clinicians of the change.

### *Estimated average glucose measurements*

As glycosylated hemoglobin levels are related to blood glucose concentrations and formulas, the American Diabetes Association (ADA) has proposed an alternative approach with the introduction of the estimated average glucose measurement (eAG).

Glycosylated hemoglobin provides information about the overall levels of glucose to which tissue is exposed. For a non-insulin-using patient with T2DM with regular fasting plasma glucose (FPG) levels of 6.5 mmol/L, an HbA<sub>1c</sub> of around 53 mmol/mol (7%) would be expected, but prandial elevation of blood glucose makes an additional contribution to the rate of glycosylation, thus affecting individual results [10].

A large international study has recently established a strong correlation between continuous blood glucose monitoring results and HbA<sub>1c</sub> ( $r = 0.92$ ) in 507 Caucasian adults. The authors proposed a formula to derive eAG [11], and led to the recent ADA position statement recommending the use of the eAG measure [5]. Concerns about the extent to which the relationship between HbA<sub>1c</sub> and eAG are generalizable, the limited information about applicability to all ethnic groups and the potential for patient confusion about the measurements have led to limited adoption outside the USA.

The extent to which eAG are related to diabetes complications is controversial. There are no long-term studies relating continuous blood glucose measurement to long-term diabetes outcomes. Instead, HbA<sub>1c</sub> remains both a target of intervention in many trials, as well as a measure of success in improving glycemic control. This approach is based on the demonstrated relationships between HbA<sub>1c</sub> and diabetes outcomes. There is therefore concern that the introduction of an eAG might lead patients and clinicians to place weight on measurement of blood glucose, while the assay is actually of HbA<sub>1c</sub>.

### *Use of HbA<sub>1c</sub> in the diagnosis of diabetes*

Current guidance continues to recommend that the diagnosis of diabetes is based on at least two laboratory measurements of blood glucose  $\geq 7$  mmol/L or random samples of  $\geq 11.1$  mmol/L. In the event of uncertainty, an oral glucose tolerance test is pro-

posed. HbA<sub>1c</sub> offers a potentially easier, non-fasting and therefore more acceptable test. Furthermore, there appears to be less intra-individual variation with HbA<sub>1c</sub> than glucose testing. Previously, there were concerns that despite the variation in results of oral glucose testing within the same person, the alternative of a single HbA<sub>1c</sub> test would be unsatisfactory because the threshold for screening (usually identified as 53 mmol/mol [7%]) would miss a substantial number of people with diabetes. There is also considerable potential for confusion, because current guidance for people with diabetes is to aim, if possible, for HbA<sub>1c</sub> levels of 48–59 mmol/mol (6.5–7.5%) [7]. One possible alternative to simplify diagnosis is the combined measurement of fasting blood glucose and HbA<sub>1c</sub>, making use of an algorithm developed from studies in which the two measurements were compared against the results of an oral glucose tolerance test [12]. There are ongoing discussions about the use of HbA<sub>1c</sub> as a diagnostic test and, at the time of writing, it has been proposed that an HbA<sub>1c</sub> of 48 mmol/mol (6.5%) would be diagnostic of diabetes. This test will not replace the glucose criteria as in many parts of the world HbA<sub>1c</sub> is not available.

#### Point of care HbA<sub>1c</sub>

Point of care testing for HbA<sub>1c</sub> is now possible with clinic-based analyzers and may allow timely decisions on therapy changes when needed. A recent study of their use, however, carried out in a clinic setting, does not yet provide sufficient information about the benefits to justify their widespread deployment [13,14].

#### Measurement of fructosamine

Albumin is the main component of plasma proteins. Albumin contains free amino groups which can react non-enzymatically with glucose to form fructosamine. Measurement of fructosamine reflects glucose levels over the previous 1–3 weeks. Fructosamine measurement is not appropriate for routine use because the assay is markedly affected by excessive turnover or excretion of albumin in, for example, renal disease. In addition, fructosamine assays are not standardized in the same way as HbA<sub>1c</sub> assays. Fructosamine testing remains useful in a number of circumstances, for example in pregnancy where glucose requirements change rapidly, or in the preconception period where motivation to improve control is high and the changes can be evaluated at shorter intervals. With the lower cost and increased standardization of HbA<sub>1c</sub>, however, it is possible that more frequent measurements of HbA<sub>1c</sub> may be an alternative strategy, particularly if evaluating potentially large improvements in the blood glucose over the preceding 4–6 weeks contributing to a clinically important change from a previous HbA<sub>1c</sub> result [15].

#### Blood glucose

Blood glucose (or the level of glucose to which the body's organs are exposed) is expressed as the plasma glucose concentration. Blood glucose was traditionally given as whole blood values, but plasma glucose levels are now measured and reported by most laboratories. Blood samples for analysis need to be taken under

controlled conditions to allow accurate measurement of glucose levels. Red blood cells may continue to metabolize glucose after collection, continuing glycolysis, and thus leading to reductions in glucose levels. This should be avoided by rapid centrifugation, collection onto ice and storage in a refrigerator. If blood is to be transported at room temperature it should be collected into fluoride-containing tubes which inhibit further glucose metabolism. If a patient has an intravenous line *in situ*, blood should be drawn from the arm opposite to the one with the line to prevent contamination of the sample from any infusion.

Blood glucose measurement is a term that is frequently used without precise definition. Measurement of glucose levels is usually carried out either on capillary or venous samples of blood. Most laboratories measure the level of glucose in plasma, which again differs from measurements made on whole blood. Table 25.3 shows the equivalent measurements from the different sites and samples taken.

Blood glucose levels are expressed in SI (Système International) units as millimoles/liter (mmol/L). The traditional unit for measuring blood glucose is milligrams/decilitre (mg/dL), although use of these units is now largely confined to the USA. To convert mmol/L glucose to mg/dL, multiply by 18 (Table 25.4).

Sampling and preparation of the sample affect measurement. Whole blood glucose is also affected by the concentration of protein (mainly hemoglobin) in the sample. Whole blood concentrations are therefore 12–15% lower than plasma concentra-

**Table 25.3** Values for diagnosis of diabetes mellitus.

Time of measurement	Glucose concentration (mmol/L)*			
	Plasma		Whole blood	
	Venous	Capillary	Venous	Capillary
Fasting	≥7.0	≥7.0	≥6.1	≥6.1
2 h after a glucose load	≥11.1	≥12.2	≥10.0	≥11.1

\* 1 mmol/L = 18 mg/dL.

**Table 25.4** Correlation of HbA<sub>1c</sub> with average glucose.

HbA <sub>1c</sub> (%)	Mean plasma glucose	
	mg/dL	mmol/L
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4
11	269	14.9
12	298	16.5

tions. Venous blood glucose levels are normally similar to arterial and capillary levels when fasting. The arterial and capillary levels most closely reflect the glucose concentrations at the organ level. After meals, venous blood will have lower glucose concentrations than arterial blood and can be as much as 10% lower.

### **Analytical techniques and quality assurance**

A range of analytical techniques are used for the laboratory measurement of blood glucose levels. Chemical oxidation/reduction methods have a low cost for reagents and, although less specific, are still valid. Enzymatic analysis of glucose is more specific, although more expensive. The enzymatic reference method for glucose is the hexokinase/G6PDH method. The glucose oxidase methods are comparable, although the presence of reducing substances may cause error. Glucose oxidase methods are frequently used because of their convenience and lower cost. Measurements are accurate and precise with measurement coefficient of variance of around 2%. Self-measurement of blood glucose is possible using capillary blood glucose meters with test strip systems. Specific issues associated with their use are considered in the next section.

Capillary blood glucose meters use test strips that release gluconic acid and hydrogen peroxide from a blood sample. The reaction is quantified by one of a range of methods to measure blood glucose. Most of the currently marketed handheld capillary blood glucose meters give results as an equivalent to venous plasma glucose but this is not always the case. The same type of handheld meter may be calibrated to report whole blood glucose in one country and plasma values in another. Until this issue is resolved, the calibration of a meter should be checked and the thresholds for action set accordingly.

In a hospital or “site-of-care” setting, capillary blood glucose measurement can be used to replace venepuncture, with greater comfort and more rapidly available results. Standards have been laid down to ensure that bedside glucose determinations can be made accurately and include the need for well-defined policies which include adequate training, quality control procedures and regular maintenance of equipment [16]. Blood glucose meters may require entry of a number or insertion of a coding chip to ensure calibration to the batch of testing strips used.

### **Accuracy of blood glucose meters**

Although laboratory methods of blood glucose measurement are accurate, the convenience and rapidity of capillary blood glucose meters means that, despite their higher coefficient of variance compared to laboratory testing and the possibility of user error, they are in wide use. The majority conform to international standards ([www.iso.org](http://www.iso.org)), with 95% of readings within 0.83 mmol/L for readings <4 mmol/L and within 20% for higher glucose readings. The newer meters have minimized the possibility of user error by requirement for smaller volumes of blood for measurement and automated calibration methods. Operator error, however, remains a significant source of error, including failure to calibrate meters (some newer meters do not require

external calibration), poor handwashing technique and dirty meters [17].

Measurement error can be minimized by careful training and consistent technique in making measurements, incorporating an allowance for the possibility of error in the reading when calculating insulin dose, and undertaking regular testing to identify results that do not fit the usual pattern, with retesting as necessary.

Despite their imprecision, blood glucose meters remain helpful at higher blood glucose values, where, for example, it is of less importance to distinguish a plasma glucose of 11 mmol/L from one of 14 mmol/L. In such circumstances, the aim of management is to achieve a substantial reduction in plasma glucose. At lower plasma glucose levels, however, the consequences of an imprecision of 15% are much greater. For many well-controlled patients aiming to keep their glucose levels in the range 4–6 mmol/L, the majority of readings below 4 mmol/L will result from the variance of the measurement rather than reflecting a true “low” value.

### **Measurement of urinary glucose**

Measurement of glucose in urine has limited arguments in favor of its use for routinely monitoring diabetes. It is rapid, inexpensive, non-invasive and can provide a quantitative result, however, it does not reflect the changing levels of hyperglycemia with any accuracy and so interpretation may be difficult if not impossible. In addition, the renal threshold varies between individuals and varies during pregnancy and with aging. In any case, glucose is not excreted renally at levels where blood glucose is significantly elevated above that which should be targeted to minimize diabetic complications.

Urine fraction should be analyzed immediately, preserved at pH <5 to inhibit bacterial metabolism or stored at 4°C. The enzyme used is glucose oxidase/oxidase which may lead to false-positive results with hydrogen peroxide and false-negative test results with the presence of ascorbic acid.

Urine testing should no longer be used in most health care settings because of the availability of alternative and more accurate tests. For the moment it may have a role in resource-poor settings where identification and treatment of individuals with poorly controlled diabetes is the highest priority.

---

## **Monitoring in clinical practice**

Glycated hemoglobin measurement is recommended to assess the maintenance of glycemic control and should be measured with high precision methods. Results should be reported in IFCC units (mmol/mol) or eAG (mmol/L or mg/dL) alongside the DCCT aligned (%) units. In general, HbA<sub>1c</sub> measurements should be performed at least twice a year in patients meeting treatment targets and with stable glycemic control. An interval of 3 months between tests is usually recommended following changes in therapy or when levels are unstable, although a test after 2 months may provide some additional information [18].

**Figure 25.2** Correct technique for self-monitoring of blood glucose improves accuracy of testing.

Self-monitoring of blood glucose (SMBG) is a standard of care for patients with T1DM and necessary for insulin-treated patients with T2DM, although optimal use in this group is not established. SMBG may also be helpful for some non-insulin-treated patients with T2DM, although it is unlikely to offer benefit to well-controlled patients. SMBG requires a high level of motivation and if people using SMBG are not aware of how to interpret the results and what actions they should take, it is unlikely to be a clinically effective or cost-effective procedure. People with diabetes need to be taught how to perform the test accurately and how to use the data to adjust therapy in relation to food intake and physical activity. Correct technique involves obtaining the blood sample from the side of the finger pulp, wiping and using the second drop of hanging blood, using the meter correctly and disposing of the lancet (Figure 25.2). Alternative sites for sampling include the base of the thumb, forearm and thigh. Pre-meal readings will be the same between sites, but at times of rapid glucose change (in the post-prandial period or during hypoglycemia) forearm and thigh results will be different from the fingertip results.

### Type 1 diabetes

For patients with T1DM, blood glucose control should be measured with HbA<sub>1c</sub> every 2–6 months depending on the level and

stability of blood glucose control and change in therapy. HbA<sub>1c</sub> measurement should be provided either at site of care or carried out by the laboratory before clinical consultation. Patients should be encouraged to use SMBG using capillary blood glucose meters. With treatment regimens intended to produce intensive glycemic control, testing should be frequent (e.g. four or more times a day).

When using a typical basal bolus regimen including three injections of short-acting insulin and one or more injection of long-acting insulin, at least four time-points during the day need to be monitored, pre-breakfast, pre-lunch, pre-dinner and before bedtime. There is some evidence that tests 1 hour post meals may allow more accurate adjustment of pre-meal short-acting insulin although this needs to be offset against the greater inconvenience. Frequent glucose testing allows identification of periods during the day when plasma glucose levels are higher or lower than ideal and appropriate adjustment of the short-acting or bedtime injections. If the individual has regular routines and varies little in food intake and physical activity from day to day, then monitoring can take place at a frequency of less than four tests a day; for example, a daily fasting blood glucose with either 1 or 2 days a week with four-point sampling, or each day testing at one or more additional time-points to build a picture over the week. Until the dose of long-acting insulin has been established, a series of paired bedtime and fasting readings are needed.

Tight control brings with it the risk of hypoglycemia [4]. For some people (limited duration of life, inability to make the adjustments required for tight control) intensive control is inappropriate. Accepting less tight control allows use of less complicated regimens and less frequent monitoring.

For individuals using conventional rather than analog long-acting insulin, and with biphasic regimens more frequent monitoring may be required because of the less stable time course of the long-acting components of the insulin.

Glycated hemoglobin measurement complements blood glucose measurement by providing a check on the extent to which the glucose results are providing an accurate picture of overall blood glucose control. A schedule of blood glucose measurements indicating good control may need to be examined if an HbA<sub>1c</sub> measure indicates that control is not so good. For example, timing of measurements and user technique may need reassessing.

SMBG should be carried out three or more times daily for patients using multiple insulin injections or insulin pump therapy. For patients using less frequent insulin injections, SMBG may be useful as an additional guide to the success of therapy and to support adjustment of insulin dose. In addition to measurement at defined time-points, additional checks on blood glucose levels can be made in relation to the risk of hypoglycemia, for example, before exercise or driving and in the presence of symptoms that may indicate hypoglycemia.

Glycemic targets for adults are for an HbA<sub>1c</sub> of 48–59 mmol/mol (6.5–7.5%). Targets for children (aged 0–12 years) are higher because of the high risk of and vulnerability to hypoglycemia.

Adolescents and young adults are at particular risk with developmental and psychologic issues, but should nevertheless aim for control  $<59$  mmol/mol ( $<7.5\%$ ).

### Type 2 diabetes

For patients with T2DM, blood glucose control should be monitored using high precision methods for measurement of HbA<sub>1c</sub> every 2–6 months depending on the level and stability of blood glucose control and change in therapy. HbA<sub>1c</sub> measurements should be provided either at site of care or from the laboratory before clinical consultation.

Insulin-treated patients with T2DM need to make use of SMBG, particularly in the period of titration of insulin dose. For those patients using a long-acting insulin, fasting glucose readings can be used to guide incremental increases in insulin dose, with readings averaged over longer periods as the fasting glucose falls towards the target range. While fasting plasma glucose levels remain elevated, insulin dosage can be increased by up to 10%.

Although some patients report that they are able to gain motivation from regular blood glucose testing, others note their frustration when they are unable to make sense of what appears to be a random pattern of test results [19]. They report that health professionals do not appear interested in their carefully recorded results, and that this also leads them to question the value of the procedure. Many recent recommendations about the use of self-monitoring have stressed the need for self-monitoring to be accompanied by education about use of the results to promote optimal health behaviors. The extent to which understanding of test results might be improved by further support or training from health professionals is uncertain [19]. Other forms of evidence are therefore needed.

Evidence from large population-based clinical studies provides a mixed picture for the benefits of SMBG. Records from thousands of patients receiving care in the USA and Germany were examined to look at the outcomes of patients who were using SMBG compared with those who were not. Their results suggest that more frequent monitoring leads to improvements in glycemic control [20] and overall mortality [21]. Large studies of this type, however, have a high likelihood of bias. Although some statistical adjustments can be made for differences between users and non-users, there is likely to be a strong association between regular use of a blood glucose meter and take-up of other health promoting behaviors. In contrast, other studies using similar methods have identified no association between use of a blood glucose meter and improved outcomes [22]. Other research designs have therefore been used to identify an effect of SMBG.

Randomized trials provide an alternative approach to looking at the potential effectiveness of SMBG in improving outcomes for people with diabetes. Although they avoid potential bias through randomly allocating people to using or not using a meter, those people who agree to enter such a trial may not be completely typical of the wider group of people who might benefit from the intervention. Since the year 2000, there have been six randomized

trials of at least 6 months' duration that compared the use of self-monitoring with no self-monitoring. These trials were summarized in a recent review. The overall identified benefit from use of self-monitoring in terms of improvement in glycemia was a decrease in HbA<sub>1c</sub> of 0.2% [23]. Those trials that directly compared self-monitoring, and included state-of-the-art patient education for both the SMBG user group and the non-user group, did not show a benefit [24]. These trials were also limited by including a substantial proportion of reasonably well-controlled patients. Other reviews have raised the possibility that, when used with patients who have less well-controlled diabetes, SMBG might be helpful [25]. Although most studies have focused their attention on potential benefits of SMBG, there is also the possibility of adverse outcomes. For example, two recent trials [26,27] have raised the possibility that, as the result of self-monitoring, some patients might become depressed or anxious compared to others not self-monitoring.

Most trials of self-monitoring have focused on the potential for SMBG to contribute to improved motivation and lifestyle adjustment. One recent trial has focused directly on adjustment of oral glucose-lowering medication. The study compared use of SMBG to titrate oral medication in comparison with usual care, and identified a small but significant improvement in glycemic control among patients allocated to self-testing compared with those assigned to usual care [28]. Further studies are needed to explore the extent to which there are long-term advantages of including SMBG compared to, for example, the more frequent use of HbA<sub>1c</sub> measurement, as part of the management pathway for titration of glucose-lowering medication.

Some studies have also examined the costs that are associated with SMBG for non-insulin-treated patients. These studies vary in their assessment of the extent to which SMBG might be considered a cost-effective intervention. Some studies have used estimates of cost–benefit derived from selected cohort studies [29]. Other estimates of costs using more conservative estimates of SMBG efficacy and based on detailed cost data collected from clinical practice, suggest that any benefit in outcomes obtained from improved glucose control might be balanced out by the impact of a lower quality of life. Even when modeled over a long-term time horizon, use of SMBG failed to reach a conventional threshold of cost-effectiveness [27].

There are many unresolved questions about SMBG, including frequency and timing of testing, its value in new users and ongoing users, and if and how users act on the results. It is clear, however, that SMBG should only be used as part of a structured self-management program and when it serves an identified purpose in self-management.

### Gestational diabetes mellitus

Women with diabetes should be advised to test fasting blood glucose levels and blood glucose levels 1 hour after every meal during pregnancy. Women should be able to adjust their insulin dose to maintain target blood glucose levels. Many oral glucose-lowering medicines are not recommended for use during preg-

nancy, particularly during the first trimester, so early training in the use of SMBG and insulin therapy is often necessary.

### Monitoring diabetes in a hospital setting

Within a hospital setting, laboratory and point-of-care testing should be supported by certified quality assurance schemes. Some meters used in hospitals support quality assurance procedures by restricting access to trained personnel and transferring the results directly to the electronic patient record.

Blood glucose measurements should be available from meters situated on hospital wards. Measurement of glucose on admission to hospital is needed to identify hypoglycemia or hyperglycemia and to provide appropriate patient care. Confirmation from laboratory measurement is necessary for a proportion of these samples. Continuous monitoring may be appropriate for some patients while in hospital.

Critically ill surgical patients should have blood glucose levels maintained as close to 6.1 mmol/L as possible, and generally <7.8 mmol/L using an intravenous insulin protocol. Targets for non-surgical critically ill patients are less well defined, but some studies provide evidence for maintaining levels <7.8 mmol/L. For non-critically ill patients there is no evidence about optimum glycemic goals. Concerns about hypoglycemia mean that some institutions have concern about the safety of these goals as initial targets.

Self-management of diabetes in the hospital setting may be appropriate where adult patients are alert, able to self-manage their diabetes at home and have stable requirements for insulin. This may also provide an opportunity for providing support in learning techniques of insulin adjustment in line with carbohydrate intake.

### Monitoring diabetes in a community setting

Glycated hemoglobin and SMBG testing are the two primary techniques for monitoring success in achieving glycemic goals, adjusting therapy and providing information to support lifestyle change.

#### Glycated hemoglobin testing

Glycated hemoglobin testing is usually carried out on a non-fasting venous sample obtained in EDTA tubes and sent to a locally accredited laboratory measured using one of the available techniques for measurement. In addition, capillary blood can be sent to the laboratory in capillary tubes or preserved as dry blood on a filter paper and sent to the laboratory, although chromatographic methods are less suitable for HbA<sub>1c</sub> measurement in dry blood. Point-of-care testing systems are also available, either using an analyzer or small meters with test-strips.

HbA<sub>1c</sub> provides a measure of glycemia that can be used to adjust treatment for patients with T1DM or T2DM. For patients with poorly controlled non-insulin-treated diabetes, advice about weight loss may bring about an improvement in glycemia, in the presence of some endogenous insulin secretion. Continuing poor control usually leads to initiation or increases in oral glucose-

lowering medication as an appropriate further response. If these measures fail to improve glycemia, or there is concern about possible hypoglycemia, then characterizing the daily course of blood glucose in relation to food and physical activity may be appropriate.

To facilitate clinical decisions, patients are often asked to provide blood for HbA<sub>1c</sub> testing before a clinic visit so that the results are available at a face-to-face consultation. Differences of 0.5% in HbA<sub>1c</sub> in measurements made at the same laboratory using the same assays will indicate clinically relevant changes and provide a guide to the necessity of changes in treatment or facilitating lifestyle change.

#### Blood glucose testing

Blood glucose testing carried out by the patient with diabetes may enhance understanding of the impact of diabetes and treatment and adjust medication. For patients with T1DM and insulin-treated T2DM, the need to adjust insulin requires measurement, interpretation and appropriate adjustment to be carried out on a regular basis at home. Detailed records of blood glucose measurements and actions are needed to allow review by both the patient and their clinician. Blood glucose measurements are particularly helpful in situations where frequent adjustment of therapy is needed.

A single measurement of post-meal glucose used as a screening tool is likely to identify most inadequately controlled patients [10]. Blood glucose levels are usually high following meals, and thus contribute to overall blood glucose control. Some studies have been interpreted to suggest that post-prandial glucose levels correlate with development of complications better than fasting blood glucose levels (or that glycemic variability may be related to poor outcomes). Attempts to titrate oral hypoglycemic medication by taking account of post-meal measures, however, have not been successful [30].

Fasting blood glucose measurements can be used to inform management for patients with both T1DM and T2DM. Preprandial blood glucose levels are often equated with, but are not equivalent to, fasting blood glucose levels, which require an 8-hour fast. Preprandial measurements, however, may be useful for evaluating the impact of a complex insulin schedule, particularly with fast-acting analog insulin. For insulin treated patients, pre-breakfast levels, compared with the previous evening's readings, indicate the effectiveness of any long-acting insulin being taken.

For patients with non-insulin-treated T2DM, the within-person coefficient of variation of pre-fasting (pre-breakfast) blood glucose levels is low and measurements vary little from day to day. They are therefore a means of assessing day-to-day control and making adjustments to therapy or assessing the impact of lifestyle changes, although the cost-effectiveness in relation to HbA<sub>1c</sub> testing has not been established. The frequency of fasting blood glucose measurement for non-insulin-treated T2DM has been suggested from once a week to once a day. The evidence for a particular frequency of testing, however, is lacking, and indi-

vidual variations (familiarity with ensuring measurement techniques, variation in lifestyle, availability of professional help in supporting patients in interpretation of measurements) will require that a judgment is made on the precise purpose of monitoring.

SMBG may provide some patients with T2DM, not requiring glucose lowering therapy, with insight about the impact of day-to-day activities on blood glucose. Evidence to support the use of SMBG in this way derives from qualitative and observational studies. Measurement of fasting glucose, if HbA<sub>1c</sub> is unavailable, may be used as an alternative indicator of overall glycemic control. It is also possible that, in patients unable to achieve target HbA<sub>1c</sub>, characterizing the extent of hyperglycemia 1–2 hours after a meal, aiming to reduce post-meal levels below 10 mmol/L may be a recommendation worth further evaluation.

A target capillary plasma glucose of 3.9–7.2 mmol/L is recommended on the basis of outcome studies such as UKPDS and DCCT in which HbA<sub>1c</sub> was shown to predict complications. Most patients with T2DM treated with long-acting insulin also continue oral glucose-lowering medication. The recommended schedules for monitoring are derived from trials that have sought to achieve reductions in HbA<sub>1c</sub> to within recommended levels [20]. The intensity of these schedules has not yet been evaluated in wider populations and those more representative of primary care populations. Fasting blood glucose levels carried out twice a week will allow the weekly or 2-weekly titration of the long-acting insulin to achieve tight control. Additional 4 or 7-point profiles may be helpful every 3–4 weeks to identify patterns of blood glucose control that require further attention, for example, to address the possibility of hypoglycemia or to identify high levels of post-prandial glucose that may require the use of pre-meal short-acting insulin.

### Continuous blood glucose measurement

The need to provide more frequent SMBG measurements to document glucose excursions and guide insulin therapy has led to the development of innovative technologies that can provide nearly 300 measurements a day. Detailed data on the magnitude and duration of glucose fluctuations can be used to guide lifestyle and drug therapy in an attempt to produce a near-physiologic control of glucose levels.

There are a number of different systems currently available. All require calibration using capillary blood glucose measurement and utilize a subcutaneously implanted sensor that can remain *in situ* for up to 7 days. All the continuous glucose monitoring systems (CGMS) are intended for intermittent use in order to identify periods of hyperglycemia that can be corrected by changing therapy (e.g. increasing the dose of insulin or changing timing of injections), or detecting periods of biochemical hypoglycemia that may be too brief to cause symptoms but may nevertheless cause some impairment in cognitive function.

Evidence for effectiveness of CGMS in selected patients aged over 25 years with T1DM using intensive insulin therapy comes from a randomized trial with 322 people with T1DM in which

those allocated to the CGMS arm experienced a 0.5% (6 mmol/mol) reduction in HbA<sub>1c</sub> from 7.6 to 7.1% (60 to 54 mmol/mol) compared to conventional therapy [31]. Evidence for HbA<sub>1c</sub> lowering is less strong in children, teens and younger adults, although there may be specific clinical circumstances in which CGMS might be helpful. Success correlates with adherence to the ongoing use of the device.

Use of CGMS has also been evaluated for pregnant women with diabetes treated with insulin. In a randomized trial those women randomized to continuous glucose monitoring had lower mean HbA<sub>1c</sub> levels from 32 to 36 weeks' gestation compared with women randomized to standard antenatal care. The authors concluded that continuous glucose monitoring during pregnancy is associated with improved glycemic control in the third trimester, lower birth weight and reduced risk of macrosomia [32].

CGMS is now being used as a research tool among patients with T2DM, but the extent to which the procedure is useful to the patient or to the clinician remains unclear and its use cannot be recommended in routine clinical practice. Advocates of the procedure suggest that it might be useful as a means of helping patients to recognize aspects of their lifestyle that lead to hyperglycemia [33].

### Resource-poor settings

Costs of SMBG using test meters remain high in relative terms, and testing with this equipment may not be appropriate in a resource-poor setting. Particularly for patients with T1DM, there is an urgent need for lower cost test strips, although a requirement for rigorous quality control procedures to maintain accuracy limits the potential for lower cost equipment.

Urine glucose testing remains a viable alternative to blood testing or HbA<sub>1c</sub> measurement for patients in a country where health care resources are limited, or in a health care setting where costs of testing equipment are borne directly by the patient. There are few data on self-monitoring using urine glucose testing. A meta-analysis from 2005 [34] included two studies that compared SMBG and self-monitoring of urine glucose and reported a non-significant reduction in HbA<sub>1c</sub> of 2 mmol/mol (0.17%) in favor of SMBG. Many patients, however, do not find the procedure acceptable or helpful [35]. Measurement of urine glucose should therefore not be seen as a substitute for SMBG, but can be used as an alternative where SMBG is not accessible, affordable or desired. Interpretation of information needs to be focused on the period between last voiding and the production of the current urine specimen. Most people have a renal threshold for glucose of around 8 mmol/L, so information about glucose levels is limited below this threshold. The renal threshold can drop during pregnancy, and so glycosuria is more likely in this situation.

---

### The future

Current research is focusing on a number of non-invasive methods to enable continuous monitoring. Methods being con-

sidered include using infrared, electric currents and ultrasound. Currently available continuous monitoring systems require calibration, but are then able to record blood glucose levels at 5-minute intervals for up to 72 hours. Efforts are currently being made to develop integrated systems with glucose meters and insulin pumps. Computerized algorithms for controlling insulin pumps on the basis of blood glucose levels have been developed and have already been evaluated in the setting of intensive care. Mobile phones have also been linked to blood glucose meters to allow easy review of charted data, real-time feedback of support and integration of data with medical records [36].

## Conclusions

Glycemic control should be monitored regularly for all patients with diabetes. The optimal method of determining risk of long-term complications is through HbA<sub>1c</sub> measurement, although if this is not available, then examination of a series of blood glucose measurements, including fasting tests, may provide some guidance. Management of therapy depends on the clinical setting and the type and stage of the patient's diabetes. Patients with non-insulin-treated diabetes have little scope for adjusting therapy on the basis of routine SMBG measurements, although some individuals may benefit from exploring the extent of glycemic variability, self-titration of glucose-lowering medication or checking whether symptoms are related to low-blood glucose readings. For adult patients with T1DM and pregnant women treated with insulin, the evidence for active and regular blood glucose testing (including use of continuous glucose monitoring) to achieve intensive blood glucose control through adjustment of insulin dose in relation to lifestyle is strong. There is also good evidence for the routine use of SMBG for insulin-treated patients with T2DM. Rigorous trials of SMBG in well-controlled non-insulin-treated patients do not demonstrate a clinically important effect. Until further studies suggest settings or groups of patients where SMBG is likely to contribute to the impact of an educational intervention, it should be used only in circumstances where the information obtained through testing can be used to adjust treatment actively, enhance understanding of diabetes and assess the effectiveness of the management plan on glycemic control.

## Drug Therapy: Special Considerations in Diabetes

**Bernard M.Y. Cheung<sup>1</sup> & Robin E. Ferner<sup>1,2</sup>**

<sup>1</sup>College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK

<sup>2</sup>West Midlands Centre for Adverse Drug Reactions, City Hospital, Birmingham, UK

### Keypoints

- Many drugs interfere with glucose homeostasis or interact with antidiabetic agents and thus can disturb glycemic control in people with diabetes. Specific diabetic complications, such as nephropathy and neuropathy, may require particular drugs to be used with care.
- Hyperglycemia can be caused or worsened by numerous drugs. Those that induce insulin resistance include glucocorticoids, certain oral contraceptives, antipsychotic drugs, HIV protease inhibitors, the fluoroquinolone gatifloxacin and  $\beta$ -adrenoceptor antagonists. Diabetogenic drugs that damage the  $\beta$ -cell include pentamidine and cyclosporine (ciclosporin).
- Sulfonylureas and related agents commonly cause hypoglycemia by interacting with other drugs that block their metabolism in the liver, e.g. ciprofloxacin inhibits CYP2C9, which degrades glyburide (glibenclamide), or that impair renal function and decrease their elimination (e.g. non-steroidal anti-inflammatory agents).
- Hypoglycemia can be induced by drugs that stimulate insulin secretion (e.g. quinine, especially in children with cerebral malaria); and sulfamethoxazole, which binds to the sulfonylurea receptor. Pentamidine can induce transient hypoglycemia, by causing passive loss of insulin from the  $\beta$ -cell, as a prelude to permanent diabetes.
- Hypoglycemia can complicate overdosage with acetaminophen (paracetamol), following hepatic necrosis; or aspirin, which blocks hepatic glucose output and stimulates peripheral glucose uptake. Alcohol inhibits hepatic gluconeogenesis and can provoke, prolong or exacerbate hypoglycemia.
- Non-selective  $\beta$ -adrenoceptor antagonists inhibit insulin secretion and can impair glucose tolerance. They also decrease certain catecholamine-mediated symptomatic and metabolic responses to hypoglycemia; awareness of hypoglycemia may therefore be reduced, and recovery of normoglycemia delayed. These adverse effects are much less pronounced with cardioselective  $\beta_1$ -adrenoceptor antagonists.
- Thiazide diuretics used at low dosages (e.g. 2.5 mg/day bendroflumethiazide) lower blood pressure effectively and are suitable for use in patients with diabetes.
- Certain drugs require special consideration in patients with diabetic complications. Metformin and several sulfonylureas are cleared through the kidney; they are therefore contraindicated in advanced nephropathy and should not be co-administered with nephrotoxic drugs. Vasodilators and ganglion-blocking agents exacerbate postural hypotension.

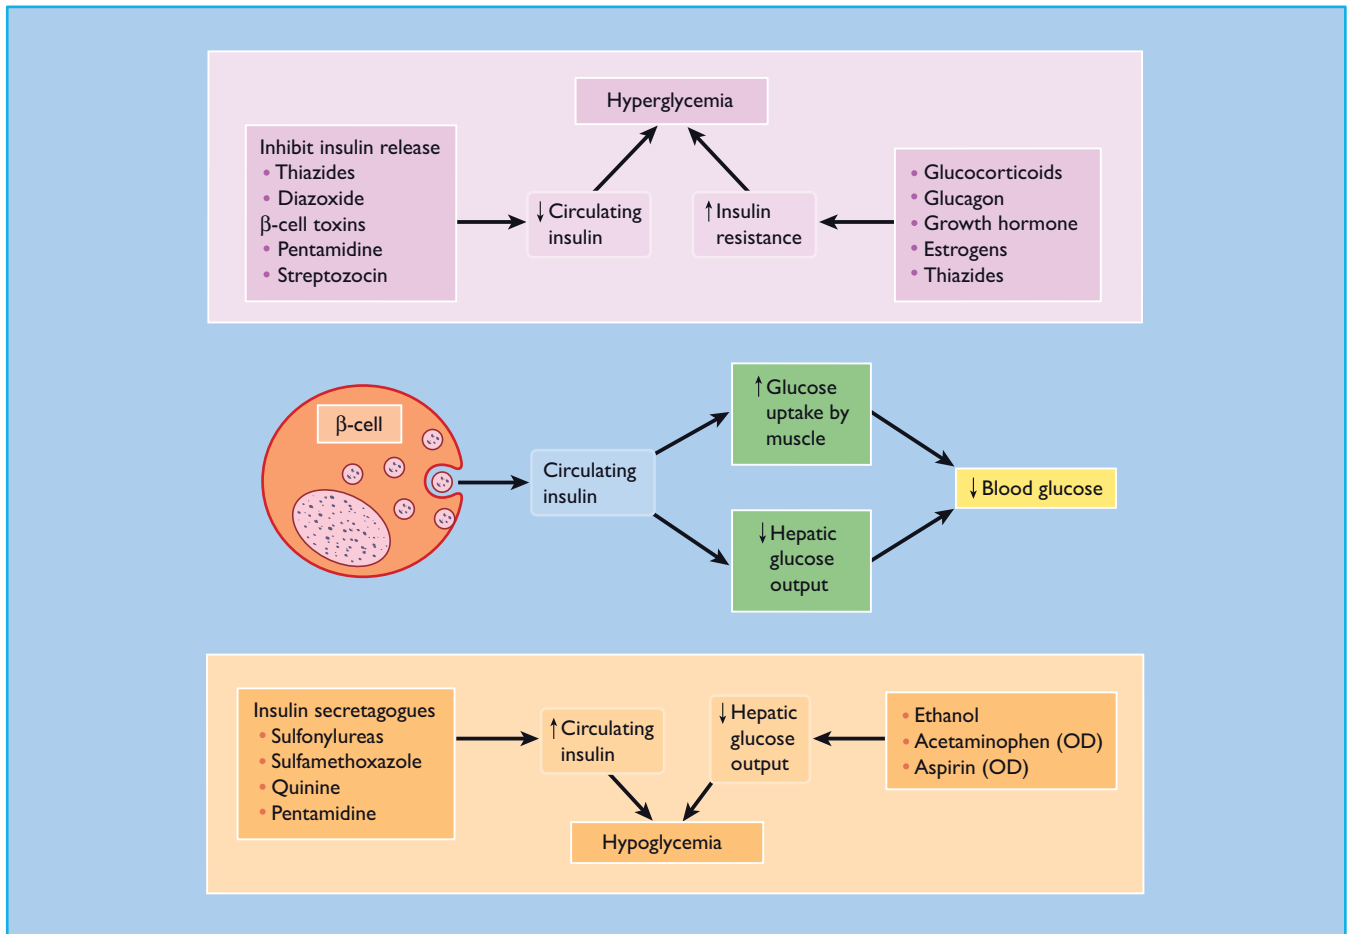

This chapter discusses the problems posed by drug therapy in the management of people with diabetes. Numerous drugs can affect diabetic control, causing hyperglycemia or hypoglycemia, by interfering with insulin secretion or action or both, or by interacting with antidiabetic agents. Some important examples are illustrated in Figure 26.1. The special considerations that apply when using other drugs in patients with diabetes and in the presence of specific diabetic complications are also discussed.

### Drugs that raise blood glucose concentrations

Drug-induced diabetes is now recognized as a distinct etiologic category, and diabetogenic drugs are discussed in detail in Chapter 16. The main culprits are shown in Table 26.1. Most of these drugs – notably glucocorticoids (a common and important cause of iatrogenic diabetes), contraceptive steroids and  $\beta$ -adrenoceptor antagonists – act by inhibiting insulin action. By contrast, insulin secretion is inhibited by diazoxide, while pentamidine can cause permanent  $\beta$ -cell damage. In recent years, antipsychotic drugs, HIV protease inhibitors and the fluoroqui-

**Figure 26.1** General mechanisms of drug-induced hyperglycemia and hypoglycemia. OD, overdose.

nonlone antibiotic gatifloxacin have emerged as important causes of hyperglycemia.

## Drugs that lower blood glucose concentration

Many drugs can cause hypoglycemia (Table 26.2) [1–10]. These include some that interact with and enhance the action of glucose-lowering drugs. Others act in their own right as insulin secretagogues, or to enhance or mimic the effect of insulin in suppressing glucose production by the liver and stimulating glucose uptake into peripheral tissues. Some drugs (e.g. non-selective  $\beta$ -adrenoceptor antagonists) specifically block the warning symptoms or the neuroendocrine counter-regulatory responses that are normally triggered by hypoglycemia, and so can prolong and intensify hypoglycemic episodes.

Drugs should always be suspected whenever patients with previously well-controlled diabetes experience unexplained hypoglycemic episodes, or if dosages of insulin or oral hypoglycemic agents decline. As well as prescription drugs, patients should be asked about herbal, traditional and other alternative medicines.

These are now widely used by people with diabetes – up to one-third of patients in one study [11] – and some products may contain naturally occurring or synthetic glucose-lowering agents (Table 26.3).

### Sulfonylureas

Sulfonylureas are an important and sometimes unrecognized cause of symptomatic hypoglycemia (see Chapter 33). They are also affected by numerous interactions with other drugs (Figure 26.2).

The long-acting sulfonylureas glibenclamide and chlorpropamide are especially troublesome. In one outpatient survey, 20% of patients treated with glibenclamide reported symptoms of hypoglycemia within the previous six months [12], while other surveys suggest that tolbutamide is much less likely to cause severe hypoglycemia (i.e. requiring hospital admission) than either glibenclamide or chlorpropamide [13,14]. A Swiss study [15] defined the risk of severe hypoglycemia as two episodes per 1000 persons per year in those given glibenclamide, over twice as high as in those taking shorter-acting sulfonylureas such as tolbutamide, gliclazide or glipizide. The novel sulfonylurea, glimepir-

**Table 26.1** Drugs that may cause or exacerbate hyperglycemia.

Potentially potent effects	Minor or no effects
Glucocorticoids	Oral contraceptives
Oral contraceptives	Progestogen-only pills
High-dose oestrogen	Levonorgestrel in combination pills
Thiazide diuretics (especially high dosages)*	Loop diuretics
Non-selective $\beta$ -adrenoceptor antagonists	Calcium-channel blockers
$\beta_2$ -Adrenoceptor agonists	$\alpha_1$ -Adrenoceptor antagonists
Salbutamol	Growth hormone (physiologic doses)
Ritodrine	Somatostatin analogs†
Antipsychotics	Androgen deprivation therapy for prostate cancer
HIV protease inhibitors	Selective serotonin reuptake inhibitors
Indinavir, nelfinavir, zidovudine and others	Nicotinic acid
Others	Lamivudine
Pentamidine	Isoniazid
Gatifloxacin	
Streptozotocin	
Diazoxide	
Cyclosporine (ciclosporin)	
Tacrolimus	
Temsirolimus	
Interferon- $\alpha$	
L-Asparaginase	

\* "High" dosages of thiazides correspond to  $\geq 5$  mg/day bendroflumethazide.

† Somatostatin analogs may induce hyperglycemia in type 2 but not type 1 diabetes.

ide, is said to carry a relatively low risk of hypoglycemia because it binds to a different site on the sulfonylurea receptor from classic sulfonylureas and also has distinct pharmacokinetic properties. None the less, the rate of hypoglycemia is still substantial, with 10–20% of patients experiencing at least one mild episode each year [16].

Several factors other than the individual drug per se can increase the risk of hypoglycemia from sulfonylureas, notably increasing age and renal impairment [13,14,16–18]. Reduced food intake during intercurrent illness can also contribute [17,18]. Drug interactions that enhance the action of sulfonylureas are considered below.

Not all those who have sulfonylurea-induced hypoglycemia are patients with type 2 diabetes (T2DM): "bystanders" have included toddlers who ate a grandparent's tablet [19], nursing-home residents given the treatment of other patients [20] and people whose prescriptions for other drugs have been misread [21].

Sulfonylurea-induced hypoglycemia can be profound and prolonged, and difficult to manage. Patients with sulfonylurea-induced hypoglycemia may require admission and treatment with glucose until the effect of the sulfonylurea has worn off although caution is needed as indicated in the case report below.

**Table 26.2** Drugs that may cause or exacerbate hypoglycemia.

Antidiabetic drugs
Insulins
Sulfonylureas, e.g. gliclazide
Repaglinide
<b>Drugs that interact to enhance the actions of sulfonylureas</b> (Table 26.4)
Quinolone antibacterials: Levofloxacin, gatifloxacin [4]
Corticosteroids, including inhaled corticosteroids (when withdrawn may lead to adrenal insufficiency) [5,6]
<b>Other drugs</b>
Aspirin (in overdosage)
Cibenzoline
Disopyramide
Doxycycline [7,8]
Etanercept
Ethanol
Hydroxychloroquine
Imatinib
Mefloquine
Non-selective $\beta$ -adrenoceptor antagonists
Paracetamol (in overdosage)
Pentamidine
Quinidine
Quinine
Sulfamethoxazole (in co-trimoxazole)
Valproate (in neonates exposed <i>in utero</i> ) [9]
Venlafaxine (in overdosage) [10]

Insulin hypersecretion induced by sulfonylureas can be suppressed effectively with either diazoxide (which opens the  $\beta$ -cell  $K_{ATP}$  channel that is closed by sulfonylureas) [22,23] or by the somatostatin analog octreotide [24].

### Case report: Severe relapsing sulfonylurea-induced hypoglycemia

A 62-year-old woman was admitted with acute confusion and became unresponsive 2 hours after admission. She had type 2 diabetes with impaired renal function (serum creatinine 176  $\mu$ mol/L) and had been taking 40 mg gliclazide twice a day. Her blood glucose concentration was 1.8 mmol/L. The hypoglycemia was reversed with an intravenous bolus of 50 mL 50% glucose but subsequently she had repeated episodes of hypoglycemia and required continuous intravenous glucose infusion for 3 days. A blood sample taken when she was hypoglycemic showed raised serum insulin and C peptide concentrations, indicating increased insulin secretion. This patient had impaired renal function. It is likely that this caused gliclazide to accumulate, leading to hypoglycemia. Intravenous glucose restored consciousness, but also stimulated further insulin secretion, leading to further episodes of hypoglycemia.

### Other antidiabetic agents

These are described in Chapter 29.

- *Metformin* used alone is not expected to cause hypoglycemia in therapeutic use; but instances of “hypoglycemia” were reported by the UK Prospective Diabetes Study (UKPDS) during metformin treatment [25]. They were not generally confirmed by blood glucose measurements.
- *Thiazolidinediones* (e.g. rosiglitazone and pioglitazone) potentiate the peripheral actions of insulin. They do not induce hypoglycemia in their own right, but can enhance hypoglycemia caused by sulfonylureas or insulin when used in combination with them.
- *Repaglinide* stimulates insulin release by a mechanism distinct from that of the sulfonylureas and so causes hyperinsulinemic hypoglycemia. A case of factitious hypoglycemia from repaglinide has been reported [26].
- *Acarbose* inhibits intestinal disaccharidase, and so reduces the hydrolysis of sucrose and thus glucose absorption. It does not cause hypoglycemia when used as monotherapy. Acarbose-treated patients who develop hypoglycemia from other glucose-lowering drugs should be warned that oral glucose, not sucrose, is needed to treat the episode.
- *Exenatide* and *liraglutide* are incretins, that is, peptide hormones that enhance the pancreatic insulin response to glucose in the gut. They are agonists of the glucagon-like peptide-1 (GLP-1) receptor. They slow down stomach emptying and stimulate insulin secretion. Unlike insulin, they do not tend to cause hypoglycemia. They also increase pancreatic  $\beta$ -cell mass and promote weight loss. The major disadvantages are nausea, the need for subcutaneous injections, and the high cost relative to sulfonylureas.
- *Gliptins* increase the circulating levels of incretins by inhibiting dipeptidyl peptidase 4 (DPP-4), the enzyme that breaks down incretins and other peptides. The oral route of administration is an advantage, but the long-term effects of DPP-4 inhibition remain unknown. Exenatide and gliptins are indicated for glycemic control as alternatives to thiazolidinediones or acarbose in patients with T2DM on metformin therapy in whom a sulfonylurea is not tolerated or inappropriate.
- *Inhaled insulin preparations* deliver insulin by the pulmonary route, and have a value in patients who have a phobia of needles. Because of poor sales and safety concerns, the first inhaled insulin marketed has been withdrawn. There could be a revival of interest in inhaled insulin if long-acting formulations become available.

### Other drugs

#### Antimicrobials

- *Quinine and quinine derivatives*. Patients with falciparum malaria are often extremely ill, and may have hypoglycemia because of the effects of cytokines and malnutrition, both of which diminish hepatic gluconeogenesis. In this context, it is easy to overlook quinine-induced hypoglycemia, which can be profound, especially in children [27,28]. It is caused by insulin hypersecretion, as quinine has insulin secretagogue activity [29]. Octreotide (a long-acting somatostatin analogue) has been used

successfully to inhibit insulin release and raise blood glucose concentrations under these conditions [30]. Quinidine and mefloquine may occasionally cause hypoglycemia, while chloroquine does not [28].

- *Sulfamethoxazole*, which is combined with trimethoprim in co-trimoxazole, has a sulfonylurea-like action and can stimulate insulin secretion; several cases of severe hypoglycemia have been described [31]. This tends to be long-lasting, perhaps because excessive amounts of glucose solution are infused; this may paradoxically worsen hypoglycemia by further stimulating insulin secretion. Elderly patients receiving high dosage, and patients in renal failure (which causes the drug to accumulate) are at particular risk [32], as are patients infected with HIV who receive high doses of co-trimoxazole to treat *Pneumocystis jirovecii* pneumonia (formerly known as *Pneumocystis carinii*) [33].
- *Pentamidine*, a drug used to treat and prevent *P. jirovecii* pneumonia, can also damage pancreatic  $\beta$ -cells. This initially leads to the passive leakage of insulin out of secretory vesicles, causing hypoglycemia, but diabetes may develop subsequently [34]. In two series of patients with HIV treated with pentamidine, 25% [35] and 14% [36] developed symptomatic hypoglycemia; they invariably developed renal damage from the drug as well. Even inhaled pentamidine can cause hypoglycemia [37].
- *Doxycycline* has been suggested to cause hypoglycemia, but the reaction is infrequent and no mechanism has been identified [38].
- *Quinolones*, particularly gatifloxacin, can cause hypoglycemia (and also hyperglycemia). A case-control study defined an adjusted odds ratio for hypoglycemia with gatifloxacin treatment of 4.3 (95% confidence interval [CI] 2.9–6.3) compared with macrolide treatment [4]. There was a small increase in risk with levofloxacin.

#### Miscellaneous drugs

- *Disopyramide* and *cibenzoline (cifenline)*, class Ia antiarrhythmic agents, can rarely cause symptomatic hypoglycemia; this can occur either with or without hyperinsulinemia [39], suggesting that peripheral effects contribute. In normal subjects, disopyramide produces a small but statistically significant fall in fasting glucose concentration [40]. In a Japanese case-control study, cibenzoline treatment was associated with an eightfold increase in the risk of hypoglycemia; disopyramide did not significantly increase the overall risk, but the confidence intervals were wide [41]. The effect of disopyramide appears to be dose-dependent. In one case, a man developed severe hypoglycemia while taking disopyramide only after starting treatment with clarithromycin for an intercurrent infection [42]; clarithromycin inhibits the hepatic microsomal enzymes that metabolize disopyramide and so greatly increases serum disopyramide concentrations.
- *Antidepressants*, including monoamine oxidase inhibitors, selective serotonin reuptake inhibitors and nefazodone, have been reported to reduce blood glucose concentrations [43].

#### Drugs in overdose

- *Acetaminophen (paracetamol)*, in overdose, can cause hypoglycemia as a complication of acute hepatic necrosis. Overdosage

of *aspirin* and other salicylates inhibits hepatic glucose production and also increases peripheral glucose utilization, leading to hypoglycemia, especially in children. Paradoxically, and for unknown reasons, hyperglycemia can be encountered in adults.

- *Ethanol* inhibits gluconeogenesis; consequently, it can cause hypoglycemia in children or fasting adults and exacerbate hypoglycemia from another cause even when consumed in relatively modest amounts (see Chapter 24). Results of experimental studies are unclear: modest concentrations of ethanol impaired the growth hormone response to insulin-induced hypoglycemia in volunteers with type 1 diabetes (T1DM), but did not affect glucagon response [44]. The same dose of ethanol impaired glucagon, although not growth hormone (GH), response to the same degree of hypoglycemia in patients with diet-treated T2DM [45]. Rebound hypoglycemia can follow 2–3 hours after drinking alcohol with a glucose load in the form of sweet drinks or foods – so-called “gin-and-tonic hypoglycemia” [46]. Alcohol ingestion also increases the risk of severe brain damage or death in people who take an intentional overdose of insulin [47].

### Non-pharmacopoeial drugs

Some “herbal,” “traditional” and “folk” remedies contain compounds with glucose-lowering properties that are generally weak [48]. Some preparations, however, have caused severe hypoglycemia and have been found on analysis to contain an undeclared sulfonylurea [49].

## Drug interactions that affect blood glucose concentrations

Several potential mechanisms underlying drug interaction cause hyperglycemia or hypoglycemia. Pharmacokinetic interactions can influence the effective concentrations of a glucose-modifying drug; examples are the increased concentrations of disopyramide following co-administration of clarithromycin, as described above, and the large number of drugs that increase or decrease circulating concentrations of sulfonylureas (see below).

Pharmacodynamic interactions occur when the observed action of one drug is modified by the action of another, without a change in the circulating concentration of either. The drugs can act at the same site (e.g. sulfamethoxazole is a ligand at the SUR-1 sulfonylurea receptor) or at different sites. Examples of the latter include  $\beta$ -adrenoceptor antagonists and other drugs that influence the physiologic response to hypoglycemia, and so alter the duration or severity of hypoglycemia from another cause.

### Drugs that interact to enhance the actions of insulin secretagogues

Many drugs have pharmacokinetic or pharmacodynamic interactions with sulfonylureas that can cause clinically important disturbances in glycaemic control. Some of the more important examples are shown in Table 26.4 and Figure 26.2. The most

**Table 26.4** Drugs that interact with sulfonylureas.

#### Drugs that may enhance the hypoglycemic effect of sulfonylureas

Azapropazone, phenylbutazone  
Salicylates  
Probenecid  
Sulfonamides  
Clarithromycin  
Nicoumalone  
Fluconazole, ketoconazole, miconazole, voriconazole

#### Drugs that may reduce the hypoglycemic effect of sulfonylureas

Rifampicin  
Chlorpromazine

common outcome is hypoglycemia, brought about by reduced metabolic or renal clearance. Transient effects from displacement of protein-bound drug may occasionally also be important. Major dangers include the potentiation of the effects of tolbutamide, and possibly of chlorpropamide, glibenclamide and glipizide, by azapropazone (apazone), oral chloramphenicol and fluconazole. Miconazole interacts with glibenclamide and glipizide as well as tolbutamide. All these interactions are secondary to the inhibition of the metabolism of sulfonylurea in the liver. Similarly, ciprofloxacin increases the plasma concentrations and therefore enhances the hypoglycemic action of glibenclamide, apparently by inhibiting the hepatic CYP2C9 enzyme that metabolizes glibenclamide [50].

By contrast, rifampicin reduces the action of glibenclamide by inducing CYP2C9 and enhancing the hepatic clearance of sulfonylurea. Chlorpromazine also decreases the glucose-lowering effect of sulfonylurea, possibly by inhibiting insulin secretion.

Another important interaction with chlorpropamide (and, to a much lesser extent, with other sulfonylureas) is the cutaneous vasodilatation of the face and occasionally the trunk that is induced by ethanol, the chlorpropamide–alcohol flush (see Chapter 29).

Clarithromycin has been reported to interact with glibenclamide and glipizide, leading to hypoglycemia [51].

Some patients may be more susceptible to drug-induced hypoglycemia than others. For example, a Japanese case–control study suggested that patients taking levothyroxine and who also had liver disease were at substantially increased risk of mild hypoglycemia, with an odds ratio of 14.7 (range 1.6–137) [52].

Several oral hypoglycemic agents, including glimepiride, glipizide, glibenclamide, tolbutamide and nateglinide, are metabolized by CYP2C9, and a study suggests that among other factors, individuals with genetically determined low CYP2C9 activity are at an increased risk of sulfonylurea-associated severe hypoglycemia [53].

A meta-analysis confirms the impression that hypoglycemia is more likely with glibenclamide than other insulin secretagogues (relative risk 1.52 [95% CI 1.21–1.92]) [51].

Surreptitious ingestion of sulfonylureas such as glibenclamide in alternative medicines can cause hypoglycemia [54].

### Interactions with metformin

Metformin has a high renal clearance. Cimetidine reduces the renal clearance of metformin, and causes it to accumulate (Figure 26.2). Drugs that impair renal function, such as non-steroidal anti-inflammatory agents and aminoglycosides, should be used with care, as they can also raise metformin concentrations, increasing the risk of lactic acidosis. Metformin should be stopped 24 hours before prolonged fasting (e.g. before surgery) and 48 hours before procedures requiring intravenous radiocontrast media. Patients on metformin are advised to avoid alcohol or to drink in moderation as hepatic damage poses a risk of hypoglycemia and lactic acidosis.

### Interactions with other antidiabetic agents

- *Rosiglitazone* is metabolized by the hepatic microsomal enzyme CYP2C8, raising the theoretical possibility of interaction with other agents metabolized by the same enzyme. These include cerivastatin, now withdrawn in the USA and the UK, and paclitaxel [55], but no clinically significant interactions have yet been reported.
- *Repaglinide* is metabolized by CYP3A4, which also breaks down glibenclamide and several other important drugs, and is then excreted in the bile. Clarithromycin, an inhibitor of CYP3A4, has been reported to increase repaglinide concentration and the risk of hypoglycemia [56]. Rifampicin, which induces the same enzyme, reduces the effective concentrations of repaglinide by 25% in healthy volunteers, and could potentially worsen glycemic control in patients with T2DM [56]. Repaglinide is also metabolized by CYP2C8, and its plasma concentration is greatly increased by gemfibrozil, an inhibitor of CYP2C8. This interaction can result in hypoglycemia [56].
- *Glimepiride* is broken down by CYP2C9, and its metabolism is significantly inhibited by fluconazole, thus potentially enhancing its hypoglycemic action [57].

---

## Hazards of general drugs when used in patients with diabetes

The presence of diabetes can influence the choice of agent for treating several important conditions. Drugs to treat cardiovascular diseases – hypertension, angina, arrhythmias and heart failure – and hyperlipidemia are of particular importance, because these conditions are common in people with diabetes.

### Drugs with cardiovascular actions

#### $\beta$ -Adrenoceptor antagonists

These are useful in the treatment of hypertension, angina, arrhythmias and in some cases of heart failure. There is also evidence that  $\beta$ -adrenoceptor antagonists (beta-blockers) are

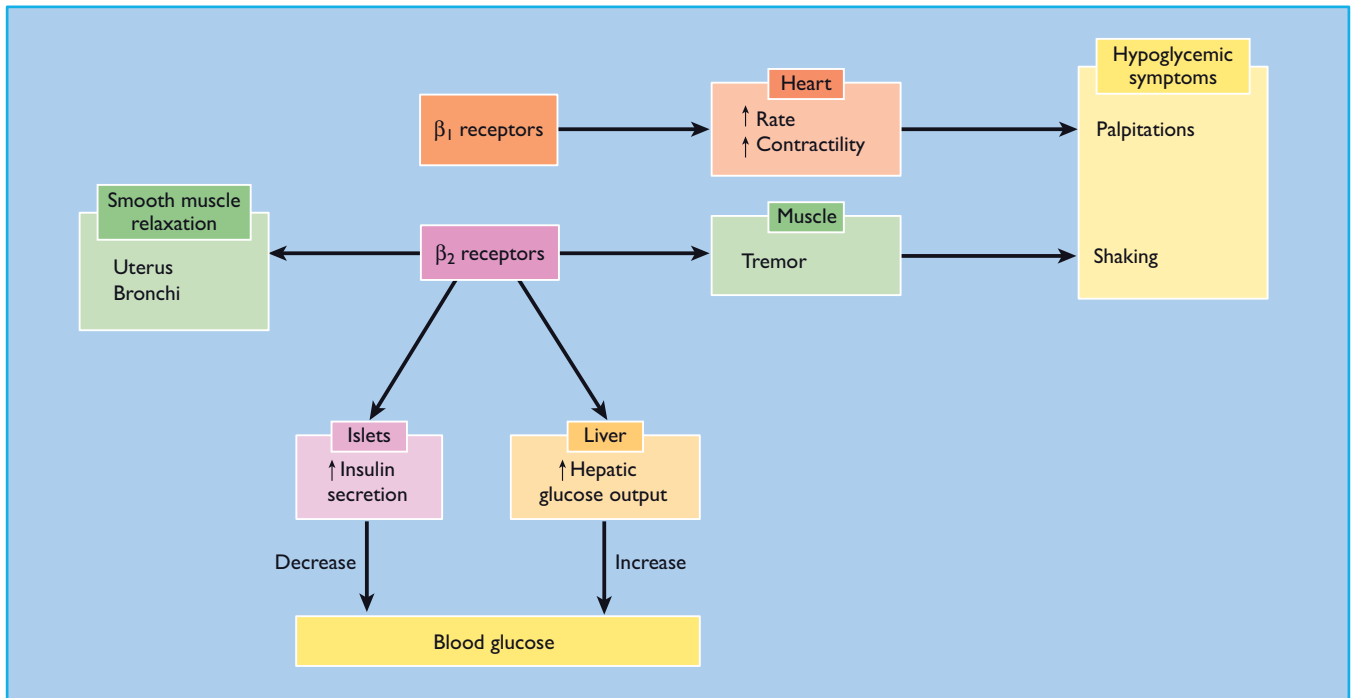

effective cardioprotective agents that reduce mortality following myocardial infarction in subjects both with and without diabetes [58,59].  $\beta$ -Adrenoceptor antagonists are indicated in patients with chronic heart failure as they improve left ventricular function and reduce mortality [60]. The  $\beta$ -adrenoceptor antagonists should be started in stable patients, at a very low dose which should be escalated gradually.

$\beta$ -Adrenoceptor antagonists can, theoretically at least, interfere with several aspects of glucose homeostasis (Figure 26.3). In the islets, insulin secretion is enhanced by  $\beta_2$ -adrenoceptor stimulation, while the  $\beta_2$ -adrenoceptor-mediated response to hypoglycemia in the liver promotes hepatic glycogenolysis and increases hepatic glucose output, a crucial part of the counter-regulatory response that restores blood glucose to normal.

Long-term treatment with  $\beta$ -adrenoceptor antagonists, especially in combination with high-dose thiazide diuretics, has been shown to be diabetogenic. This is discussed further in Chapter 16.  $\beta$ -Adrenoceptor antagonists were used in combination with thiazide diuretics in most of the early large clinical trials in patients with hypertension. In clinical trials testing a  $\beta$ -adrenoceptor antagonist on its own, its effect on stroke was less favorable than comparative drugs. This led to its relegation to fourth line treatment in the fourth British Hypertension Society guidelines [61]. In people with diabetes, their effect on insulin resistance may make them a less suitable choice than angiotensin-converting enzyme (ACE) inhibitors for example. People with diabetes, however, have a more stringent blood pressure target (130/85 mmHg), which necessitates the use of multiple classes to control blood pressure. In such instances, a beta-blocker could be added. People with diabetes frequently have ischemic heart disease, which is another indication for  $\beta$ -adrenoceptor antagonists.

$\beta$ -Adrenoceptor stimulation is responsible for major hypoglycemic symptoms: the pounding heart and palpitation are secondary to  $\beta_1$ -adrenoceptor-mediated increases in heart rate and contractility, while tremor and sweating are both  $\beta_2$ -mediated (sweating also has a cholinergic component) (Figure 26.3). Non-selective  $\beta$ -adrenoceptor antagonists that antagonize both  $\beta_1$ - and  $\beta_2$ -receptors can therefore delay recovery from hypoglycemia and also reduce the patient's awareness of hypoglycemia.

Cardioselective  $\beta_1$ -adrenoceptor antagonists are less likely to interfere with awareness of or recovery from hypoglycemia, and so are preferable in patients treated with insulin or sulfonylureas. Even low doses of cardioselective  $\beta_1$ -adrenoceptor antagonists can modify some of the symptoms and signs of hypoglycemia (e.g. tachycardia), while other symptoms that are robust indicators of hypoglycemia (e.g. sweating) are unchanged or even more pronounced in the presence of  $\beta_1$ -blockade [62,63]. Overall, cardioselective  $\beta$ -adrenoceptor antagonists rarely impair recognition of hypoglycemia. The incidence of hypoglycemia is not increased during treatment with  $\beta_1$ -selective adrenoceptor antagonists, even in patients prone to the condition [64,65]. By contrast, the non-selective drugs can impair recovery from hypoglycemia [62,66,67].

**Figure 26.3** Effects mediated by  $\beta$ -adrenoceptors.

Concerns about the adverse metabolic effects of  $\beta_1$ -selective adrenoceptor antagonists have probably been exaggerated and the potential benefits of their cardioprotective effects underplayed [58]. Moreover, studies in heart failure have now provided extensive data showing that low-dose  $\beta$ -adrenoceptor antagonists are relatively safe in older, vulnerable patients [68].

#### Calcium-channel blockers

*In vitro* and *in vivo* studies have suggested that calcium-channel blockers may impair glucose metabolism, possibly because of impaired insulin secretion. Very few cases of clinically significant hyperglycemia, however, have been reported, and most of these were associated with excessive dosages of the drugs. When used appropriately, calcium-channel blockers are as safe in patients with diabetes as in people without diabetes (see Chapter 40). In people of Asian or African origin, calcium-channel blockers are relatively more efficacious in lowering blood pressure. This is especially relevant in populations that have a high incidence of stroke.

#### Angiotensin-converting enzyme inhibitors

ACE inhibitors are now widely used to treat hypertension and heart failure in both people with and without diabetes. The evidence of benefit of ACE inhibition after myocardial infarction, in systolic ventricular dysfunction and chronic heart failure is strong [69–71]. Similarly, ACE inhibitors reduce proteinuria and the endpoint of doubling of serum creatinine, or the need for dialysis or transplantation [72]. This protective effect on the kidney is encouraging their use in normotensive patients with early nephropathy (see Chapter 37). By contrast, the use of

ACE inhibitors in patients with coronary heart disease without systolic ventricular dysfunction remains controversial. Two large randomized controlled trials showed reductions in cardiovascular events [73,74], but this was not confirmed in a third trial [75].

ACE inhibitors do not cause hyperglycemia, and neither do they adversely affect lipid metabolism [76,77]. Indeed, there is some evidence from the HOPE study that ACE inhibitors may reduce the likelihood of new-onset diabetes [78]. The DREAM study, which specifically addressed this issue, did not confirm this. In comparison with diuretics and beta-blockers, the effect is striking. ACE inhibitors can improve insulin sensitivity and lower blood glucose concentrations, occasionally causing severe hypoglycemia [79,80]. Case-control studies in the Netherlands and Scotland have demonstrated a threefold increase in the risk of severe hypoglycemia (requiring hospital admission) in patients with diabetes who were taking ACE inhibitors [81,82].

In people with and without diabetes, ACE inhibitors are contraindicated if the renal arteries are stenosed because of the high risk of renal impairment, which is usually reversible but sometimes permanent. There may be significant renal artery stenosis in up to 20% of patients with both hypertension and T2DM [83].

#### Angiotensin receptor blockers

Like ACE inhibitors, angiotensin receptor blockers (ARBs) are also indicated for hypertension, heart failure, post-myocardial infarction and diabetic nephropathy [84]. One study showed a marked reduction in stroke and mortality in patients with diabetes on an ARB-based regimen [85]. There is also evidence that ARBs reduce the risk of new-onset diabetes [86].

There are no trials demonstrating that ARBs are superior to ACE inhibitors in terms of outcome, and they are currently more expensive. On the other hand, ARBs do not cause the characteristic dry cough associated with ACE inhibitors.

Combining an ACE inhibitor and an ARB has no demonstrable value in coronary heart disease or diabetic nephropathy, other than reducing urinary albumin excretion further [87,88]. Furthermore, it may be associated with significant hyperkalemia.

#### **$\alpha_1$ -Adrenoceptor antagonists**

$\alpha_1$ -Adrenoceptor antagonists are effective hypotensive agents. They are generally thought to have beneficial metabolic effects, including improved insulin sensitivity, with falls in blood insulin, glucose and lipid concentrations [89–91], although one report [92] has suggested that the use of doxazosin may worsen glycemic control in patients with diabetes. Despite their potential advantages, these drugs are not currently in extensive use, perhaps because of the side effect of postural hypotension. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the  $\alpha$ -blocker arm of the study was prematurely terminated because of an increased incidence of congestive heart failure compared to the diuretic arm [93]. This probably reflects the benefit of diuretics in treating the symptoms of heart failure rather than induction of heart failure by  $\alpha$ -adrenoceptor antagonists.

#### **Thiazides and other diuretics**

##### **Thiazides**

It has become unfashionable to use thiazide diuretics in patients with diabetes, even though they are generally well tolerated, inexpensive and at least as effective as newer agents in preventing stroke and myocardial infarction. The concerns are the reversible impairment of glucose tolerance that can occur with thiazides, unfavorable changes in serum lipid profile and the worry that they may make men impotent [94–111]. Many of these concerns stem from old trials in which high doses of thiazide diuretics (e.g. 5 mg bendroflumethiazide) were used.

The diabetogenic potential of the thiazides is discussed in detail in Chapter 16. The consensus is that low dosages (e.g. 2.5 mg bendroflumethiazide), which are just as effective as higher dosages in lowering blood pressure, cause little if any deterioration in glycemic control [112]. The effects on lipids of low dosages are minor, and outweighed by the benefits of blood pressure reduction [109,110,113]. Finally, one large study (Treatment of Mild Hypertension Study) found no excess of impotence attributable to thiazide treatment among middle-aged hypertensive men, who had a high baseline incidence of this complaint [111]. Overall, the thiazides have a useful place in the treatment of hypertension in people with diabetes [114].

##### **Loop diuretics**

Loop diuretics, such as furosemide, ethacrynic acid and bumetanide, seem to have less impact on glucose homeostasis than thiazide diuretics, although several reports suggest that they can

cause hyperglycemia [115,116]. Recent *in vitro* studies have shown that furosemide inhibits enzymes in the glycolytic pathway [117], so leading to poor glucose utilization and hyperglycemia. In practice, however, few problems are encountered in using loop diuretics in people with diabetes; it has been argued that any insulin resistance and hyperglycemia are not actually drug-induced, but instead are the consequence of the conditions that require potent diuretic therapy.

#### **Antihyperlipidemic agents**

The relationship between diabetes mellitus and dyslipidemia is discussed in detail in Chapter 40. Hypertriglyceridemia is often ameliorated by the effective treatment of hyperglycemia; conversely, some evidence indicates that lowering lipids (including free fatty acid concentrations) can improve blood glucose control. In practice, drugs are often prescribed independently for diet-resistant hyperglycemia and hyperlipidemia, so interactions between agents used to treat the conditions are potentially important.

##### **Statins**

Statins (hydroxymethyl-glutaryl coenzyme A inhibitors) seem to pose few problems in this respect. Meta-analysis has shown that people with diabetes treated by a statin enjoy the same relative risk reduction in major cardiovascular events as people without diabetes [118]. In general, people with diabetes have a higher absolute risk of myocardial infarction and stroke; their annual cardiovascular risk is comparable with that in non-diabetic patients with a history of myocardial infarction. Therefore, diabetes is regarded in many guidelines as an indication for lipid lowering therapy.

##### **Fibrates**

Early studies suggested that clofibrate could improve glycemic control in patients with poorly controlled T2DM taking sulfonylureas [119] or metformin [120]. More recently, similar benefits have been reported with bezafibrate [121], although these observations have not been widely pursued.

##### **Nicotinic acid and its derivatives**

Nicotinic acid (niacin) has recently been confirmed as an effective treatment for dyslipidemia in patients with diabetes; it does not appear to interact with antidiabetic therapy, and may be an alternative to fibrates or statins in those who are unable to tolerate them [122]. It can, however, cause hyperglycemia [123] and unpleasant flushing. A slow-release formulation that causes less flushing is now available. Acipimox is an analog of nicotinic acid that does not cause hyperglycemia (see Chapter 16) [124].

##### **Anion-exchange resins**

Anion-exchange resins such as cholestyramine could theoretically reduce the absorption of antidiabetic drugs from the gut, although clinically significant interference has not been reported. By contrast, ezetimibe does not have this effect.

**Combined statin and fibrate therapy**

This is sometimes indicated for dyslipidemia that is refractory to treatment with single agents. Myalgia and more serious muscle damage (with rhabdomyolysis and myoglobinuria) are rare but well-established complications of both statins and fibrates, and the risks are substantially increased by co-administration.

**Other drugs**

The UK Summaries of Product Characteristics of many products contain contraindications to using the product in patients with diabetes, or diabetic complications. Some of the less obvious examples are oxymetazoline hydrochloride nasal spray and verruca gels containing salicylic acid [125]. In addition, there is a wide range of warnings that medicines should be used with

caution in diabetes; for example, oral rehydration solutions and ribavirin [125].

**Special precautions in diabetic complications**

Some drugs are relatively or absolutely contraindicated in the presence of certain diabetic complications. These include oral contraceptives or hormone replacement therapies in women with diabetes and severe vascular disease, the antiplatelet agents abciximab and cilostazol, and growth hormone in patients with proliferative retinopathy, and propranolol by injection in patients prone to hypoglycemia [125]. Important examples are shown in Table 26.5.

**Table 26.5** Drugs requiring caution in specific diabetic complications.

Complication and drug	Problem	Action to be taken
<b>Nephropathy</b>		
Sulfonylureas	Accumulate in renal failure; increased risk of hypoglycemia and toxicity	Use insulin or a sulfonylurea not cleared through the kidneys (e.g. gliquidone, gliclazide)
Metformin	Accumulates in renal failure; increased risk of lactic acidosis	Avoid
ACE inhibitors or ARBs	Initial rise in plasma creatinine; risk of hyperkalemia	Use with caution and appropriate monitoring of renal function
NSAIDs or COX-2 inhibitors	Further compromise renal function	Avoid if possible
Radiocontrast media	Reduce renal function	Adequate hydration before procedure
<b>Cardiovascular disease</b>		
$\beta$ -Adrenoceptor antagonists	Accentuate hypoglycemia May cause modest VLDL elevation	Consider alternative antihypertensive, antianginal or antiarrhythmic drugs (e.g. ACE inhibitors, calcium-channel blockers)
Thiazide diuretics (high dose)	Worsen glycemic control in type 2 diabetes  Exacerbate hyperlipidemia	Reduce dose, or use loop diuretic or alternative antihypertensive drugs
<b>Retinopathy</b>		
Mydriatics (eyedrops or systemic atropinic drugs)	In patients with rubeosis or previous eye surgery, glaucoma may be precipitated	Seek ophthalmologic advice before dilating pupils
Anticoagulants	May predispose to vitreous hemorrhage in patients with proliferative changes	Avoid if possible
Abciximab	May predispose to vitreous hemorrhage in patients with proliferative changes	Avoid if possible
Somatropin	Can worsen proliferative retinopathy	Avoid
<b>Autonomic neuropathy</b>		
Phosphodiesterase inhibitors (e.g. sildenafil)	Aggravates postural hypotension	Avoid, especially in the elderly and those taking nitrates
Ganglion-blocking agents and vasodilators	Aggravate postural hypotension	Use with caution
<b>Impotence</b>		
Ganglion-blocking agents	Aggravate erectile failure	Use alternative antihypertensive drugs (e.g. ACE inhibitor, calcium-channel blocker or $\alpha$ -adrenergic blocker)
$\beta$ -Adrenergic blockers		
Clonidine		
$\alpha$ -Methyldopa		

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; COX, cyclo-oxygenase; NSAID, non-steroidal anti-inflammatory drug; VLDL, very low density lipoprotein.

There has been controversy about the risks of inducing vitreous hemorrhage with thrombolytic treatment (e.g. streptokinase) for myocardial infarction in patients with proliferative retinopathy. Current advice is to give thrombolytic drugs according to the usual indications, as the likely benefits far outweigh the potential threat to vision.

---

## Drug interference with monitoring of diabetic control

Urine testing for glucose, still favored by many elderly patients, is subject to interference by several drugs [126], including ascorbic acid, which can give false-negative urine glucose readings with glucose oxidase strips (see Chapter 25) [127].

Blood glucose measurements, using dry-reagent glucose oxidase test strips, can potentially be affected by drugs such as aspirin if present in very high concentrations [128]. Readings can also be misleading if fingers are contaminated with alcohol from swabs (which inactivates glucose oxidase) or with glucose (e.g. from sugary drinks) [129].

The complex sugar icodextrin, used as a peritoneal dialysate, can give spuriously high glucose concentrations; this can mask underlying hypoglycemia [130].

---

## Conclusions

Rational prescribing is a difficult task whose success demands the integration of data about the drugs being used, the patient, and the conditions that affect the patient. There are three major areas of difficulty when prescribing for patients with diabetes. First, a large number of drugs affect glucose tolerance. They include important agents, such as oral corticosteroids, which can be life-saving but confound attempts to achieve euglycemia. Secondly, patients with diabetes are now commonly asked to take several medicines to control glycemia, and to treat the complications of diabetes. The number of potential interactions between pairs of drugs increases rapidly with the number of different drugs prescribed. As the number of prescribed medicines increases from 5 to 10, the number of possible pair-wise interactions increases from 10 to 45 (and the number of three-way interactions from 10 to 120). Thirdly, patients with diabetes are at high risk of other disorders whose management conventionally involves the prescribing of a range of medicines. For example, treatment of patients after myocardial infarction, five times more likely in the presence of diabetes, would commonly involve one or more antiplatelet agents, a statin, an ACE inhibitor, and a  $\beta$ -adrenoceptor antagonist.

Rational prescribers will consider, in consultation with the patient, therapeutic purpose, and the potential benefit and the possible harm of any additional treatment in the individual patient prior to prescribing. They will also review long-standing prescriptions from time to time to revisit previous decisions in

the light of changes in the patient, the reason for prescribing, and the pharmacopoeia.

## Insulin and Insulin Treatment

Stephen Gough<sup>1</sup> & Parth Narendran<sup>2</sup>

<sup>1</sup>Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford and Churchill Hospital, Oxford, UK

<sup>2</sup>Institute of Biomedical Research, The Medical School, University of Birmingham, Birmingham, UK

### Keypoints

- Insulin is a potent anabolic hormone essential for life. Insulin has a circulating concentration of 15–20 mU/L in the fasting state, and 60–80 mU/L post-prandially.
- Early insulins were extracted from the pancreata of pigs and cows but good glycemic control was difficult to achieve because of residual impurities after the purification process. The newer and purer animal insulins are better tolerated and can potentially achieve a level of glycemic control similar to synthetic human insulins. Clinically significant hypoglycemia rates between the human and animal insulins also appear to be similar.
- The challenge of insulin replacement therapy is to reproduce a normal physiologic insulin profile without incurring significant hypoglycemia. A range of insulin preparations with differing durations of actions are available to achieve this: rapid-acting insulin analogs (about 3 hours), soluble insulin (about 6–8 hours), neutral protamine Hagedorn (NPH) insulin (12–18 hours), lente insulins (about 12–24 hours), long-acting insulin analogs (about 24 hours).
- Current recommendations for the injection of insulin are that the skin is pinched to reduce the risk of injecting into muscle, and to inject at a right angle to the skin after which the fold should be held for 5–10 seconds before removing the needle. Injection needle lengths of 5–12 mm are available to ensure that the insulin is delivered deep enough into the subcutaneous tissue to prevent back-leakage, but not so deep that it is intramuscular. Alternative modes of insulin administration such as continuous subcutaneous insulin infusion can also be highly effective.
- Multiple-dose insulin therapy is an appropriate initial approach to reproducing the physiologic insulin profile in patients with absolute insulin deficiency such as those with type 1 diabetes. This consists of a long-acting insulin preparation administered once or twice a day to meet the basal insulin requirement, with the injection of a short-acting insulin preparation with each meal.
- A number of different insulin injection regimens are available for patients with type 2 diabetes who may already be treated with non-insulin-based therapies. These include a once daily injection of a long-acting insulin, a once daily injection of a long-acting insulin with an injection of a short-acting insulin with the main meal, twice a day injections of insulin mixtures, and multiple dose injections.

### Life (and death) before insulin

Insulin is a potent anabolic hormone, and its absence induces a profound catabolic state that affects fat, carbohydrate and protein stores. Absolute insulin deficiency, such as that characterized by type 1 diabetes (T1DM), will result in death if left untreated (Figure 27.1). What the study of patients with diabetes in the pre-insulin era teaches us is the surprisingly long period that can be survived without insulin. Leonard Thompson was the first patient to have effective insulin treatment. He was 12 years old when he was diagnosed with diabetes in 1919 and had survived over 2 years when at 11 AM on January

22, 1922 he received his first injection of insulin. This said, it was a miserable existence without insulin. Other than the weight loss, constant tiredness, thirst, urination and frequent infections, there was the certain knowledge that a death sentence had been passed, and that death would be an agonizing and slow process. The most effective therapy available at that time appeared to be severe nutritional restriction, perhaps most popularly expounded by Allen [1] from the Rockefeller Institute in New York. However, this was a difficult regimen which did not appear to prolong life expectancy significantly, and when death came it was not clear whether it was the result of diabetes or starvation.

### The discovery of insulin

Although there had been previous attempts to identify a pancreatic agent that could control blood sugar, most notably by the

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

**Figure 27.1** A patient with diabetes before and after insulin therapy.

Romanian physiologist Nicolas Paulesco, the story of insulin may be considered to start in the autumn of 1920 when Frederick Grant Banting who, while preparing a lecture on carbohydrate metabolism, considered a way to isolate the internal secretion of the pancreas. By the summer of the next year he had arranged with John Macleod, Professor of Physiology at the University of Toronto, for facilities and the support of a science student Charles Best to start experimentation (Figure 27.2). They showed that tying off the pancreatic ducts induced atrophy of the exocrine glands of the pancreas, thus allowing the “internal” secretions to be isolated. They tested the effect of this internal secretion on blood sugar by injecting it into dogs rendered diabetic through pancreatectomy. With the help of a biochemist, James Collip, they were able to purify this abstract sufficiently for the early experiments on patients. For this work, Banting and Macleod shared the Nobel Prize for Medicine in 1923.

By no means was this discovery a straightforward process, and according to one particularly harsh commentator, “the production of insulin ... originated in wrongly conceived, wrongly conducted and wrongly interpreted series of experiments” [2]. The discovery of insulin nevertheless was a defining moment in the history of diabetes and the molecule has gone on to be well

studied, with work contributing to three further Nobel Prizes: Frederick Sanger in 1958 for determining its primary amino acid sequence; Dorothy Hodgkin in 1964 for X-crystallographic studies; and Rosalyn Yalow *et al.* in 1977 for contributing to the development of radioimmunoassays.

---

### The first insulins

Commercially available insulin was initially extracted from porcine and bovine pancreata. The organs would be freshly collected from abattoirs and frozen immediately to prevent the enzymatic degradation of the insulin protein. The tissue would undergo acid-ethanol treatment to solubilize insulin, which would then be salted out with sodium chloride, precipitated and then crystallized [3]. This procedure resulted in insulin with a purity of 80–90%, the contaminants largely being pancreatic polypeptides and glucagon. Although this insulin was effective, it was often complicated by immune-mediated side effects, in particular lipoatrophy and antibody-mediated insulin resistance [4], both of which that can profoundly influence the kinetics of insulin action. These impurities also contributed to an allergic

**Figure 27.2** Charles Best and Frederick Banting on the roof of the medical building at the University of Toronto, summer 1921.

reaction which sometimes resulted in swelling and pain at the site of injection.

## Animal and human insulins

Animal insulin continues to be porcine and bovine derived. The amino acid structure of bovine insulin differs from that of human by three amino acids (position 30 of the B chain, and 8 and 10 of the A chain) and that of porcine from human by just one amino acid (position 30 of the B chain) [5,6]. These differences aside, it was the purity of the insulin preparation that appeared to influence its immunogenicity.

In the 1970s, additional purification steps using gel filtration and ion exchange chromatography resulted in an insulin, called mono-component or single component insulin, with fewer side effects and which was better tolerated (Table 27.1). The incidence of lipoatrophy and allergy decreased as these purer insulins became more widely available. It was a logical step therefore to

move on to treatment with human insulin in an effort to further reduce immune-mediated complications and improve glucose control.

Human insulin has been obtained using three techniques. The earliest attempts were to isolate and purify it directly from human cadaveric pancreata. The supply of human tissue, however, was never sufficient to enable this technique to provide sufficient quantities. The technique of “semi-synthesis” chemically converts porcine insulin to the human sequence through the substitution of the one amino acid difference in the primary sequence. It was only in 1980 with the introduction of recombinant DNA technology that human insulin therapy became widely available. The technique involves the insertion of the human DNA sequence into a host cell, usually bakers’ yeast or the bacteria *Escherichia coli*, allowing it to synthesize the insulin molecule [7]. The protein would then be purified usually via chromatography columns to achieve a 99.5–99.9% insulin purity. The quality of the human insulin preparation achieved with this technique, as indeed with the purified porcine insulin, has virtually eliminated problems associated with immune-mediated side effects.

Counter to expectations, rigorous and well-designed studies comparing purified animal insulin with recombinant human insulin have yet to demonstrate a significant benefit in glycemic control. A recent meta-analysis of 45 randomized controlled trials involving a total of 2156 participants comparing animal and human insulin failed to show a significant difference between these two therapies [8]. Most (36 of the 45) studies used highly purified porcine insulin, which many believe to be less immunogenic than bovine insulin and this may explain the favorable results for animal insulins. Overall, there is a marked absence of good studies demonstrating a superiority of human over animal insulin with regard to glycemic control. Bovine insulin was associated with a higher titer of anti-insulin antibodies, but these titers did not appear to influence the dose of insulin required, or the level of glycemic control achieved.

The move from animal to human insulin was associated in some patients with reports of greater hypoglycemia, anecdotally

brought about by changes in hypoglycemia warnings [9,10], but systematic reviews have failed to substantiate this finding in population studies [8,11].

There has been a large-scale uptake of recombinant human insulin such that less than 7% of global insulin sales are now animal insulin. This shift has probably resulted at least in part, because of the phasing out of animal insulins by the leading insulin manufacturers. Several companies continue to provide this alternate source, and both bovine and porcine-derived insulin remain available. Although cheaper to produce, the price of animal insulins in the UK is structured at a cost comparable to that of recombinant human insulin (£17–18 per 10 mL vial; BNF 2009). This pricing strategy is not the same worldwide; in the developing world for example, the cost of animal insulin is about half that of recombinant human insulin, a factor that may influence the choice of insulin preparation [12].

### Soluble and long-acting insulin preparations

The biologic action of soluble insulin lasts about 5–6 hours and the early preparations were often also associated with pain and swelling at the site of injection. Attempts were therefore made in the 1920s and 1930s to provide the patient’s daily insulin requirement in just one injection. To this end, modifying agents such as lecithin, oil and cholesterol were used [13]; however, their duration of action varied significantly from injection to injection which made their clinical use very difficult.

In 1936 a method for incorporating insulin into a poorly soluble complex, thus slowing its absorption, was reported [14]. This technique involved the addition of a highly basic protein, protamine, derived from the sperm of salmon or trout. The complex was further stabilized by the addition of a small amount of zinc such that it lasted about 24 hours, and this insulin was called protamine-zinc insulin. It was difficult to make

consistent batches and absorption again tended to be erratic. In 1946, the technique was further refined such that protamine and zinc were added in stoichiometric proportions (so that there was no free protamine or zinc), which resulted in a preparation that was absorbed at a more consistent rate and lasted 12–24 hours. This insulin was called isophane or neutral protamine Hagedorn (NPH), and became available clinically in 1940.

In 1951, a development that prolonged the action of insulin without the need for protamine was reported; this required zinc to be added in excess and in acetate buffer, resulting in crystals of relatively insoluble zinc-insulin complexes, called the lente insulins [15]. The size of the crystals could be adjusted by changing the pH such that larger crystals, which were more slowly absorbed (ultralente), and smaller crystals (semilente) could be produced. A preparation containing a 70:30 ratio of the ultralente and semilente insulins (lente insulin) was the most popular form of the zinc insulins and was used widely in clinical practice.

### Rapid and long-acting insulin analogs

Insulin circulates as single molecules in the blood at concentrations of approximately  $10^{-9}$  mol/L. At higher concentrations, such as in commercial preparations, insulin molecules tend to associate non-covalently into dimers, tetramers and hexamers [16]. The presence of zinc further stabilizes the hexamer association. Following injection, fluid is drawn into the injected insulin depot through osmosis. This leads to dilution of the insulin and dissociation of the insulin molecules, a spontaneous but gradual process that must occur before insulin can cross the capillary walls as monomers into the blood circulation [17,18]. Patients are therefore advised to inject their soluble insulin 15–20 minutes before a meal so that circulating insulin levels are optimal at the time their meal is being absorbed (Figure 27.3). A significant

**Figure 27.3** Time-action profiles of the different insulin formulations.

proportion of patients find it hard to follow this advice because of the planning required. Even when they do, the calculated doses may be inaccurate, particularly when the preparation of the meal is not under the patient's control.

The association between insulin molecules can be reduced by specific changes to the amino acid sequence of insulin [19]. These changes result in faster absorption of the insulin into the bloodstream, and allow it to be injected just before, or even immediately after eating a meal [20]. To date, three such rapid-acting analogs (RAIs) have become available: insulin lispro (Humalog®, Lilly), insulin aspart (Novorapid®, Novo Nordisk) and insulin glulisine (Apidra®, Sanofi-Aventis). These analogs act more quickly (within 10–20 minutes) and have a shorter duration of action (3–5 hours) than soluble insulin (30–60 minutes, and 6–8 hours, respectively) (Figure 27.3) [21]. A number of studies have now demonstrated the safety of RAIs in both T1DM and type 2 diabetes (T2DM), as part of a “basal bolus” insulin injection regimen combined with intermediate-acting insulins, and in continuous subcutaneous insulin infusion (CSII) [22]. The time-action profile of RAIs is well suited to mimicking the requirement at meal times, and therefore they probably control post-prandial hyperglycemia more effectively than soluble insulin. As a result, patients can achieve better glycemic control with fewer episodes of hypoglycemia with RAIs than with soluble insulin. The benefits of RAI over soluble insulin appears to be clearer in studies involving patients with T1DM than T2DM, and using CSII than for multiple dose injections [21].

Although delayed-action insulin such as insulin lente and isophane can cover the 12–24-hour period, their absorption from subcutaneous tissue can vary significantly [23]. Therefore, attempts at stringent glucose control can be associated with an increased risk of hypoglycemia. The modification of the primary amino acid sequence of the insulin molecule can result in a shift in the isoelectric point towards neutrality (the isoelectric point is that at which the molecule is least soluble). This shift in the isoelectric point therefore encourages insulin to precipitate following injection into the subcutaneous tissue (which is at neutral pH), and results in a slower and, more importantly, a more reproducible absorption [24]. Early studies of the long-acting analog insulins, designed to demonstrate equivalence rather than superiority over the isophane NPH insulins, have failed to show a clear benefit in glycemic control [25]. However, what the studies do appear to show is that achieving glycemic control with the long-acting insulin analogs is associated with less symptomatic and nocturnal hypoglycemia [26].

### Reproducing physiologic insulin delivery – the size of the problem

In health, the background insulin secretion is low and stable between meals, with significant prandial surges (Figure 27.4). The stimulus and pattern of insulin secretion is reviewed in Chapter 6, but suffice it to say that the background as well as the prandial

**Figure 27.4** Pancreatic insulin secretion in a healthy non-obese individual. Meals were consumed at 0900, 1300 and 1800. Statistically significant pulses of secretion are shown by the arrows. Reproduced from Polonsky *et al.* [27], with permission from the American Society for Clinical Investigation.

insulin secretion can vary significantly within the same individual; the former according to the level of counter-regulatory hormones such as growth hormone and catecholamines, and the latter according to the carbohydrate and protein content of the meal [27].

Furthermore, the insulin is secreted into the portal circulation, with about 50% of the insulin removed in the first pass through the liver [28]. The continuous low levels (15–20 mU/L) of insulin secretion act to suppress hepatic glucose output. Peripheral tissues such as muscle also take up glucose but this is at higher insulin concentrations (60–80 mU/L) and tends to occur predominantly post-prandially.

The challenge of insulin replacement therapy is to reproduce the physiologic insulin profile without incurring significant risk of hypoglycemia.

### Routes of insulin administration other than subcutaneous

The early experiments of Frederick Banting quickly revealed that the oral route of insulin administration was not an effective means of delivery, and subsequently that the insulin molecule was functionally degraded by gut peptides. Subcutaneous injection of

insulin has become the most popular route of insulin delivery because of its relatively reproducible kinetics of absorption, and the relative ease with which it can be administered, but it is worth visiting some of the other routes.

Intramuscular injection is more painful and absorption more rapid than the subcutaneous route [29] but is useful, for example, in the emergency situation when intravenous access is difficult. Inadvertent intramuscular administration should be considered in the slim patient with diabetes who complains of pain on insulin injection, and who may have erratic glucose control and hypoglycemia. The correct choice of insulin needles can help address this problem.

Intraperitoneal insulin administration is absorbed more quickly than the subcutaneous route and has gained some interest recently for use with implantable insulin pump therapy [30]. An advantage is that the major part of absorbed insulin is into the portal circulation [31], thus reducing the risks of high levels of peripheral insulin that may conceivably contribute to the vascular complications of diabetes and development of obesity [32,33]. Certainly, the early studies of implantable intraperitoneal pumps appear to achieve better glucose control and less hypoglycemia than the subcutaneous route. A longer experience of intraperitoneal insulin delivery has been obtained in patients requiring renal replacement therapy using continuous ambulatory peritoneal dialysis where the insulin is administered along with the dialysis fluid. There are some reports that this route is associated with more consistent absorption and lower peripheral insulin levels; however, there are no robust trials to show that any one route is superior to another [34,35].

The oral administration of insulin is a route by which this drug can enter the portal circulation, thus avoiding high levels of peripheral insulin. There are emerging reports that such an approach may be possible. Techniques such as insulin modification to engender resistance to degradation [36,37] have been reported to increase circulating insulin concentrations effectively and decrease blood glucose in early phase clinical trials.

### Subcutaneous route of insulin administration

Subcutaneous insulin administration is the most popular route of insulin therapy and suggested sites for injection are the abdomen, thigh and deltoid. Despite a scarcity of clinical trials on this subject, the current recommendations are that the skin is pinched to reduce the risk of injecting into muscle, and to inject at right angles to the skin, after which the fold should be held for 5–10 seconds before removing the needle (Figure 27.5) [38].

The increasing availability of insulin pens, which are easier to use than the traditional needle and syringe, has seen a shift towards this mode of delivery. A selection of the pen types available from the major insulin manufacturers is shown in Figure 27.6. Currently available needle lengths are 12.7, 8, 6 and 5 mm. There are few if any indications for prescribing the 12.7 mm

Figure 27.5 The recommended technique for the subcutaneous injection of insulin.

Figure 27.6 A selection of the available insulin injection devices. These are the most commonly used injection devices, although others are also available. Most are available on prescription.

needle, and shorter needles are associated with a lower risk of intramuscular injection and may well be perceived to be less traumatic. Nevertheless, there is some evidence that unless the injection technique is good, the shorter needles are associated with a greater risk of back-leakage of insulin. For a non-obese patient who uses the pinch technique on the abdomen, arm or legs, the 6–8 mm needle is usually the most appropriate.

Standard insulin preparations have a shelf life of 4–6 weeks when stored at under 25°C. Storage for longer periods will require that they be kept in a fridge (4°C), which then allows them to be stored till their expiry date. Exposure of insulin to high temperatures or to microwaves can render them inactive, a technique that may be employed by patients who wish to manipulate their treatment secretly.

Some preparations of delayed-action insulin exist in a two-phase solution which needs to be mixed adequately for complete suspension. It is important that patients are educated on the importance of this to ensure consistent amounts of insulin are drawn up on each occasion [39]. This mixing is not required for the long-acting insulin analogs.

Insulin preparations consist of insulin at or over 40 U/mL, which will exist largely as monomers, dimers or hexamers. Fluid drawn into the injected depot by osmosis following injection results in the dissociation of the oligomers into single molecules which are then able to traverse the capillary membrane and enter the circulation. Circulating insulin binds onto the insulin receptor on the target cell, is internalized and triggers a number of intracellular pathways. This internalization and degradation of insulin is the major route of insulin disposal, with less than 1% excreted by the kidney [40]. Overall, about 60–80% of insulin is degraded in the liver, 10–20% in the kidney and 10–20% in skeletal muscle and fat tissue [41]. Hence, failure of liver or renal function can and does result in the persistence of circulating insulin, with the risk of hypoglycemia.

Studies of absorption of subcutaneously administered insulin have used a variety of techniques including measuring the rate of loss of <sup>125</sup>I labeled insulin from the site of injection using a gamma counter [42]. Studies show that the rate can vary significantly between individuals, but also from one injection to another within the same individual [43]. Absorption rates in the obese patient are slower than in the non-obese patient, and there does not appear to be any clear differences in the rate of absorption between the different injection sites. In the non-obese patient, the absorption of soluble insulin from the abdomen appears to be faster than the arm or leg [44], and the upper abdomen faster than the lower abdomen [45]. These differences across injection sites appear to be less apparent with the insulin analogs than with soluble insulin [24,46].

Repeated injection of insulin at the same site results in local hypertrophy of adipose tissue, resulting in slower and more erratic insulin absorption. Patients should always be advised to rotate their insulin injection sites to avoid this complication, but the non-obese patient must also be warned that the rates may vary when they move from one part of the body to the other.

Other local factors such as edema or local inflammation can influence rates of absorption. Exercise results in greater blood flow to the skin and can result in faster uptake of insulin, particularly when injected into an area close to the muscle groups being exercised; patients who are planning to run, for example, should be advised that injection into the leg may be less favorable than injecting into the arm or abdomen [47]. Similarly, temperature influences cutaneous blood flow and can influence insulin absorption [48]; hot climates or sitting in the sauna may result in a rapid surge in insulin levels whereas the converse, traveling to cooler climates, can result in a slower uptake. There are also reports that hypoglycemia and smoking can reduce the rate of insulin absorption [49,50].

### Complications of subcutaneous insulin therapy

The most serious complication of insulin injection for most people is hypoglycemia. The causes, avoidance, consequences and management of hypoglycemia are discussed in Chapter 33. With respect to insulin treatment, the fear of hypoglycemia may be a major barrier to insulin initiation and achievement of tight glycemic control.

Insulin can not only restore fat and muscle mass in newly or suboptimally treated insulin-requiring patients, but can also lead to excessive weight gain [51,52]. This remains a major concern for many patients, particularly for the already overweight patient with T2DM who can no longer be controlled on oral hypoglycemic agents. Weight gain can be reduced by concomitant advice from the dietitian and an insulin regimen tailored to the individual needs of the patient, that wherever possible provides most insulin when needed (i.e. at meal times). Overaggressive insulin titration regimens leading to low blood glucose and stimulation in appetite can lead to excessive weight gain. Some patients, particularly but not exclusively young females, can pose a management challenge when they reduce their insulin dose to suboptimal levels to manipulate body weight (see Chapter 55).

Immune responses to the older animal insulins have been well reported but such responses to current human and analog insulins are extremely uncommon. Allergies may very rarely develop in response to both insulin and agents added to the insulin preparation. Most commonly, but again rarely, local acute urticarial reactions develop and are best treated by switching to an alternative insulin. Occasionally, the urticarial reaction may develop into a subcutaneous nodule. Antihistamines may be of benefit in such patients as too may be the use of high dose steroids in exceptional circumstances.

With the introduction of increasingly purified animal insulins, human insulin and analog insulin, antibodies to exogenous insulin are rare but, when detected, are usually induced by animal insulin products [53], polyclonal in nature, and directed against various parts of the insulin molecule. Clinically, they may lead to local allergic reactions described above and may have a retardant effect on short-acting insulins by reducing peak and raising trough levels. Such effects are likely to be unpredictable. While many clinicians speculate, in difficult to manage patients, over

the potential effect of insulin antibodies on blood glucose levels and glycemic control, there is little evidence, outside anecdotal case reports, to substantiate any significant effect.

Lipoatrophy, in which subcutaneous tissue at the site of injection disappears or atrophies, is an allergic response seen predominantly with the older animal insulins; it is rarely seen today. In contrast, lipohypertrophy is not uncommon, is not an allergic response at all but develops as an increase in adipose tissue as a trophic response to insulin. It is most commonly seen in patients with a poor injection technique and usually in patients who do not rotate their insulin injection sites. The patient usually finds the appearance unsightly and further injections into sites of hypertrophy can lead to poor and delayed insulin absorption with consequent effects on blood glucose levels [54]. Lipohypertrophy tends to settle if injections are avoided in that particular area. Occasionally, mild ulceration, pitting and, more commonly, bruising can occur at injection sites. Moving to another area for injection is advisable and, particularly when bruising occurs, a shorter needle may be preferable.

---

## Insulin regimens

As insulin preparations have evolved from the early animal insulins to both human and analog insulins we have also seen the development of more versatile and flexible treatment regimens that enable the doctor and nurse to provide the patient requiring insulin with a bespoke treatment that fits in better with their individual needs and lifestyle.

In people without diabetes it is well known that the  $\beta$ -cells of the pancreas have the ability to produce insulin both between meals and at meal times to maintain blood glucose values within a narrow physiologic range. In people with T1DM, who are no longer producing endogenous insulin, the administration of exogenous insulin is required to try, as far as is possible, to mimic physiologic insulin release using a combination of both fast or rapid-acting insulin to deal with the glucose challenge presented at meal times and more longer acting or basal insulin to provide a background control of glucose between meals. In people with T2DM, the principle is the same although as the  $\beta$ -cells may still be producing some insulin, the addition of exogenous insulin to existing oral hypoglycemic agents can be used to try to achieve control of blood glucose levels.

We discuss how each of the individual insulins discussed above can be used, alone or more often in combination, in conjunction with lifestyle and diet to control blood glucose.

### Basal only regimen

In excess of 50% of people with T2DM will require insulin injections at some point in their lives [55]. Often, as T2DM progresses, the transition from oral hypoglycemic agents to insulin injections can be a time of great stress and anxiety to many people for a number of related reasons [56]. While health care professionals employ a variety of skills and techniques to minimize what people

see as a life-changing event, we remain very aware of the many anxieties insulin injections can induce. These can include a sense of personal failure in not being able to control blood glucose levels with lifestyle, diet and oral therapy; a feeling that the diabetes is now much more serious than it was, as it now requires injections rather than tablets; apprehensions, fears and, very occasionally, real phobias over the need to self-inject a treatment [56]; worries of hypoglycemia leading to coma and death; concerns over weight gain; and also that the use of insulin may impact severely on a patient's occupation and lifestyle activities.

One way in which insulin injections can be introduced to people no longer able to manage their blood glucose on diet, lifestyle and oral therapy alone is to start with only one injection a day. This is usually added on to existing oral therapies rather than as a replacement therapy. An increasing number of studies have now been published demonstrating that a once a day basal insulin can be used as an add-on therapy to metformin, a sulfonylurea, the thiazolidinedione pioglitazone and as an add-on to these agents when used as a dual or triple oral therapy [57]. National and international guidelines in the UK, Europe and the USA also recommend the use of a basal insulin with oral therapy as a way of initiating insulin in patients with T2DM [58–60]. At the time of writing, some of the newer agents including the dipeptidyl peptidase 4 (DPP-4) inhibitors and the glucagon-like peptide 1 (GLP-1) receptor agonists do not have a license for use with insulin therapy in people with T2DM although trials are ongoing and this may change.

The initiation of insulin therapy, whether in the hospital or, more commonly, in the community, should only take place within a structured program employing active insulin dose titration. The program should include appropriate education, ongoing telephone, text and/or email support, the use of blood glucose self-monitoring to help with dose titration to an agreed target, an understanding of diet, avoidance and management of hypoglycemia and support from appropriately trained and experienced health care professionals.

A number of guidelines continue to recommend initiation with a human NPH insulin taken once or twice a day according to need [60]. However, many health care professionals opt for long-acting insulin analogs particularly in people who require assistance with injections from a carer or health care professional and where the use of an analog would reduce the number of injections from twice to once a day. Long-acting analog insulins may also be preferred in people whose lifestyle is restricted by recurrent symptomatic hypoglycemia, those who would otherwise need twice daily insulin injections in combination with oral therapy and those who have difficulties with the device required for injection of NPH insulin [57]. Similarly, indications for switching from NPH insulin to a long-acting basal analog include failure to reach an agreed HbA<sub>1c</sub> target because of hypoglycemia regardless of HbA<sub>1c</sub>.

Once started on a basal insulin it is important to adjust insulin doses appropriately to achieve an agreed target. A number of algorithms have been developed to assist with this with almost all

based upon the fasting blood glucose measured in the patient's home and usually by patient themselves [57,61,62]. While self monitoring of blood glucose is important in the dose titration process, the ultimate measure that determines the success or otherwise of the basal insulin is the HbA<sub>1c</sub> value. If this is proving difficult to control with satisfactory fasting plasma glucose values, the next step would be to add a prandial fast or rapid-acting insulin component.

### Combinations of prandial and basal insulins

In patients with T2DM, a rising HbA<sub>1c</sub> in the face of normal or near-normal fasting glucose values suggests significant post-prandial glucose excursions and the need for a meal time insulin. This can be achieved by the addition of a prandial insulin with the main meal followed as needed by the addition of a prandial insulin before every meal [57]. Alternatively, patients can be switched from a basal insulin to a premixed insulin which traditionally has been given twice daily, at breakfast and the evening meal, but which increasingly is also given initially once a day with the main meal and increased up to three times a day [59,63].

Clearly, for patients with T1DM, a basal insulin alone is inadequate and either a complete basal bolus regimen is required with prandial insulin before each meal alongside a basal insulin or alternatively a twice or thrice daily insulin premix can be used.

### Basal plus

The addition of a fast-acting human insulin or rapid-acting analog insulin prior to the main meal of the day can be a useful next step in intensification after starting a basal insulin in patients with T2DM [59,64]. Increasingly, health care professionals are using rapid-acting insulin analogs over fast-acting human insulins for convenience, as they can be given immediately before, during and even immediately after a meal [65–67]. The dietary intake of the individual will determine which the main meal of the day is and therefore with which meal the single injection of fast- or rapid-acting insulin will be given. Once again it is impor-

tant to titrate the prandial insulin to a glucose target. The ideal time to test the impact of the prandial insulin, and certainly a rapid-acting insulin analog, is 90 minutes to 2 hours after the meal. As with basal insulin adjustment it is advisable not to make too frequent a change in insulin dosage and ideally no less than every 3 days or no more than twice a week. The patient may vary the amount of insulin administered based upon the size of the meal, although as the insulin is given with the main meal of the day, the dose is usually fairly stable from one day to another. As glycemic control becomes more difficult to achieve a second prandial insulin injection may be necessary, taken before the second main meal of the day using a similar dose titration procedure as that for the single prandial injection [64].

### Basal bolus

The use of the basal bolus regimen in patients with T1DM and T2DM attempts to mimic, as closely as possible, the normal physiologic secretion of insulin by providing a background 24-hour coverage of insulin along with a bolus injection at each meal time (Figure 27.7). In most patients, with the development of long-acting analog insulins, the basal injection is administered once a day. However, based on the results of pre-meal self-monitored blood glucose values some patients may require two basal injections approximately 12 hours apart to achieve satisfactory before meal glucose values without hypoglycemia.

Traditionally, with animal and then human insulins, basal injections are given in the evening, often before bed. This is less important with the basal analog insulins and indeed many patients benefit from having their once a day basal injection at the same time each morning. It is important that insulin doses are adequately titrated to achieve target glucose and HbA<sub>1c</sub> values and for the basal bolus regimen the dose of the basal insulin is determined by measurement of fasting (pre-meal) glucose values and the most appropriate fast human or rapid-acting analog insulin dose is best determined by 2 hour post-prandial glucose values.

**Figure 27.7** Schematic representation of the attempt to mimic physiologic insulin release following three main meals using a basal bolus regimen.

### Insulin mixtures

While some patients still self-mix either animal or human fast-acting and long-acting insulins prior to injection, most people using insulin mixes inject premixed insulin preparations. In recent years, we have seen a whole spectrum of insulin premix insulins ranging from a 10:90 to 50:50 short:long-acting insulin ratios. In reality, many of these premixes were not required and consequently through lack of use the range of premixes has contracted down to 25:75, 30:70 and 50:50 mixes.

Most patients use premixed insulin twice a day, before breakfast and the evening meal. In people with T2DM, insulin initiation may start with a once a day premix insulin with the main meal, increasing up to two injections a day when needed based on self-monitored blood glucose values and the HbA<sub>1c</sub> [59,64]. Some patients with T1DM, but more frequently patients with T2DM, move to three injections a day by also administering an injection before lunch. For patients moving up to three injections a day, the 50:50 mixture providing more rapid-acting insulin at meal times may be more appropriate than the more commonly used 25:75 or 30:70 mixture, usually given twice a day.

---

### Selecting the most appropriate insulin regimen

Most people with T1DM and T2DM try a number of treatment regimens throughout their lives. There are many factors that influence the decision to opt for a specific regimen and ultimately the most important is patient choice rather than evidence from clinical trials.

#### Type 1 diabetes

All patients with T1DM, unless they have been fortunate enough to become insulin independent following a pancreas or islet cell transplant, will require exogenous insulin to provide 24-hour background and meal time coverage. For many patients this is provided by the basal bolus regimen. The advantages of such an approach are that it is generally better at providing a more physiologic insulin replacement with a greater degree of 24-hour flexibility than less frequent premixed insulin. While it has the disadvantage of more daily insulin injections and for many more frequent self blood glucose monitoring, which is not popular with some patients, particularly young and teenage children, it does provide a much greater degree of flexibility throughout the day. Importantly, it allows the patient to vary the meal time dose at up to three different time points during the day to accommodate different daily activities and meal sizes. For some, this “freedom” is less important and the administration of only two injections a day sways them towards an insulin premix.

#### Type 2 diabetes

While in some patients with T2DM insulin requirements are similar to those with T1DM, for many, insulin initiation and

intensification is a more gradual process. Views differ on the insulin of choice for initiation, particularly as an add-on to oral hypoglycemic therapy. Prior to the introduction of the long-acting basal analogs, many patients requiring insulin were started on a twice a day premixed insulin often as an add-on to metformin. If patients were also on a sulfonylurea this was usually stopped. Supported by clinical trials, using long-acting basal analogs as an add-on to existing oral therapy and low rates of hypoglycemia compared to those seen with NPH insulin, once a day long-acting basal insulins are now recommended in T2DM treatment guidelines and have found significant popularity, particularly in the community as a means of introducing the patient to insulin [57,61]. Anecdotally, while this is a popular way of starting insulin, many health care professionals struggle to achieve satisfactory glycemic targets with this regimen and many patients will require a second insulin injection with a meal time component within 6–12 months.

Trials comparing twice daily premixed insulins with a long-acting basal analog when added to metformin in insulin-naïve patients appear to show a benefit in favor of twice daily premixed insulin with respect to the numbers of patients achieving target HbA<sub>1c</sub> values [68,69]. The relative merits of basal only, prandial only and premixed insulin are unclear [70] and are currently being further evaluated [71]. Clearly, there are advantages and disadvantages associated with each approach. A pragmatic response is to consider each patient individually and their lifestyle, social circumstances and co-morbidities and taking into account what their insulin needs are likely to be in the longer term to make a clinical judgment. If it seems likely that if started on a basal insulin they are likely to remain on this as a single injection or as part of a basal bolus regimen in the future, the basal insulin may be the best option. However, if it seems likely that the patient will be switched to a premixed insulin if a long-acting bolus does not achieve target, then initiating with a premixed insulin would seem sensible. Starting the premixed insulin as a once a day injection increasing to two and sometimes three injections is also an option with some clinical evidence to support it.

#### Starting insulin for the first time

In the past, insulin initiation, particularly for people with T1DM, was conducted either as an inpatient or as a day case in a hospital diabetes center. As confidence grows with the development of purer animal insulins and most recently with human and analog insulins and also with the introduction of disposable syringes, pen injectors and needles, more insulin initiations are performed on an outpatient basis. Most recently, with an increased emphasis on community-based diabetes care, insulin initiation, particularly in patients with T2DM, is taking place in health centers and GP surgeries [72]. While older algorithms for helping to decide when and where insulin should be initiated have been published, national and local guidelines now seem more appropriate as varying levels of expertise, infrastructure and service delivery are present in different health settings.

**Table 27.2** Outpatient/community pathway for people starting insulin for the first time.**Session 1**

- The need for insulin has already been discussed with the patient by a doctor or diabetes nurse specialist and patient has been seen by a dietitian
- A regimen will have been agreed upon and the first prescription has been obtained by the patient
- A review of “what is diabetes” including what insulin does and the need for insulin injections usually takes place
- Nurse demonstrates the basics and use of insulin injection device and patient gives first injection
- Further discussions including:
  - (i) sites for injection/site rotation
  - (ii) timing of injections
  - (iii) where and how to obtain equipment (insulin, pens, needles, self blood glucose monitoring equipment, sharps disposal equipment)
  - (iv) recognition and management hypoglycemia and hyperglycemia
  - (v) self blood glucose monitoring
  - (vi) driving and legal issues surrounding insulin
- 24-hour contact details provided

**Session 2** (around 2 weeks after insulin initiation)

- Prior to session 2 patient and nurse will usually have had telephone contact over insulin injections and blood glucose readings
- Review of information provided in session 1
- Review of insulin injection technique

**Session 3** (around 4 weeks after insulin initiation)

- Review of session 1 and 2
- Further information provided about:
  - (i) insulin on holiday and when traveling
  - (ii) insulin injections when traveling through time zones (e.g. transatlantic travel)
  - (iii) insulin management during periods of acute sickness
  - (iv) foot care, other diabetes-related complications and in females of childbearing age, pregnancy

**Session 4** (around 10 weeks after insulin initiation)

- Review of previous sessions
- Assessment of glycemic control and need for further doctor/nurse follow-up
- Book follow-up clinic/surgery appointment

Wherever insulin is initiated it is vital that for it to be successful a good insulin initiation program is in place, with a qualified and competent diabetes nurse specialist. A number of programs are available, most with appropriate training courses for health care professionals. Insulin initiation involves much more than teaching a patient how to use a needle and syringe and the process of starting and successfully stabilizing a patient on insulin will require a number of structured contacts with the nurse and also a 24-hour emergency contact number for any urgent problems that may arise (Table 27.2).

For those patients presenting acutely ill with nausea and vomiting, with or without ketosis, admission to hospital for insulin initiation and, where needed, intravenous fluids, is a necessity.

**Use of animal, human and analog insulins**

The evolution from animal to human and then analog insulins has been discussed at the start of this chapter. We have subsequently outlined above some of the advice included in national guidelines regarding the use of human and analog insulin. In clinical practice all three types of insulin are in regular use. At the present time, patients wishing to stay on animal insulin should, wherever possible, be allowed to do so. There are also advantages associated with the use of the analog insulins although generally they are more expensive to prescribe than human insulin and concerns have been raised over cost–benefit when prescribed routinely. While some of the individual benefits appear small, collectively these benefits are likely to have an impact on many patients [65]. While those responsible for health care budgets seek persuasive clinical trial data it is most unlikely that we will ever see direct head to head studies that provide incontrovertible data one way or another. Ultimately, it will come down to clinical judgment and a decision involving the patient.

**Assessments of glycemic control**

While national and international guidelines have made recommendations on glycemic targets based predominantly on the HbA<sub>1c</sub> [58–60,73], self-monitoring of blood glucose not only helps patients achieve HbA<sub>1c</sub> targets by adjustment of insulin doses, but also helps patients better understand their own diabetes and blood sugar levels better. The timing of glucose tests and their role in determining the most appropriate insulin dose is discussed above and is discussed in greater detail in Chapter 25. Generally speaking, patients should be advised to test at different times on different days including pre-meal and 2 hours post-prandial testing to obtain 24-hour glucose profiles over a number of days rather than performing a large number of tests every day. To achieve strict glycemic control, as seen in the T1DM DCCT [52], pre-meal blood sugar readings should fall between 4 and 7 mmol/L and post-meal levels from 4–10 mmol/L, with a value >7 mmol/L before bed. While individual specialists often follow their own dose adjustment algorithms, in general terms a change in dose of 2 units or 10% of a dose (whichever is the greater) is a sensible adjustment for most patients.

Similar targets may be sought for people with T2DM although recent trials based on achieving very tight HbA<sub>1c</sub> values, with some aiming for <6%, serve to highlight the dangers of hypoglycemia [74]. The frequency of blood glucose testing is extremely variable, with patients being recommended to test anything from seven times a day to four or five tests a week. The most important aspect of regular self-monitoring by patients on insulin is that the test result should be used as part of a management plan to help decide prospectively on insulin dose. There are other points that should be considered when advising on the timing of self-testing, including intercurrent illness, symptoms and treatment of hypoglycemia, and foreign travel. While more frequent testing generally provides more information, it is also important to remember not to recommend unnecessary and costly testing as

pricking the finger is painful and for most patients is worse than injecting insulin.

## New Technologies for Insulin Administration and Glucose Monitoring

**Howard Wolpert & Judy Shih**

Joslin Diabetes Center, Boston, MA, USA

### Keypoints

- Continuous subcutaneous insulin infusion pumps and continuous glucose monitors can be effective tools for improving metabolic control in patients with type 1 diabetes.
- Pump therapy provides increased lifestyle flexibility, and can reduce the risk for hypoglycemia.
- Real-time continuous glucose monitoring devices provide detailed information on glucose patterns and trends, and alarms that are triggered by both hyperglycemia and hypoglycemia.
- Randomized trials indicate that this technology can lead to a reduction in HbA<sub>1c</sub> without an associated increase in hypoglycemia.

### Introduction

The development of capillary blood glucose monitors set the stage for the era of intensive insulin therapy, and technologic advances continue to be an important driver for improvements in diabetes care. In this chapter we highlight the developments of the past decade focusing on those technologies that show the most promise in improving the lives of people with diabetes, in particular, insulin pump therapy and real-time continuous glucose monitoring. In recent years, inhaled insulin has been an area of intense investigation; however, interest in this mode of insulin delivery has been diminished by concerns about potential pulmonary toxicity.

### Continuous subcutaneous insulin infusion pumps

Continuous subcutaneous insulin infusion (CSII) pumps were first introduced over 30 years ago [1,2]. They consist of an insulin reservoir and a delivery catheter that continuously infuses insulin into the subcutaneous tissue. In recent years, there has been growing adoption of this technology in diabetes care. Several factors have contributed to this increased use, including the focus on intensive therapy triggered by the Diabetes Control and Complications Trial (DCCT); improvements in the reliability

and usability of pumps; patient preferences; and also the growing recognition by clinicians that CSII delivery is associated with reduced risk for hypoglycemia. Because a comprehensive review of insulin pump therapy is beyond the scope of this chapter, we focus on issues that have received most attention in the recent literature, including the potential advantages of pumps as a tool for insulin administration and newer developments in pump technology such as bolus calculator software. In addition, we provide some practical pointers about pump therapy for the clinician.

### Glycemic control with insulin pumps compared with multiple daily insulin injections

Several published meta-analyses have examined the role of CSII pumps as a tool for intensifying glycemic control [3–5]. These meta-analyses of the randomized controlled trials in the published literature indicate that CSII use in patients with type 1 diabetes mellitus (T1DM) is associated with 0.4–0.5% (5–6 mmol/mol) lower HbA<sub>1c</sub> than multiple daily injection (MDI) therapy. The improvements in HbA<sub>1c</sub> with the change to pump therapy appear to be greater in individuals who have poorer glycemic control [6,7]. Most of the studies examined in these meta-analyses involved MDI regimens using NPH or ultralente insulins; however, more recent randomized controlled trials suggest that CSII is also superior to MDI regimens using the newer long-acting insulin analogs [8,9]. Data about potential complications of pump therapy (such as ketoacidosis, pump malfunction and insulin site problems) is not reported in many of the published randomized trials, and most evidence suggesting that CSII is associated with an increased risk for ketoacidosis date from the 1980s [10–12]; however, device malfunction and infusion site problems

do still occur with modern pump technology, which points to the importance of giving education on proper catheter site care and ketoacidosis prevention to all patients using pumps.

Because of the more controlled delivery of insulin, CSII can be an effective tool for reducing glycemic variability, and this can be of benefit for reducing the risk for hypoglycemia brought about by insulin replacement therapy [13]. Clinical guidelines from several national and international organizations recommend consideration of pump therapy for individuals with T1DM with suboptimal glycemic control and problematic hypoglycemia (Box 28.1) [14–16]. However, conclusions from the meta-analyses about whether the mode of insulin delivery has an impact on hypoglycemia have yielded conflicting results [5,17,18], in large part because of methodologic issues and differences in trial selection [19,20]. The meta-analysis of randomized controlled trials by Pickup & Sutton [17], which was restricted to studies published since 1995 (i.e. since the introduction of more reliable pump technology) with a baseline (pre-trial) rate of severe hypoglycemia of >10 episodes/100 patient years and ≥6 months of CSII use, showed that there was a 2.9-fold (95% confidence interval [CI] 1.45–5.76) reduction in severe hypoglycemia during CSII compared to MDI. The analysis also indicated that the benefit from pump therapy was greater in individuals with higher rates of severe hypoglycemia ( $P < 0.001$ ) and those with longer duration of diabetes ( $P = 0.025$ ) [17]. A meta-analysis commissioned by the Endocrine Society reached different findings, and concluded that in comparison with MDI, CSII was not associated with a significant reduction in severe or nocturnal hypoglycemia [18]. The validity of these conclusions is limited by the inclusion of studies of relatively short duration with low incidence rates of severe hypoglycemia that would bias against the detection of any potential benefit from pump therapy. In addition, the rates of minor and nocturnal hypoglycemia were determined using intermittent fingerstick glucose monitoring, which can be unreliable in detecting nocturnal hypoglycemic events [21] and would therefore be relatively insensitive to detecting treatment-related differences. Furthermore, it should also be noted that the studies examined in this analysis were almost entirely performed using older pump types that did not incorporate the bolus calculator software now available in updated pumps which can help to limit hypoglycemia related to doses stacking up from repeated boluses. These factors limit the generalizability of the conclusions from this analysis to clinical practice, and the weight of evidence from studies reported in the literature suggest that clinicians caring for motivated patients with T1DM who have recurrent hypoglycemia and especially a history of severe hypoglycemic reactions should recommend a trial of insulin pump therapy.

Evidence in insulin-requiring type 2 diabetes mellitus (T2DM) regarding the potential benefits of pump therapy in comparison with MDI is limited. The studies of Raskin *et al.* [22] and Herman *et al.* [23] showed similar HbA<sub>1c</sub> changes with both modes of insulin delivery. A small-scale cross-over study in obese subjects with T2DM with insulin resistance has demonstrated a significant

### Box 28.1 Pump therapy: indications and considerations

- Severe hypoglycemia and hypoglycemia unawareness
- HbA<sub>1c</sub> above goal
  - *Caution:* Intentional insulin omission (to facilitate weight loss) is a not uncommon cause for poorly controlled diabetes, especially in young women [32]. Before initiating pump therapy, it is important to rule out this problem. Because these patients habitually underdose insulin and are frequently hyperglycemic, they do not routinely troubleshoot for insulin non-delivery by the pump and can therefore be at increased risk for developing ketoacidosis
- Diurnal variations in basal insulin requirements caused by the dawn phenomenon [33,34] and steroid therapy can be more readily managed using the multiple basal rates provided by the pump than by long-acting injected insulins [35]. Continuous subcutaneous insulin infusion can be of special benefit for the post-renal transplant diabetes patient on steroid therapy who is striving for intensive glycemic control
- Preconception and pregnancy
- Practical advantages of pumps for bolus insulin delivery include:
  - *Dosing precision:* The extra precision of insulin dosing with pumps can be an important advantage for young children (especially infants and neonates) [36] and adults who are on very low insulin doses. In addition, accurate dosing of insulin boluses in fractions of a unit allows the patient to correct hyperglycemia more precisely without overshooting and causing hypoglycemia. For those patients in whom fear of hypoglycemia is an impediment to tight glycemic control, this added assurance can be critical in overcoming reluctance to intensification. In practice, it can be helpful to reduce missed food boluses, facilitate interprandial “correction” bolusing, and help simplify eating at restaurants and social occasions (with the use of extended/square wave boluses and multiple bolusing)
  - *Optimizing post-prandial insulin coverage:* Facilitates dosing for higher fat, complex carbohydrate and/or larger meals. Dietary fat delays gastric emptying [37] and induces post-prandial insulin resistance [38], so high-fat meals cannot usually be adequately covered using a single injection of rapid-acting insulin [39]. Use of the extended/dual bolus and increased temporary basal can help optimize post-prandial glycemic control following these meals [40–42]. (For practical strategies see Wolpert [43].)
  - *Gastroparesis:* Use of the extended/dual wave bolus can allow for better matching of carbohydrate absorption and insulin action

reduction in HbA<sub>1c</sub> and postmeal glucose excursion with use of pump therapy [24]. Where patients are unable to achieve adequate glycemic control, several practical issues should be considered (Box 28.2).

### Box 28.2 Practical issues to consider in the pump patient with erratic glucose control

- *Infusion site issues including scarring, lipohypertrophy and lipodystrophy:* Infusion sites should be routinely examined in pump users with unexplained glucose fluctuations
- *Infusion catheter kinking or dislodgement:* Plastic catheters that are perpendicular to the skin surface and have a small base for attachment (e.g. Medtronic MiniMed Sofset™, Disetronic Ultraflex™) are more prone to kink or become dislodged especially with activity or perspiration. Solutions include changing to metal needle infusion sets, plastic sets with a shorter cannula, or other types of plastic infusion sets that are less prone to kinking. These include the Medtronic MiniMed Quickset™ (which has a broad base of attachment to the skin), and sets that insert obliquely such as the Medtronic MiniMed Silhouette™, Roche Disetronic Tender™ and Animas Comfort™
- *Failure to change the pump reservoir and infusion system on a regular basis:* This may manifest in a tendency for elevated and erratic glucose in the period preceding infusion set changes
- *Review of pump downloads can be helpful:*
  - Check priming history to assess how frequently the infusion system is being changed
  - Check bolus history to detect possible missed meal boluses
  - Check percentage of basal to bolus insulin. A high percentage of basal insulin in the patient with frequent hyperglycemia may indicate that bolus doses are frequently being missed. A high percentage of basal insulin in the patient with frequent hypoglycemia may indicate that high basal rates are contributing to hypoglycemia, and would point to a need to re-evaluate basal rate settings
  - Check for a history of pump suspension or basal rate reduction. Even temporary removal of the pump to bathe can lead to elevations in the glucose levels; patients need to be reminded to bolus to replace the missed basal when reconnecting the pump. Some patients using the pump will get in the practice of reducing the basal rate or suspending the pump when they are hypoglycemic; the end result will often be exaggerated rebound hyperglycemia
- *Insulin instability in the pump infusion system:* This can manifest as increases in the glucose levels in the period preceding infusion set changes or even precipitation in the infusion system [46]
- Pump malfunction
- Air bubbles in infusion system resulting from poor filling technique

### Quality of life benefits and patient expectations

Many patients describe improvements in quality of life when they change to pump therapy; however, there have been few carefully designed studies that have examined patient perspectives of pump therapy, and differences in psychosocial functioning with

CSII compared to MDI [4,25]. The published literature suggests that use of pumps is associated with improved quality of life compared to MDI [26–28]; however, this has not been confirmed in all studies [29]. Patients will vary in their perceptions about the potential quality of life benefits (including increased lifestyle flexibility, dietary freedom, reduced fear for hypoglycemia) relative to some of the potential drawbacks of CSII (including body image concerns and the need for frequent blood glucose monitoring) [30]. Wolpert and colleagues conducted a focus group investigation of 30 patients followed at the Joslin Diabetes Center to examine how psychosocial factors impacted the use of the pump [31]. Patients with better glycemic control viewed the pump as a tool for diabetes self-management rather than as a panacea. In contrast, the pump patients with poorer HbA<sub>1c</sub> had more unrealistic expectations including the perception that use of technology was a substitute for attentiveness to self-care and that pump therapy allowed them to do whatever they wanted, particularly with regard to eating. Before initiating pump therapy, health care professionals need to assess patients' expectations of the pump, dispel unrealistic notions (often promoted by marketing materials) and ensure that patients recognize that while the pump allows life with diabetes to be more flexible and convenient, it is not a vehicle for total freedom from diabetes.

### New developments in pump technology: bolus calculators

In recent years, new software programs that assist patients with bolus calculations have been incorporated into insulin pumps. The patient's insulin:carbohydrate ratio (the number of carbohydrate grams covered by 1 unit of insulin) and correction/sensitivity factor (a measure of the glucose-lowering effect of 1 unit of insulin) is programmed into the pump software. Based on planned carbohydrate intake of the patient and the blood glucose level, the bolus calculator will recommend a bolus dose. Although this dose calculation software can simplify the daily self-care routines of the pump users, patients should receive appropriate education to ensure that they can manually calculate bolus doses in the event they need to discontinue pump therapy. In addition, it is important that the programming of the bolus calculator software is adjusted to individual needs and not automatically left at the manufacturer's default settings. These bolus calculators have an important role in minimizing the risk for hypoglycemia from multiple boluses and dose stacking which are a common practical problem with some pump users [43]. When calculating an insulin dose, the pump software will consider the amount of active insulin-on-board (commonly referred to as IOB) and subtract this IOB from the recommended dose. This IOB calculation is based on insulin action plots which predict the amount of insulin remaining as a function of time; the assumed insulin duration of action used by the software in this calculation is individually programmed by the patient or health care professional, and can be varied from 2 to 8 hours depending on the pump type [44]. As outlined in Chapter 27 the absorption of insulin analogs can vary markedly even within individuals. In practice, the major

consideration in setting the insulin duration of action in the bolus calculator software is usually a best guess based on a clinical assessment of the hypoglycemia risk of the patient and the imperative for achieving tight glycemic control (in particular, pre-conception and pregnancy) [45]. For individuals with frequent hypoglycemia, hypoglycemia unawareness or a history of severe hypoglycemic reactions, the duration of action should be set 5 hours or even longer, whereas for the woman who is pregnant or trying to conceive, the duration of action is often set at 2–3 hours. The glucose records of the patient can be assessed to determine if the duration of action settings are appropriate. If the duration of action time programmed into the software is less than the true duration of action, the pump will indicate that there is less IOB than is actually the case, and the patient will mistakenly take more insulin than required; the glucose records will show evidence of hypoglycemia from “stacking” of doses. Conversely, if the setting

programmed into the pump is longer than the true duration of insulin action, this can lead to underdosing of insulin and hinder attempts to optimize glycemic control.

### Real-time continuous glucose monitoring

In the last several years, several real-time continuous glucose monitoring (RT-CGM) devices (Abbott Freestyle Navigator®, DexCom Seven®, Medtronic Guardian®/Paradigm® system) have received the CE mark and approval from the US Food and Drug Administration (FDA) for long-term use in ambulatory patients with diabetes (Figure 28.1). These devices have transcutaneous glucose oxidase-based electrochemical sensors that measure the glucose concentration in the interstitial fluid every 1–5 minutes (Figure 28.2). Because of accuracy limitations [47,48], the current

**Figure 28.1** Three components of continuous glucose monitoring (CGM) device: sensor, transmitter and receiver unit.

**Figure 28.2** Modal day report from patient who eats breakfast at 9:00 am and supper at 10:00 pm daily. Indicates rapid spike in glucose levels post-meal that had not been detected with intermittent fingerstick blood glucose monitoring. Treatment recommendations focused on changing to more slowly absorbed lower glycemic index carbohydrates (e.g. oatmeal) and/or injection of bolus insulin earlier before the meal.

**Figure 28.3** Device download: top panel shows continuous glucose tracing, and bottom panel shows insulin delivery (each blue bar represents an insulin bolus with units of insulin shown on the vertical axis on the right). Following breakfast the glucose level increased to 300 mg/dL (16.7 mmol/L) prompting the patient to take multiple boluses with resultant hypoglycemia.

generation of CGM devices do not have regulatory approval for use as stand-alone devices, and patients are required to perform adjunctive capillary blood glucose measurements; however, this limitation is compensated by the additional detailed information provided by the CGM about glucose patterns, the rate and direction of change in the glucose level and adjustable alarms that are triggered by both hyperglycemia and hypoglycemia (Figure 28.3) [49].

### Clinical efficacy of RT-CGM

Because RT-CGM is a relatively new technology, to date only a few randomized controlled trials have been performed. The initial reported studies, which were only several days in duration, showed that use of RT-CGM leads to a reduction of both hyperglycemic and hypoglycemic excursions with more time in the target glucose range [50,51]. The GuardControl trial using the Medtronic Guardian was the first longer duration study of RT-CGM. This study enrolled 156 adults and children with T1DM using both pumps and MDI therapy [52]. At 3-month follow-up, the group randomized to RT-CGM use had  $1.0 \pm 1.1\%$  ( $11 \pm 12$  mmol/mol) reduction in HbA<sub>1c</sub> (down from  $9.5 \pm 1.1\%$  [ $80 \pm 12$  mmol/mol] at baseline) compared to  $0.4 \pm 1.0\%$

( $5 \pm 11$  mmol/mol) reduction in the control group ( $P = 0.003$ ). In addition, at 3 months, 50% of subjects in the CGM group had HbA<sub>1c</sub> reductions of  $\geq 1\%$  compared to 15% of subjects in the control group, and 26% in the CGM group had HbA<sub>1c</sub> reductions of  $\geq 2\%$  compared to 4% in the control arm. Reported results from this industry-supported study have not included any specific information on the treatment protocols used in the trial or data about the effect of CGM on hypoglycemia.

To date, the results of two large-scale multicenter randomized controlled trials of 6 months' duration have been published in the literature: the industry-supported Star 1 trial and the Juvenile Diabetes Research Foundation (JDRF) sponsored CGM trial. The Star 1 trial enrolled 146 subjects aged 12–72 years with T1DM treated with CSII pumps [53] who were randomized to pump therapy with RT-CGM using the Medtronic 722 pump system or pump therapy with fingerstick self-monitoring of blood glucose. The primary endpoint was not achieved; there was a similar reduction in HbA<sub>1c</sub> ( $0.71 \pm 0.71\%$  in the sensor group vs  $0.56 \pm 0.072\%$  in the control group;  $P =$  non-significant) over the 6-month trial. Importantly, in the subjects using RT-CGM, the improvement in glycemic control was accomplished without any

change in biochemical hypoglycemia ( $P < 0.0002$ ), whereas in the control subjects using fingerstick glucose monitoring there was an increase in biochemical hypoglycemia (documented with blinded CGM devices). More severe hypoglycemic events occurred in the group using RT-CGM than in the control group (11 vs 4;  $P = 0.04$ ). During six of the 11 severe events in the RT-CGM group, subjects were not using a sensor. The Data Safety Monitoring Board determined that in the remaining five severe hypoglycemic events there was evidence of the following:

- 1 Failure of subjects to respond to alarm warnings of hypoglycemia;
- 2 Multiple insulin boluses without use of the pump bolus calculator, resulting in dose stacking; or
- 3 “Blind boluses” (i.e. treatment decision based on sensor readings showing hyperglycemia without confirmatory fingerstick capillary blood glucose measurements).

This clinical experience from the Star 1 trial was incorporated into the treatment protocols and patient education materials used in the JDRF CGM trial.

The JDRF CGM trial enrolled 451 patients with T1DM aged 8–74 years and  $HbA_{1c} < 10\%$  (86 mmol/mol) to a RT-CGM group or control group that continued with capillary blood glucose monitoring [54,55]. This study involved patients using both insulin pumps and injection therapy and used three different CGM devices (Abbott Navigator®, Dexcom Seven® and Medtronic Guardian/722® system), with assignment based on patient preference with investigator guidance. By design, the cohorts with  $HbA_{1c}$  at randomization of  $< 7.0\%$  ( $< 53$  mmol/mol;  $n = 129$ ) and 7–10% (53–80 mmol/mol;  $n = 322$ ) were analyzed separately.

For individuals with T1DM who have already managed to achieve  $HbA_{1c}$  levels in the optimal target range with intermittent capillary blood glucose monitoring, the main therapeutic challenge is minimizing the risk for hypoglycemia that accompanies intensive glucose control. Accordingly, for the cohort enrolled in this trial with baseline  $HbA_{1c} < 7.0\%$  ( $< 53$  mmol/mol), the pre-specified primary endpoints were focused on changes in hypoglycemia rather than  $HbA_{1c}$  per se. At 26 weeks, biochemical hypoglycemia  $\leq 3.9$  mmol/L (70 mg/dL) was less frequent in the CGM group than the control group using intermittent fingerstick monitoring (median 54 vs 91 minutes/day), but this was not statistically significant. Median time spent with glucose level  $\leq 3.3$  mmol/L (60 mg/dL) was 18 vs 15 minutes/day, respectively ( $P = 0.05$ ). There were similar numbers of severe hypoglycemic events in the two groups; however, the trial was not adequately powered to detect a treatment group difference. More subjects in the CGM group than the control group had a decrease in  $HbA_{1c}$  of  $\geq 0.3\%$  without having a severe hypoglycemic event (28% vs 5%;  $P < 0.01$ ) [56].

For the cohort with baseline  $HbA_{1c}$  7–10% (53–86 mmol/mol), the pre-specified primary endpoint was  $HbA_{1c}$  reduction. A significant between-group difference in change in  $HbA_{1c}$  from baseline to 26 weeks was seen in patients  $\geq 25$  years old, favoring the continuous monitoring group (mean difference in change  $-0.53\%$ ;  $P < 0.001$ ), but not in the younger subjects. Biochemical

hypoglycemia evaluated by CGM was similar in the two treatment groups. Similarly, there were no significant differences in the incidence of severe hypoglycemic events between the study groups. In the adult cohort, the frequency of the combined outcome of 26-week  $HbA_{1c} < 7.0\%$  ( $< 53$  mmol/mol) and no severe hypoglycemic events was 30% in the CGM group and 7% in the control group ( $P = 0.0006$ ) [55]. This finding, that RT-CGM leads to an improvement in glycemic control without an associated worsening in hypoglycemic events, is in direct contrast to other intervention studies such as the DCCT in which intermittent capillary glucose monitoring had been used to guide intensification of metabolic control, and points to the promise this new technology offers for people with T1DM.

### Practical issues with use of RT-CGM

The randomized controlled trials that have demonstrated the benefits of RT-CGM have involved patients with a high level of engagement in their diabetes self-care (mean number of daily capillary blood glucose measurements performed by subjects enrolling in the JDRF trial was six). Furthermore, to use this technology successfully, patients need to have advanced diabetes self-management skills (Box 28.3). In the next sections we discuss several key issues that need to be addressed in the training of patients starting on CGM.

#### Physiologic lag between blood and interstitial glucose

The lag in the equilibration of glucose levels between the capillary blood (measured using home blood glucose monitoring device) and the interstitial fluid in the subcutaneous tissue (measured by the CGM device) [57,58] has important practical implications. In general, increases or decreases in the glucose concentration will first be apparent in the blood followed by the interstitial fluid. Currently available CGM devices are calibrated using fingerstick capillary blood glucose measurements, and to optimize sensor accuracy it is important that the device only be calibrated when the glucose level is relatively stable, and there is steady-state equilibration between glucose concentrations in the blood and interstitial fluid. In practice, calibrations should be performed

#### Box 28.3 Patient teaching points: Adjusting bolus doses based on rate of change of glucose [63]

- If glucose  $\uparrow$  by 0.056–0.11 mmol/L/minute (1–2 mg/dL/minute): +10% to calculated food/correction bolus
- If glucose  $\uparrow$  by  $> 0.11$  mmol/L/minute ( $> 2$  mg/dL/minute): +20% to calculated food/correction bolus
- If glucose  $\downarrow$  by 0.056–0.11 mmol/L/minute (1–2 mg/dL/minute): –10% from calculated food/correction bolus
- If glucose  $\downarrow$  by  $> 0.11$  mmol/L/minute ( $> 2$  mg/dL/minute): –20% from calculated food/correction bolus

**Box 28.4 Patient teaching points: Calibration do's and don'ts**

- Before calibrating the sensor, the patient should check to be sure that there are no arrows on the sensor display indicating that the glucose is changing rapidly
- Calibration should not be performed:
  - Within 3–4 hours of a meal or an insulin bolus
  - During exercise
  - After recovering from hypoglycemia

**Box 28.5 Patient teaching points: Circumstances where fingerstick capillary glucose must be checked**

- If the sensor indicates that the glucose is elevated, the reading must first be confirmed with a fingerstick capillary blood glucose measurement before the patient takes a corrective bolus
- Whenever subjective symptoms are not in keeping with the sensor reading, a fingerstick reading should be taken to confirm the glucose level
- Before or during driving, if the sensor reading is normal and the continuous glucose monitoring rate of change indicator or tracing indicates that the glucose level is falling, the patient must measure fingerstick blood glucose
- Following treatment of a low glucose, if the sensor still shows a low reading, the patient should check fingerstick blood glucose and use this measurement to decide whether to take in more carbohydrate. Reliance on the sensor reading to assess response can lead to overtreatment

preprandially or at least 3 hours after a bolus (Box 28.4). The first generation CGM devices need to be calibrated at least 4 times per day for optimal accuracy [59].

The physiologic lag has implications with regard to detection and treatment of hypoglycemia. Because of the lag of interstitial glucose behind blood glucose, when the glucose level is declining the interstitial (sensor) glucose can be in the normal range even though the actual blood glucose is low [60]. Patients should be instructed to perform a fingerstick blood glucose measurement before driving if the sensor glucose reading is normal and the trend graph or rate-of-change arrows on the sensor display indicate that the glucose level is declining (Box 28.5). As shown in the study by Wilson *et al.* [61], when the glucose is falling rapidly, the physiologic lag can also lead to underestimation by the rate-of-change indicator of the CGM device. The practical implication is that if the patient feels hypoglycemic or has reason to suspect that the glucose is declining, but this is not corroborated by the sensor, they should disregard the sensor data and carry out a fingerstick glucose measurement.

This lag phenomena also has practical implications for the treatment of hypoglycemia. During the recovery from hypoglycemia, the increase in the interstitial glucose will often lag behind the blood glucose [62], and at a time when blood glucose has already normalized the sensor/interstitial glucose may still be in the low range. Patients should be instructed of the need to perform fingerstick glucose measurements to assess the response to treatment of hypoglycemia accurately. Patients who rely on the RT-CGM to judge whether the glucose level is improving following ingestion of carbohydrates will mistakenly assume that they need to consume more.

**Setting glucose alarms**

The alarms for hypoglycemia and hyperglycemia are an important feature of RT-CGM devices. There are trade-offs in the adjustment of alarm thresholds, and settings need to be individualized based on specific clinical considerations [64]. If the alarm thresholds are set at target or ideal glucose levels (e.g. low = 5 mmol/L [90 mg/dL]; high = 10 mmol/L [180 mg/dL]), there will be increased sensitivity for detection of high and low gluces; however, the frequent false alarms can be a source of irritation and disrupt sleep leading to “alarm fatigue” in some patients with a related tendency to ignore the alarms (Figure 28.4).

The adjustment of alarm thresholds is a stepwise process:

- 1 Deciding on initial thresholds when initiating use of the sensor; and
- 2 Optimizing alarm thresholds over time based on retrospective review of continuous glucose tracings.

For patients with hypoglycemia, unawareness or a history of severe hypoglycemic reactions, where the overriding imperative is on reducing hypoglycemia, the low glucose alarm threshold should be set at 4.5 mmol/L (80 mg/dL) or higher. Because of physiologic lag between blood and interstitial glucose, when the sensor alarm is triggered, the blood glucose level will often be lower than the sensor measurement.

For individuals without a history of problematic hypoglycemia, it is a common practice to set the initial glucose thresholds at 3–3.5 mmol/L (55–60 mg/dL) and  $\geq 14$  mmol/L (250 mg/dL). This ensures that during the initial period after starting use of CGM, while the patient is mastering use of the technology, there will be fewer intrusive and irritating alarms, and less risk for alarm burnout. Over time, as the patient uses the information from the sensor to reduce glucose excursions, the alarm settings can be brought closer to target glucose levels, and this can assist with further tightening of glycemic control.

During follow-up visits, the clinician should enquire whether the sensor alarm alerted the patient to low or markedly elevated glucose levels, and whether the patient was troubled by frequent false alarms. If there are frequent high gluces (especially during the overnight period) and the patient is not being appropriately alerted by the sensor to take corrective action, the high alarm threshold should be reduced. Conversely, if the patient has experienced hypoglycemic reactions without being alerted by the

**Figure 28.4** Sensor downloads indicated that this patient had marked variability in overnight glucose control because of snacking at bedtime. Sensor high alarm threshold was set at 300 mg/dL (16.7 mmol/L) and as a result the alarm was not sounding at night. Reduction in the alarm threshold to 220 mg/dL (12.2 mmol/L) resulted in improvement in overnight glucose control and HbA<sub>1c</sub>.

CGM alarm, the low alarm threshold will need to be set at a higher level.

### Risk for hypoglycemia from excessive post-prandial bolusing

While the glucose alarms and trend indicators on CGM devices can be helpful in minimizing hypoglycemia, some patients will overreact to the post-prandial glucose spikes revealed by the continuous sensor by taking excessive doses of insulin [65], leading to an increased risk for hypoglycemia. Minimizing this tendency for post-prandial overbolusing should be a major focus in the training of the patient using RT-CGM. Patients need to factor in the amount of residual IOB from the previous bolus before taking additional insulin to treat post-prandial hyperglycemia. The newer pumps with bolus calculator software can guide patients in making appropriate dose adjustments.

The glycemic index of the carbohydrates in the meal is another factor to consider in the decision about whether additional boluses may be required to treat post-prandial hyperglycemia. High glycemic index carbohydrates will often lead to an early spike in the glucose levels (because of the mismatch between the absorption of the carbohydrate and action of the insulin bolus), and correction boluses taken within 2–3 hours after the meal can result in hypoglycemia.

### Closed-loop/artificial pancreas

Insulin pump therapy as it is currently used is considered to be an “open-loop system,” in which the patient must make executive decisions about when to check the glucose level and what to

do with the information. Clearly, there is inherent human error in this system and overdosing or underdosing of insulin based on a small miscalculation could result in subsequent hypoglycemic or hyperglycemic episodes, respectively. In a “closed-loop system” which integrates a continuous glucose monitor and insulin pump, together with an automated algorithm to control insulin delivery, the patient would be removed from the decision loop, and the system would essentially function as an artificial pancreas.

At present, one of the major challenges for the fully automated closed-loop system may be in the development of a fail-safe algorithm that is capable of “interpreting” a person’s metabolic state based on data obtained from the continuous glucose monitor and then relaying this information to the pump for automatic insulin delivery of the appropriate dose of insulin. Several algorithms including model predictive control and proportional integral derivative control are already being evaluated in both *in vivo* and *in silico* settings [66]. There are also several technical obstacles to developing a closed-loop system including having glucose sensors that are both accurate and reliable (e.g. minimal calibration drift, limited potential mechanisms for sensor failure), and also physiologic lag which can be particularly problematic during times of rapid rates of change in blood glucose levels (e.g. during meals or exercise) [67]. Thus, development of a sensor with a short lag time would also be important. The first prototype closed-loop systems that can deliver glucagon to prevent hypoglycemia are currently being evaluated [68].

Development of the first generations of an artificial pancreas is underway and several studies have already demonstrated that glycemic control can be achieved with an automated closed loop system in investigational and controlled hospital settings [69–72]. Medtronic MiniMed has developed an external physiologic

insulin delivery system that combines an external insulin pump and continuous glucose sensor with a variable insulin infusion rate algorithm designed to emulate the physiologic characteristics of the  $\beta$ -cell. Similar devices by other companies, including Abbott Laboratories, are also being developed and tested.

## Inhaled insulin

Survey studies have indicated that fear of needles and discomfort and inconvenience from injecting insulin are barriers to the use of insulin by many patients with T2DM [73,74]. An effective alternative mode for insulin administration would therefore be of potential benefit. As insulin is a peptide hormone, it cannot be taken orally, as it would be quickly degraded by the digestive enzymes of the stomach. Alternative routes of administration that have been investigated include transdermal, transbuccal and transpulmonary (inhaled) delivery of insulin.

The lung is an attractive mode for administration of a systemic drug because of its large available area for drug absorption and accessibility. In January 2006, the FDA approved the use of Exubera® (Pfizer), the first inhalable insulin.

Clinical studies have shown that pre-meal inhaled insulin achieves comparable glycemic control to subcutaneous regular insulin administration [75–77]; however, smoking can significantly alter the pharmacokinetics of inhaled insulin [78,79], and even passive smoke exposure in non-smokers can affect bioavailability [80]. Follow-up of the patients who had used Exubera in clinical trials has raised concerns about the potential long-term toxicity of insulin delivered by the pulmonary route. As of April 2008, six of the 4740 patients who used Exubera in clinical trials had developed lung cancer, compared with only one of the 4292 patients in the placebo group. All six patients with lung cancer had a prior history of cigarette smoking (Exubera label, FDA approval September 29, 2008), and this association was not statistically significant because of the small numbers. However, because of these safety concerns, as well as failure of Exubera to gain acceptance by patients and physicians, Pfizer withdrew Exubera from the market, and Eli Lilly and Novo Nordisk also gave up their efforts to develop their own insulin inhalation systems.

At present, one company, MannKind Corporation, has continued to develop an inhaled insulin, Technosphere® insulin [81]. In March 2009, a new drug application to market this insulin was filed with the FDA. Technosphere insulin contains insulin particles that are optimized for inhalation (2.5  $\mu$ m in diameter) and dissolve rapidly after inhalation (pH sensitive carrier particles). Pharmacokinetic studies have demonstrated that this formulation has very rapid systemic insulin uptake (insulin  $T_{max}$  approximately 12–14 minutes), a fast onset of action (maximum activity approximately 20–30 minutes) and a short duration of action (approximately 2–3 hours) [82] which could potentially provide better post-prandial control than subcutaneously injected insulin.

## Oral Antidiabetic Agents

Clifford J. Bailey<sup>1</sup> & Andrew J. Krentz<sup>2</sup>

<sup>1</sup> School of Life and Health Sciences, Aston University, Birmingham, UK

<sup>2</sup> Formerly, Department of Diabetes and Endocrinology, Southampton University Hospitals NHS Trust, Southampton, UK

### Keypoints

- Glycemic control is a fundamental part of the management of type 2 diabetes mellitus. Adequate glycemic control is necessary to address acute symptoms and to prevent, defer or reduce the severity of chronic microvascular and macrovascular complications.
- Treating type 2 diabetes is complicated by the multivariable and progressive natural history of the disease. Insulin resistance, a progressive decline in  $\beta$ -cell function, defects of other gluco-regulatory hormones and nutrient metabolism give rise to a continually changing presentation of the disease that requires therapy to be adjusted accordingly. Patients are often overweight or obese, exhibit substantial co-morbidity and elevated cardiovascular risk, and receive many other medications which further complicate treatment.
- Care plans and treatment programs should be tailored to fit the prevailing circumstances of the patient. Lifestyle management (diet and exercise) should be emphasized from the time of diagnosis and reinforced thereafter. Drug treatment should be undertaken promptly if lifestyle intervention does not achieve adequate glycemic control.
- Choice of drug therapy should ideally address underlying pathophysiology, but any safe means of restraining the escalating hyperglycemia may be appropriate. Combinations of differently acting agents are frequently required to provide additive efficacy, and single tablet, fixed dose combinations are available to facilitate combination therapy. Contraindications and precautions associated with each component must be respected.
- The biguanide metformin is often selected as initial oral antidiabetic drug therapy. It counters insulin resistance and lowers blood glucose through several insulin-dependent and independent mechanisms, notably reducing hepatic glucose production and also increasing glucose uptake by skeletal muscle. It does not stimulate insulin secretion, carries a low risk of frank hypoglycemia and does not cause weight gain. Metformin also exerts several potentially beneficial effects on cardiovascular risk factors independently of glycemic control, with evidence of improved long-term cardiovascular outcomes. Metformin may be conveniently combined with other classes of antidiabetic drugs. Gastrointestinal side effects including diarrhoea limit the use of metformin. The rare but serious adverse effect of lactic acidosis excludes the use of the drug in patients with significant renal insufficiency, significant liver disease or any condition predisposing to hypoxia or hypoperfusion including cardiac or respiratory failure.
- Sulfonylureas (e.g. gliclazide, glimepiride, glibenclamide/glyburide, glipizide) act on the pancreatic  $\beta$ -cells to stimulate insulin secretion. They bind to the transmembranal complex of sulfonylurea receptors SUR1 with ATP-sensitive Kir6.2 potassium efflux channels. This closes the channels, depolarizes the membrane, opens voltage-dependent calcium channels and raises intracellular free calcium concentrations. This in turn activates proteins regulating insulin secretion. The efficacy of sulfonylureas depends on adequate remaining function of the  $\beta$ -cells. Hypoglycemia is the most serious adverse effect, particularly with longer acting sulfonylureas and in the elderly. Caution with hepatic and/or renal insufficiency is warranted in accordance with the metabolism and elimination of individual preparations, and interactions with other protein-bound drugs can occur.
- Meglitinides (repaglinide and nateglinide), also known as prandial insulin releasers, are rapid and short-acting insulin secretagogues taken before meals to boost insulin levels during digestion, thereby reducing prandial hyperglycemia and decreasing risk of interprandial hypoglycemia. They act in a similar manner to sulfonylureas by binding to a "benzamido" site on the SUR1–Kir6.2 complex. They are conveniently used in combination with an agent that reduces insulin resistance.
- Thiazolidinediones (pioglitazone and rosiglitazone) produce a slow-onset glucose-lowering effect, attributed mainly to increased insulin sensitivity. They alter the expression of certain insulin-sensitive genes by stimulating the peroxisome proliferator-activated receptor  $\gamma$ , increasing adipogenesis, and rebalancing the glucose–fatty acid (Randle) cycle. Thiazolidinediones can be used as monotherapy or in combination with other classes of antidiabetic agents. They have low risk of hypoglycemia but often cause weight gain. The potential for fluid retention and an attendant risk of congestive heart failure should be borne in mind, especially in combination with insulin. Thiazolidinediones are not recommended for individuals at high risk of cardiac disease or women with reduced bone density.

- Gliptins (sitagliptin, vildagliptin and saxagliptin) act predominantly as prandial insulin secretagogues by raising the circulating concentrations of endogenous incretin hormones, notably glucagon-like peptide 1 and glucose-dependent insulinotropic polypeptide. Incretin hormones are released from the intestine during a meal and potentiate nutrient-stimulated insulin secretion, but they are rapidly degraded by the enzyme dipeptidyl peptidase 4: gliptins inhibit this enzyme. Gliptins are weight neutral and, as monotherapy, they carry low risk of interprandial hypoglycemia. They are often used in combination with metformin or a thiazolidinedione.
- $\alpha$ -Glucosidase inhibitors (e.g. acarbose) slow the digestion of carbohydrates by competitive inhibition of intestinal  $\alpha$ -glucosidase enzymes. This delays glucose absorption and reduces post-prandial glucose excursions without stimulating insulin secretion. These agents must be used in conjunction with meals rich in digestible complex carbohydrate. They do not cause weight gain or hypoglycemia as monotherapy and can be used alongside any other antidiabetic agents.
- In advanced stages of type 2 diabetes,  $\beta$ -cell function is often too severely compromised to support the continued use of oral agents alone. Insulin therapy should be initiated, continuing one or more oral agents where appropriate.

**Table 29.1** Aims of appropriate glycemic control in type 2 diabetes. Adapted from Wallace & Matthews [1].

Purpose	Complications
Prevent acute symptoms of hyperglycemia	Dehydration, thirst, polyuria, blurred vision, increased infections
Prevent acute complications	Hyperosmolar non-ketotic state
Prevent, defer or reduce severity of chronic vascular complications	Microvascular: retinopathy, nephropathy, neuropathy Macrovascular: coronary, cerebrovascular, peripheral vascular

## Introduction

Appropriate glycemic control is a fundamental pillar in the management of type 2 diabetes mellitus (T2DM). It is required to prevent and relieve acute symptoms and complications of hyperglycemia; prevent, defer and reduce the severity of microvascular complications; and afford some benefits against macrovascular complications (Table 29.1) (see Chapters 20) [1,2]. Treatment of the hyperglycemia is essential to an individualized care plan that takes account of coexistent diseases and personal circumstances, offers suitable advice on lifestyle and diet, includes other measures to address modifiable cardiovascular risk, selects realistic targets, and facilitates patient education and empowerment, as considered in detail in Part 5. This chapter focuses on the role of oral blood glucose-lowering agents (other antidiabetic therapies are addressed in Chapters 27 and 30) in the treatment of T2DM [2–5].

## Pathophysiologic considerations

The interdependent multiplicity of genetic and environmental factors underlying T2DM (see Chapters 12 and 14) give rise to a highly heterogeneous and progressive natural history [2,6,7]. The

**Figure 29.1** The UK Prospective Diabetes Study (UKPDS) shows the progressive rise in HbA<sub>1c</sub> occurring with time in groups receiving “conventional” (diet) therapy and “intensive” therapy with various antidiabetic drugs (two sulfonylureas – chlorpropamide and glibenclamide – and insulin). Data from Wallace & Matthews [1] and UKPDS [12].

pathophysiology typically involves defects of insulin secretion and insulin action [8]. Obesity, especially visceral adiposity, and abnormalities of glucagon secretion commonly contribute to the disease process, while cellular disturbances of nutrient metabolism participate both as causes and consequences of glucotoxicity and lipotoxicity [9–11]. An ideal approach to therapy might therefore address the basic endocrine defects, but any other safe means of ameliorating the hyperglycemia and attendant biochemical disruptions should provide clinical benefits.

The progressive nature of T2DM was well-illustrated by the UK Prospective Diabetes Study (UKPDS), a randomized trial of 5102 patients with newly diagnosed T2DM followed for a median of 10 years while receiving either “conventional” (diet) therapy or “intensive” therapy with various oral antidiabetic agents or insulin (Figure 29.1). Note that insulin was introduced earlier than is usual in clinical practice, and insulin was also used as necessary when oral agents were deemed inadequate. Although glycemic control (illustrated by the HbA<sub>1c</sub> level) deteriorated

**Table 29.2** Trials comparing intensive with standard (conventional) glycemic control in type 2 diabetes.

Trial	Number	Duration of follow-up	Age	Duration of diabetes	Baseline HbA <sub>1c</sub> %	Intensive HbA <sub>1c</sub> %	Conventional HbA <sub>1c</sub> %	Relative risk reduction

ACCORD, Action to Control Cardiovascular Risk in Diabetes; ADVANCE, Action in Diabetes and Vascular Disease: Preterax and Diamicon-MR Controlled Evaluation; UKPDS, UK Prospective Diabetes Study; VADT, Veterans Affairs Diabetes Trial.

<sup>a</sup>Non-obese patients.

<sup>b</sup>After a 3-month dietary run-in.

<sup>c</sup>Myocardial infarction.

<sup>d</sup>Non-significant.

<sup>e</sup>Intensive therapy discontinued at median 3.5 years because of increased deaths in the intensive (257/5128; 5%) versus conventional (203/5123; 4%) group.

<sup>f</sup>Reduction in new or worsening nephropathy. No effect on incidence of progression of retinopathy.

<sup>g</sup>Any increase in albuminuria.

with time irrespective of the treatment, the improvement in glycemic control afforded by intensive therapy (median HbA<sub>1c</sub> reduced by 0.9% [10 mmol/mol]) was associated with a 12% reduction in overall diabetes-related endpoints and a 25% reduction in microvascular endpoints [12]. An epidemiologic analysis showed that benefits of intensive therapy continued to accrue until glucose levels were returned to the normal range [13]. Moreover, the benefits of earlier “intensive” control were continued during an unrandomized post-trial follow-up (median 8.5 years) during which glycemic differences between the former groups were not maintained [14]. This illustrates the glycemic “legacy” effect in which early intensive glycemic control confers an extended reduction in complications, even when control deteriorates at later stages in the disease process.

Other large randomized trials [15–17] have confirmed fewer microvascular complications amongst those receiving more intensive glycemic management (Table 29.2). One such study, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, noted increased mortality during highly intensified (5% mortality, 257/5128) versus standard (4% mortality, 203/5123) glycemic management. This may be ascribed to unique features of the trial design outside of normal practice in an aging population at high cardiovascular risk with a long previous duration of inadequately controlled diabetes given extensive medications and experiencing high rates of hypoglycemia. Indeed, an acceptable HbA<sub>1c</sub> value does not preclude excessive daily fluctuations in glycemia with hyperglycemic excursions and hypoglycemic troughs, the latter often unrecognized nocturnally (see Chapter 33). Survival of a myocardial event appears to be reduced by hypoglycemia as well as hyperglycemia [18].

## Guidelines and algorithms

Factors to consider when selecting a glycemic target for a particular patient are deliberated in detail in Chapter 20, but it is pertinent to reiterate here that the general principle is to safely return glycemia as close to normal as practicable, avoiding hypoglycemia, minimizing potential drug interactions, and observing other necessary cautions and contraindications. An individualized approach is recommended. Current treatment algorithms [19–25] provide a framework for initiating and intensifying therapy, but clinical judgment should be applied to harmonize this with patient circumstances. Thus, a younger, newly diagnosed individual without co-morbidity who is responsive to therapy might be expected to meet a more rigorous target, while an elderly infirm individual with co-morbidity and a long history of problems with diabetes control may require more flexibility. Management of hyperglycemia should always be part of a comprehensive management program to address coexistent disease and modifiable cardiovascular risk factors.

It is emphasized that diet, exercise and other lifestyle measures should be introduced at diagnosis and reinforced at every appropriate opportunity thereafter. These measures can provide valuable blood glucose lowering efficacy and may initially enable the desired glycemic target to be achieved (see Chapters 22 and 23); however, even when lifestyle advice is successfully implemented, the progressive natural history of the disease dictates that the majority of patients will later require pharmacologic therapy, and this should be introduced promptly if the glycemic target is not met or not maintained.

The main classes of oral antidiabetic drugs and their principal modes of action are listed in Table 29.3. The main tissues through which they exert their glucose-lowering effects are illustrated in Figure 29.2, and the main cautions and contraindications associated with oral antidiabetic agents are listed in Table 29.4. Although there are several different classes from which to choose, many dilemmas continue to impinge on both strategy and individualization of treatment. For example, an increase in fasting glycemia usually accounts for the majority of the hyperglycemia in T2DM: ideally therefore, this should be adequately addressed during therapy [26]. It is also pertinent to note the link between postprandial hyperglycemic excursions and cardiovascular risk, which mandates the need to also address this component of the hyperglycemic day profile [27]. Additionally, consideration should be given to the improvements in glycemic control that can be achieved through the treatment of obesity (see Chapter 14) [28]. By the time of diagnosis, insulin resistance is usually well established and does not usually progress with extended duration of the disease [8]. Nevertheless, the association between insulin resistance and cardiovascular risk warrants the amelioration of insulin resistance as a valued therapeutic strategy. The ongoing deterioration in glycemic control after diagnosis is largely attributed to a further progressive decline in  $\beta$ -cell function [8]. Thus, preserving  $\beta$ -cell function and mass are important considerations in maintaining long-term glycemic control. If  $\beta$ -cell function deteriorates beyond the capacity of oral agents to provide adequate glycemic control, then the introduction of insulin should not be delayed. Incorporating some or all of the above into the treatment process is inevitably a challenge, and the need to

explore suitable combinations of therapies to accommodate the changing status of the disease is now accepted practice.

The increasing prevalence of T2DM amongst younger adults and pre-adults adds an extra long-term dimension to risk–benefit

**Figure 29.2** Main tissues through which oral antidiabetic agents exert their glucose-lowering effects.

**Table 29.3** Classes of oral antidiabetic drugs and their main modes of action.

Class with examples	Main mode of glucose-lowering	Main cellular mechanism of action
<b>Biguanide</b> Metformin	Counter insulin resistance (especially decrease hepatic glucose output)	Enhance various insulin dependent and independent actions including AMPK
<b>Sulfonylureas</b> Glimepiride, gliclazide, glyburide/ glibenclamide, glipizide	Stimulate insulin secretion (typically 6–24 hours)	Bind to SUR1 sulfonylurea receptors on pancreatic $\beta$ -cells, which closes ATP-sensitive Kir6.2 potassium channels
<b>Meglitinides</b> Repaglinide, nateglinide	Stimulate insulin secretion (faster onset and shorter duration of action than sulfonylureas)	Bind to benzamido site on SUR1 receptors on pancreatic $\beta$ -cells, which closes ATP-sensitive Kir6.2 potassium channels
<b>Gliptins (DPP-4 inhibitors)</b> Sitagliptin, vildagliptin, saxagliptin	Increase prandial insulin secretion	Inhibit DPP-4 enzyme, which increases plasma half-life of insulinotropic incretin hormones
<b>Thiazolidinediones (PPAR-<math>\gamma</math> agonists)</b> Pioglitazone, rosiglitazone	Increase insulin sensitivity (especially increase peripheral glucose utilization)	Activate nuclear receptor PPAR- $\gamma$ mainly in adipose tissue, which affects insulin action and glucose–fatty acid cycle
<b><math>\alpha</math>-Glucosidase inhibitors</b> Acarbose, miglitol, voglibose	Slow rate of carbohydrate digestion	Competitive inhibition of intestinal $\alpha$ -glucosidase enzymes

AMPK, adenosine 5'-monophosphate-activated protein kinase; ATP, adenosine triphosphate; DPP-4, dipeptidyl peptidase 4; PPAR- $\gamma$ , peroxisome proliferator-activated receptor  $\gamma$ .

considerations. While initial adequate intervention remains paramount, there is limited experience with oral antidiabetic agents in children and adolescents; metformin has been used safely in controlled pediatric practice from 10 years of age, and sulfonylureas have been used in pediatric presentations of certain forms of maturity-onset diabetes of the young (MODY). Treating T2DM in women who are of childbearing age carries the risk of unplanned pregnancy while receiving oral antidiabetic agents. Treatment with these agents at the time of conception and during the first trimester has not been shown to have any adverse effects on mother or fetus, and judicious use of metformin has been shown to reduce miscarriage and gestational diabetes. Insulin remains the preferred antidiabetic medication in pregnancy, however, having a substantial evidence base for safety and flexibility. A paucity of evidence contraindicates thiazolidinediones and gliptins during pregnancy and lactation.

Elderly patients are more vulnerable to most of the cautions and contraindications to glucose-lowering drugs, and deteriorations in their pathophysiologic status can occur rapidly, necessitating more frequent monitoring (see Chapter 54). Hypoglycemia is a particular concern in this age group. While safety must be judged on an individual drug–patient basis, it is noteworthy that several common medications can impair glycemic control (e.g. glucocorticoids, certain antipsychotics, diuretics and beta-block-

ers), while others may have their own minor glucose-lowering effect (e.g. aspirin, some angiotensin-converting enzyme [ACE] inhibitors and mineral supplements) (see Chapter 26). The most frequent interactions with glucose-lowering drugs are summarized in Table 29.5.

Terminology within the field of antidiabetic agents may simplify the usage of the different agents. Hypoglycemic agents have the capacity to lower blood glucose below normal to the extent of frank hypoglycemia (e.g. sulfonylureas and insulin). Antihyperglycemic agents can reduce hyperglycemia, but when acting alone they do not have the capability to lower blood glucose below normoglycemia to the extent of frank hypoglycemia (e.g. metformin, thiazolidinediones, incretins, gliptins,  $\alpha$ -glucosidase inhibitors).

## Biguanides

Metformin (dimethylbiguanide) is the only biguanide currently used in most countries (Figure 29.3). The history of biguanides stems from a guanidine-rich herb *Galega officinalis* (goat's rue or French lilac) that was used as a traditional treatment for diabetes in Europe [29]. Guanidine has a glucose-lowering effect, and several guanidine derivatives were adopted for the treatment of

**Table 29.5** Drug interactions with oral antidiabetic agents that may affect their glucose-lowering effects.

Antidiabetic agent	Increase glucose lowering	Decrease glucose lowering
Any	Combination with other antidiabetic drugs Minor insulin releasers (e.g. aspirin) Minor insulin sensitivity enhancers, e.g. ACE inhibitors, magnesium or chromium supplements	Agents that impair insulin action (e.g. glucocorticoids, some antipsychotics, minor effects of diuretics, beta-blockers, some $\beta_2$ -agonists) Impair insulin secretion (e.g. octreotide, some calcium channel blockers)
Metformin	Renal cation secretion competition by cimetidine Minor PK interaction with furosemide and nifedipine	–
Sulfonylureas	Reduce hepatic metabolism (e.g. some antifungals and MAOIs) Displace plasma protein binding (e.g. coumarins, NSAIDs, sulfonamides) Decrease excretion (e.g. probenecid)	$K^+$ -ATP channel openers (e.g. diazoxide) Metabolism secondary to enzyme induction (e.g. rifampicin)
Meglitinides	Reduce hepatic metabolism, gemfibrozil Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin, barbiturates, carbamazepine)
Thiazolidinediones	Reduce hepatic metabolism, gemfibrozil Potentially displace plasma protein binding	Metabolism secondary to enzyme induction (e.g. rifampicin)
Gliptins	Potential interactions with liver and renal metabolism and plasma protein binding	–
$\alpha$ -Glucosidase inhibitors	Slow gut motility (e.g. cholestyramine)	Potentially with agents that increase gut motility

ACE, angiotensin-converting enzyme; MAOI, mono oxidase inhibitor; NSAID, non-steroidal anti-inflammatory drug; PK, pharmacokinetic.

diabetes in the 1920s [30]. These agents all but disappeared as insulin became available, but three biguanides – metformin, phenformin and buformin – were introduced in the late 1950s. Phenformin and buformin were withdrawn in many countries in the late 1970s because of a high incidence of lactic acidosis. Metformin remained and was introduced into the USA in 1995 [31], and this has since become the most prescribed antidiabetic agent worldwide [32].

### Mode of action

Metformin exerts a range of actions that counter insulin resistance and lower blood glucose: the drug also offers some protection against vascular complications independently of its antihyperglycemic effect (Table 29.6) [33,34]. At the cellular

**Table 29.6** Diverse metabolic and vascular effects of metformin.

Features associated with diabetes		Effects of metformin
Hyperglycemia	↓	↓ HGP, ↑ peripheral glucose uptake ↑ glucose turnover
Insulin resistance	↓	↑ Receptor–postreceptor insulin signals
Hyperinsulinemia	↓	↓ Fasting and often post-prandial insulin
Obesity	↓/–	↓ or stabilizes body weight
IGT	↓	↓ Progression to type 2 diabetes
Dyslipidemia	↓/–	Modest benefits if abnormal ↓ VLDL-TG, ↓ LDL, ↑ HDL May decrease FA oxidation
Blood pressure	–	No significant effect
Pro-coagulant state	↓	Antithrombotic (↓ fibrinogen, ↓PAI-1, ↓ platelet aggregation)
Endothelial function	↑	↓ Vascular adhesion molecules
Atherosclerosis	↓	↓ MI, ↓ stroke, ↑ vascular reactivity, ↓ cIMT, ↑ life expectancy, anti-atherogenic in animals

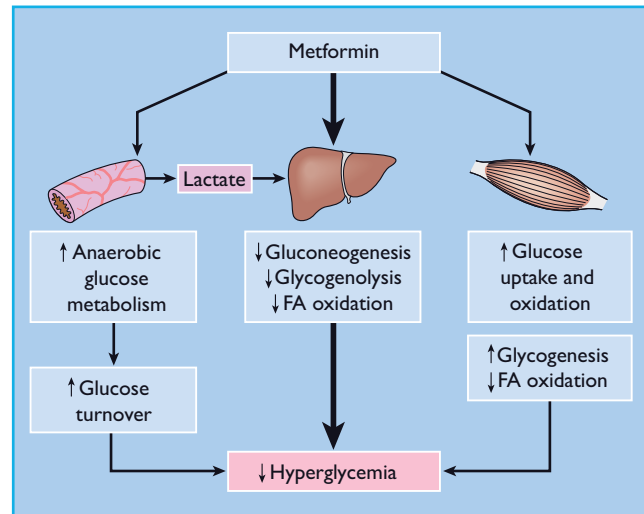

↑ Increase; ↓ decrease; – no significant effect; cIMT, carotid intima-media thickness; FA, fatty acid; HDL, high density lipoprotein cholesterol; HGP, hepatic glucose production; IGT, impaired glucose tolerance; LDL, low density lipoprotein cholesterol; MI, myocardial infarction; PAI-1, plasminogen-activator inhibitor-1; VLDL-TG, very low density lipoprotein cholesterol triglyceride.

**Figure 29.4** Multiple cellular action mechanisms of metformin involve insulin dependent and independent effects. For example, metformin can improve insulin sensitivity via effects on insulin receptor signaling and post-receptor signaling pathways of insulin action. Metformin also appears to influence cellular nutrient metabolism and energy production independently of insulin via activation of adenosine 5'-monophosphate (AMP) activated protein kinase (AMPK). Oct1, organic cation transporter 1; LKB1 protein kinase.

level, metformin exerts insulin-dependent and independent effects on glucose metabolism (Figure 29.4). For example, metformin modestly improves insulin sensitivity probably via post-receptor signaling pathways for insulin, and it also appears to influence nutrient metabolism and energy production independently of insulin via activation of adenosine 5'-monophosphate-activated protein kinase (AMPK) [35].

The glucose-lowering efficacy of metformin requires a presence of at least some insulin because metformin does not mimic or activate the genomic effects of insulin. Also, metformin does not stimulate insulin release; its main glucose-lowering effect appears to be a reduction of hepatic glucose production, but not sufficiently to cause frank hypoglycemia when used as monotherapy. Metformin reduces gluconeogenesis by increasing hepatic insulin sensitivity and by decreasing hepatic extraction of some gluconeogenic substrates such as lactate (Figure 29.5). It also decreases hepatic glycogenolysis. Metformin can enhance insulin-stimulated glucose uptake in skeletal muscle by increasing translocation of insulin-sensitive glucose transporters (GLUT-4)

**Figure 29.5** Main sites of action of metformin contributing to glucose-lowering effect.

into the cell membrane and increasing activity of glycogen synthase which promotes glycogen synthesis. Independently of insulin, metformin can suppress the oxidation of fatty acids and may reduce triglyceride levels in patients with hypertriglyceridemia. This restricts the supply of energy for hepatic gluconeogenesis and rebalances the glucose–fatty acid (Randle) cycle, allowing greater use of glucose relative to fatty acids as a cellular source of energy. Accumulation of a high cellular concentration of metformin (e.g. in the intestine) can suppress the mitochondrial respiratory chain at complex I. This may contribute to the blood glucose-lowering effect of the drug, and help to prevent body weight gain by increasing glucose–lactate turnover.

### Pharmacokinetics

Metformin is rapidly but incompletely absorbed, shows little binding to plasma proteins and is not metabolized, so it does not interfere with co-administered drugs. Metformin is widely distributed at concentrations similar to plasma (about  $10^{-5}$  mol/L), but much higher concentrations are retained in the walls of the gastrointestinal tract. The plasma half-life ( $t_{1/2}$ ) is about 6 hours with elimination of unchanged drug in the urine, mostly within 12 hours [36]. Although renal clearance is achieved more by tubular secretion than glomerular filtration, metformin is contraindicated for patients with significant impairment of glomerular filtration. Cimetidine is the only drug known to compete for clearance sufficiently to cause a clinically significant increase plasma metformin concentrations.

### Indications and contraindications

Because metformin does not cause weight gain it is often preferred for overweight and obese people with T2DM, although it shows similar antihyperglycemic efficacy in normal weight patients [37]. To preclude drug accumulation, patient suitability

should be considered very carefully if there is any evidence of impaired renal function (e.g. if serum creatinine  $>130\mu\text{mol/L}$  or creatinine clearance  $<60\text{mL/min}$  or estimated glomerular filtration rate [eGFR]  $<45\text{mL/min/1.73m}^2$ ). Further contraindications include significant cardiac or respiratory insufficiency, or any other condition predisposing to hypoxia or reduced tissue perfusion (e.g. hypotension, septicemia), as well as significant liver disease, alcohol abuse or a history of metabolic acidosis. Because the potential for acute deterioration in renal, cardiopulmonary and hepatic function should be taken into account, it is not practicable to identify precise cutoffs for starting or stopping metformin therapy. With this in mind, metformin can be used in the elderly providing renal insufficiency and other exclusions are not present. Ovulation can resume in women with anovulatory polycystic ovarian syndrome (PCOS), which is an unlicensed application of the drug in the absence of diabetes [38].

A standard (so-called immediate release [IR]) tablet or liquid formulation of metformin should be taken with meals or immediately before meals to minimize possible gastrointestinal side effects. Start with 500 or 850 mg once daily, or 500 mg twice daily (divided between the morning and evening meals). The dosage is increased slowly – one tablet at a time – at intervals of about 1–2 weeks until the target level of blood glucose control is attained. If the target is not attained and an additional dose produces no further improvement, return to the previous dose. In the case of monotherapy, consider combination therapy by adding in another agent (e.g. an insulin secretagogue or thiazolidinedione). The maximal effective dosage of metformin is about 2000 mg/day, taken in divided doses with meals, and the maximum is 2550 or 3000 mg/day in different countries.

Slow-release formulations (XR/SR/ER) of metformin are available in most countries; they can be taken once daily in the morning, or if necessary morning and evening. Metformin can also be used in combination with any other class of antidiabetic agent including insulin, and several fixed dose combination tablets are available in which metformin is combined with either a sulfonylurea or thiazolidinedione or dipeptidyl peptidase 4 (DPP-4) inhibitor (see below). Recall that although metformin alone is unlikely to cause serious hypoglycemia, this can occur when metformin is used in combination with an insulin-releasing agent or insulin.

During long-term use of metformin it is advisable to check at least annually for emergence of contraindications, particularly renal (as a minimum, serum creatinine). Metformin can reduce gastrointestinal absorption of vitamin B<sub>12</sub>, and although this is rarely a cause of frank anemia, an annual hemoglobin measurement is recommended especially for individuals with known or suspected nutritional deficiencies. Metformin should be temporarily stopped when using intravenous radiographic contrast media, or during surgery with general anesthesia or other intercurrent situations in which the exclusion criteria could be invoked. Substitution with insulin may be appropriate at such times.

## Efficacy

As monotherapy in patients who are not adequately controlled by lifestyle management, optimally titrated metformin typically reduces fasting plasma glucose by 2–4 mmol/L, corresponding to a decrease in HbA<sub>1c</sub> by approximately 1–2% (11–22 mmol/mol) [39]. This is largely independent of body weight, age and duration of diabetes provided that some  $\beta$ -cell function is still present. To accommodate the progressive nature of T2DM, it is likely that uptitration of dosage and addition of a second agent will be required to maintain glycemic control in the long term.

Metformin carries minimal risk of significant hypoglycemia or weight gain when used as monotherapy. It may lead to a reduction of basal insulin concentrations, notably in hyperinsulinemic patients, which should help to improve insulin sensitivity. Minor improvements in the blood lipid profile have been observed during metformin therapy, mostly in hyperlipidemic patients: plasma concentrations of triglycerides, fatty acids and low density lipoprotein (LDL) cholesterol tend to fall, whereas high density lipoprotein (HDL) cholesterol tends to rise [37]. These effects appear to be independent of the antihyperglycemic effect, although a lowering of triglyceride and free fatty acids is likely to help improve insulin sensitivity and benefit the glucose–fatty acid cycle.

In the UKPDS, overweight patients who started oral antidiabetic therapy with metformin showed a 39% reduced risk of myocardial infarction compared with conventional treatment ( $P = 0.01$ ) [40]. There was no obvious relationship with metformin dosage, suggesting that patients who can only tolerate a low dosage of metformin may benefit from continuing the drug, even when other agents are required to achieve adequate glycemic control. The decrease in myocardial infarction was not related to the extent of the glucose-lowering effect of metformin, or effects on classic cardiovascular risk factors such as blood pressure or plasma lipids. Reported benefits of metformin on various atherothrombotic risk markers and factors have been reported, including reduced carotid intima-media thickness (cIMT) (Table 29.6), increased fibrinolysis and reduced concentrations of the anti-thrombolytic factor plasminogen activator inhibitor-1 (PAI-1) [34]. Detracting somewhat from the generally favorable cardiovascular risk reports there is evidence that combination of metformin with a sulfonylurea may initially increase cardiovascular mortality [40,41]. One potentially confounding factor might be greater cardiovascular risk caused by more severe metabolic disease in patients needing treatment with the combination [42]. Evidence from large databases with sulfonylurea plus metformin combination therapy have been reassuring [43,44]. Indeed, recent results from the post-trial follow-up of UKPDS (without continuation of randomized groups) showed that the cardiovascular benefits of metformin were maintained [14].

When metformin is added to the regimens of patients receiving insulin therapy, a reduction of insulin dosage is often required, consistent with the ability of metformin to improve insulin sensitivity. Similarly, addition of insulin in patients already receiving metformin usually requires lesser dosages of insulin and results

in less weight gain. Lesser amounts of insulin are also associated with fewer and less severe episodes of hypoglycemia [44,45]. Although metformin is not indicated for the prevention of diabetes, it is noteworthy that the US Diabetes Prevention Program found metformin to reduce the incidence of new cases of diabetes in overweight and obese subjects with impaired glucose tolerance by 33%, compared with a reduced risk of 58% using an intensive regimen of diet and exercise [46]. The preventive effect of metformin was most evident amongst younger, more obese individuals.

### Adverse effects

The main tolerability issue with metformin is abdominal discomfort and other gastrointestinal adverse effects, including diarrhea. These are often transient and can be ameliorated by taking the drug with meals and titrating the dose slowly. Symptoms may remit if the dose is reduced, but around 10% of patients cannot tolerate the drug at any dose. The most serious adverse event associated with metformin is lactic acidosis; it is rare (probably about 0.03 cases per 1000 patient-years), but about half of cases are fatal [31,47,48]. Because the background incidence of lactic acidosis amongst patients with T2DM has not been established, it is possible that some cases previously attributed to metformin were caused by other factors.

Most reported cases of lactic acidosis in patients receiving metformin have been caused by inappropriate prescription, particularly overlooking renal insufficiency. The resulting accumulation of metformin is likely to increase lactate production, and increasing lactate will be aggravated by any hypoxic condition or impaired liver function. Hyperlactatemia occurs in cardiogenic

shock and other illnesses that decrease tissue perfusion, so metformin may only be an incidental factor in some cases. Nevertheless, metformin should be stopped immediately in all cases of suspected or proven lactic acidosis, regardless of cause.

Lactic acidosis is typically characterized by a raised blood lactate concentration (e.g. >5mmol/L), decreased arterial pH and/or bicarbonate concentration with an increased anion gap ( $[Na^+] - [Cl^- + HCO_3^-] >15$  mmol/L). Presenting symptoms are generally non-specific, but often include hyperventilation, malaise and abdominal discomfort. Treatment should be commenced promptly without waiting to determine whether metformin is a cause; bicarbonate remains the usual therapy, but evidence of its efficacy is limited. Hemodialysis to remove excess metformin can be helpful, and may assist restoration of fluid and electrolyte balance during treatment with high-dose intravenous bicarbonate.

## Sulfonylureas

Since their introduction in the 1950s, sulfonylureas have been used extensively as insulin secretagogues for the treatment of T2DM. Sulfonylureas were developed as structural variants of sulfonamides after the latter were reported to cause hypoglycemia [49]. Early sulfonylureas such as carbutamide, tolbutamide, acetohexamide, tolazamide and chlorpropamide are often referred to as “first generation.” These have been largely superseded by more potent “second-generation” sulfonylureas, notably glibenclamide (glyburide), gliclazide, glipizide and most recently glimepiride (Figure 29.6).

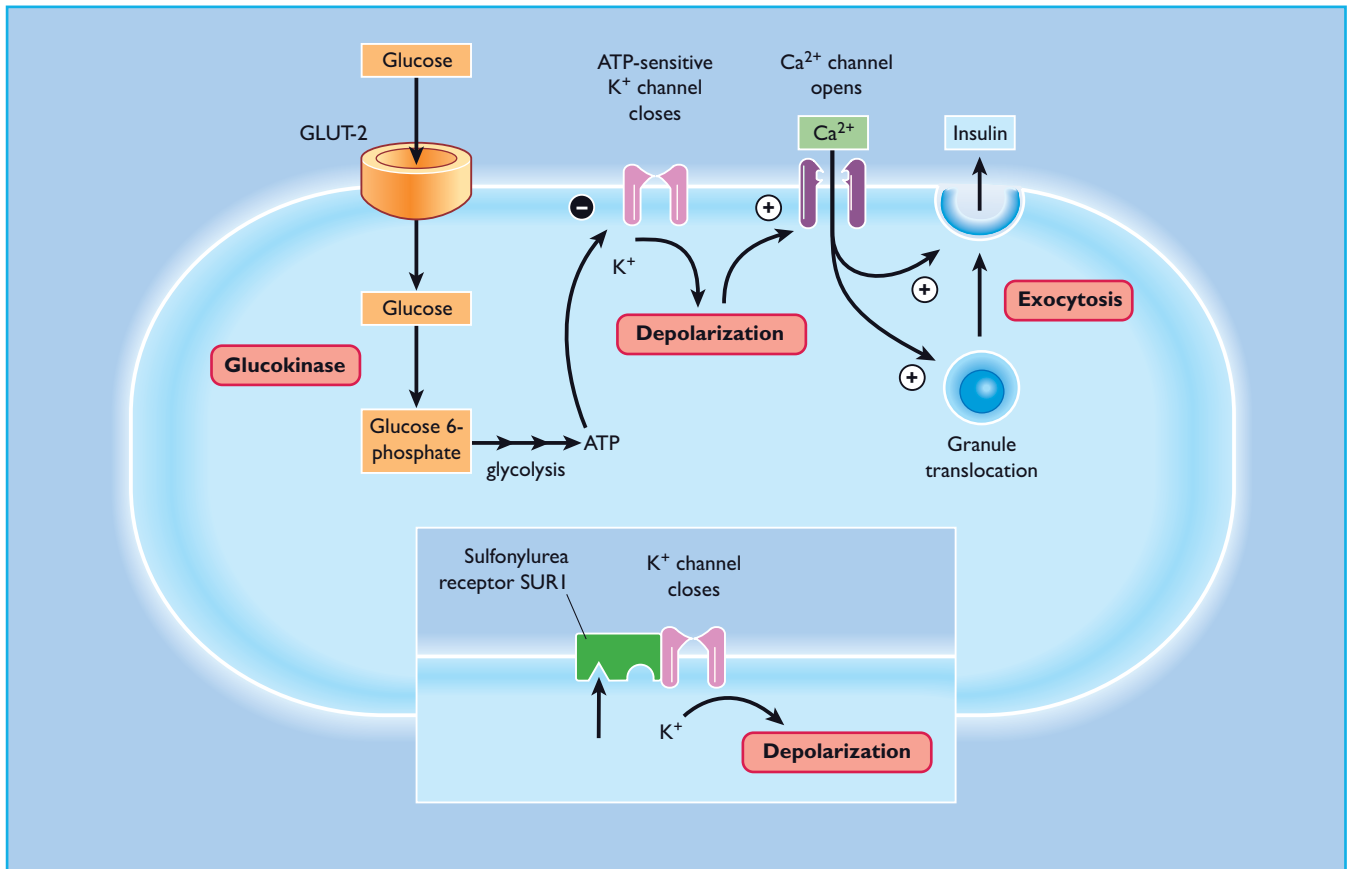

Figure 29.6 Chemical structures of sulfonylureas.

**Figure 29.7** Sulfonylureas act on the pancreatic  $\beta$ -cell to stimulate insulin secretion. They bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), causing closure of ATP-sensitive Kir6.2 potassium channels, depolarizing the plasma membrane, opening calcium channels, and activating calcium-dependent signaling proteins that control insulin exocytosis.

### Mode of action

Sulfonylureas act directly on the  $\beta$ -cells of the islets of Langerhans to stimulate insulin secretion (Figure 29.7). They enter the  $\beta$ -cell and bind to the cytosolic surface of the sulfonylurea receptor 1 (SUR1), which forms part of a transmembrane complex with ATP-sensitive Kir6.2 potassium channels ( $K^+$ ATP channels) (Figure 29.8) [50,51]. Binding of a sulfonylurea closes the  $K^+$ ATP channel, reducing the efflux of potassium and enabling membrane depolarization. Localized membrane depolarization opens adjacent voltage-dependent L-type calcium channels, increasing calcium influx and raising the cytosolic free calcium concentration. This activates calcium-dependent signaling proteins that control the contractility of microtubules and microfilaments that mediate the exocytotic release of insulin granules. Preformed insulin granules adjacent to the plasma membrane are promptly released (“first phase” insulin release), followed by a protracted (“second phase”) period of insulin release that begins about 10 minutes later [52]. The “second phase” of insulin release involves translocation of preformed and newly formed insulin granules to the plasma membrane for secretion. Sulfonylureas continue to stimulate insulin release while they are bound to the SUR1 pro-

vided that the  $\beta$ -cells are functionally competent. Some desensitization, however, occurs during repeated and protracted stimulation [53]. Because sulfonylureas can stimulate insulin release when glucose concentrations are below the normal threshold for glucose-stimulated insulin release (approximately 5 mmol/L), they are capable of causing hypoglycemia, mainly because of insulin-induced suppression of hepatic glucose production.

There is some evidence that sulfonylureas exert minor glucose-lowering effects independently of increased insulin secretion [54,55]. A small reduction in glucagon concentrations, increased peripheral glucose transport and increased hepatic glucose deposition have been reported, but these effects are not regarded to be of sufficient magnitude to be clinically relevant.

### Pharmacokinetics

Sulfonylureas vary considerably in their pharmacokinetic properties (Table 29.7), which in turn affects their clinical suitability for different patients [54,55,56]. They are generally well absorbed, and reach peak plasma concentration in 2–4 hours. Sulfonylureas are highly bound to plasma proteins which can lead to interac-

**Table 29.7** Sulfonylureas.

Agent	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Tolbutamide	500–2000	6–10	Inactive	Urine 100%
Glipizide	2.5–20	6–16	Inactive	Urine ~70%
Gliclazide	40–320	12–20	Inactive	Urine ~65%
Gliclazide MR	30–120	18–24	Inactive	Urine ~65%
Glimepiride	1.0–6.0	12–>24	Active	Urine ~60%
Glibenclamide	1.25–15	12–>24	Active	Bile >50%
Chlorpropamide	100–500	24–50	Active	Urine >90%

New patients are not usually started on first generation sulfonylureas (tolbutamide, chlorpropamide).

Glibenclamide is also known as glyburide in some countries.

MR, modified release.

tions with other protein-bound drugs such as salicylates, sulfonamides and warfarin. Also, displacement of protein-bound sulfonylurea can increase the risk of hypoglycemia (Table 29.5). Sulfonylureas are metabolized in the liver to varying extents to a range of active and inactive metabolites that are eliminated along with unchanged drug via the bile and urine. Longer acting sulfonylureas can be given once daily but carry greater risk of hypoglycemia, especially with active metabolites. Sites and rates of metabolism and elimination are also important considerations, especially in older patients and individuals with coexistent liver or kidney disease or taking several other medications.

The formulation of some sulfonylureas has been altered to modify the duration of action [3,4]. For example, a micronized formulation of glibenclamide (glyburide) in the USA increases the rate of gastrointestinal absorption for earlier onset of action. A longer acting (“extended release”) formulation of glipizide and a “modified release” (MR) formulation of gliclazide have been introduced for once-daily dosing. Interestingly, the 30 mg preparation of gliclazide MR gives similar efficacy to 80 mg of unmodified gliclazide and reduces risk of severe hypoglycemia [57].

### Indications and contraindications

Sulfonylureas are widely used as monotherapy and in combination with metformin or a thiazolidinedione. They can also be used with an  $\alpha$ -glucosidase inhibitor, and there are individuals who can benefit from combination of a sulfonylurea with an incretin or DPP-4 inhibitor or insulin. Combination of a sulfonylurea with a different type of antidiabetic agent usually affords approximately additive glucose-lowering efficacy, at least initially, but there is increased risk of hypoglycemia. The additive efficacy of a sulfonylurea with another type of insulin secretagogue is dependent on different modes of action on the  $\beta$ -cell. (Meglinide prandial insulin secretagogues act via the SUR1 complex similarly to sulfonylureas, so they generally offer no extra benefit beyond uptitration of the sulfonylurea, except on rare occasions where the two types of agent are carefully timed to coincide with unusual or unpredictable meal patterns.)

The pharmacologic theory of adding a sulfonylurea (or other insulin secretagogue) to insulin therapy for patients with T2DM is that subcutaneous insulin injections do not mimic the normal endogenous delivery of more insulin to the liver than to the periphery. Thus, where there is residual endogenous  $\beta$ -cell function, a stimulus to increase delivery of endogenous insulin to the liver should assist in reducing hepatic glucose production particularly during digestion of a meal. Hence, daytime sulfonylurea is sometimes given with bedtime insulin, and this can substantially, if only temporarily, reduce the required insulin dose [45,56]. Present guidelines have tended to favor sulfonylureas as alternative first-line oral therapy where metformin is not appropriate or not tolerated. Because sulfonylurea therapy is associated with weight gain, these agents have customarily been preferred for patients who are not overweight.

Begin sulfonylurea therapy with a low dose, preferably with self-monitoring of blood glucose by the patient at least once daily during the first few weeks. This is especially recommended where there are strong concerns about the potential consequences of hypoglycemia (e.g. in elderly patients, those living alone, operating machinery or driving). In general, patients who have responded to some extent (but still inadequately) with lifestyle measures and have less marked fasting hyperglycemia are more likely to incur hypoglycemia with a sulfonylurea. Uptitrate the dosage at 2–4 week intervals as required. Hypoglycemia, or early hypoglycemic symptoms are the main limitation to dose escalation of sulfonylureas. If evidence of hypoglycemia occurs before the glycemic target is achieved, or if a dosage increment produces no further glycemic benefit, it is advisable to return to the previous dose. Adjustment of the administration regimen may assist or an alternative class of insulin secretagogue may be more suitable. Where the sulfonylurea is taken as monotherapy and the glycemic target is not achieved, then addition of an agent to reduce insulin resistance or an  $\alpha$ -glucosidase inhibitor is the usual recourse. Note that the maximal blood glucose-lowering effect of a sulfonylurea is usually achieved at a dose that is well below the recommended maximum, indicating that maximum stimulation of insulin secretion has already been achieved.

**Efficacy**

As monotherapy in patients inadequately controlled by lifestyle measures, sulfonylureas can be expected to reduce fasting plasma glucose by about 2–4 mmol/L, equating to a decrease in HbA<sub>1c</sub> of 1–2% (11–22 mmol/mol) [3,55,56]. The glucose-lowering effect of sulfonylureas is immediate, and sulfonylureas are particularly effective in the short-term. Efficacy is dependent, however, on sufficient reserve of  $\beta$ -cell function, and this is set against the inevitable decline in  $\beta$ -cell function as the natural history of T2DM proceeds. Thus, it is expected that the dose will need to be escalated to counter the progressive loss of  $\beta$ -cell function, which can reduce the durability of the glucose-lowering efficacy [3,55]. A rapid deterioration of glycemic control during sulfonylurea therapy (sometimes termed “secondary sulfonylurea failure”) occurs in approximately 5–10% of patients per annum [55]. While this may possibly vary between compounds it largely reflects the progression of  $\beta$ -cell failure [3,54,56]. Early intervention in patients with a greater reserve of  $\beta$ -cell function usually produces a better and longer response to sulfonylureas, although not without risk of hypoglycemia, whereas late intervention in patients with severely compromised  $\beta$ -cell function is less effective.

Sulfonylureas generally have little effect on blood lipids. Occasionally, their use will cause a small decrease in plasma triglyceride or increase in HDL cholesterol.

**Adverse effects**

Weight gain, typically in the range of 1–4 kg, is common after initiation of sulfonylurea therapy; it stabilizes by about 6 months [1,3,12]. The weight gain probably reflects the anabolic effects of increased plasma insulin concentrations together with reduced loss of glucose in the urine.

Hypoglycemia is the most common and potentially most serious adverse effect of sulfonylurea therapy. Although it is only rarely life-threatening in patients with T2DM, even mild impairment of neural or motor function can endanger the patient and others, and may predispose to a poor prognosis after a myocardial infarction [3,18]. Patients treated with sulfonylureas should be given instruction on the prevention and recognition of hypoglycemia and the prompt actions required. In the UKPDS, about 20% of sulfonylurea-treated patients reported one or more episodes of hypoglycemic symptoms annually. Other studies have suggested similar rates [12,58]. Severe hypoglycemia (requiring third party assistance) during sulfonylurea therapy occurred in about 1% of patients annually in the UKPDS, and lower rates (approximately 0.2–2.5 episodes per 1000 patient-years) have been reported elsewhere. The mortality risk from sulfonylurea-induced hypoglycemia is reported to be 0.014–0.033 per 1000 patient-years [58]. Longer acting sulfonylureas, irregular meals, other antidiabetic drugs especially insulin, excessive alcohol consumption, already near-normal fasting glycemia, old age and interacting drugs can predispose to increased risk of hypoglycemia (see Chapter 33).

Sulfonylurea-induced hypoglycemia requires prompt admission to hospital. Treat with glucose by continuous intravenous

infusion, probably for more than 1 day to guard against the tendency for a recurrence of hypoglycemia where long-acting sulfonylureas are concerned. If accumulation of chlorpropamide is suspected, renal elimination may be enhanced by forced alkaline diuresis. The vasodilator diazoxide and the somatostatin analog octreotide have been used successfully (but with extreme caution) to inhibit insulin secretion in severe sulfonylurea-induced hypoglycemia. Use of glucagon in patients with T2DM should be avoided as this is itself an insulin secretagogue.

Very occasionally, sulfonylureas produce sensitivity reactions, usually transient cutaneous rashes. Erythema multiforme is rare. Fever, jaundice, acute porphyria, photosensitivity and blood dyscrasias are also rare. Chlorpropamide (no longer in common use) was known for its propensity to cause facial flushing with alcohol and increasing renal sensitivity to antidiuretic hormone, occasionally causing water retention and hyponatremia. Glibenclamide is claimed to have a mild diuretic action.

Although the efficacy of sulfonylureas depends on the stimulation of insulin secretion, this seldom raises plasma insulin concentrations beyond the range of normal (non-diabetic) and subjects with impaired glucose tolerance (IGT). The suggestion emanating from the University Group Diabetes Program study in the 1960s that tolbutamide-induced hyperinsulinemia might have a detrimental effect on the cardiovascular system remains unsubstantiated.

Further studies on the cardiovascular safety of sulfonylureas were prompted by the finding that two isoforms of the sulfonylurea receptor, SUR2A and SUR2B, are expressed in cardiac muscle and vascular smooth muscle, respectively. These isoforms lack the sulfonylurea binding site but they retain the benzamido binding site (Figure 29.8). Therefore, SUR2A/B can only bind those sulfonylureas that contain a benzamido group (glibenclamide, glipizide, glimepiride) [51]. Sulfonylureas without a benzamido group (e.g. tolbutamide, chlorpropamide and gliclazide) show very little interaction with the cardiac and vascular SUR receptors. The effects of the K<sup>+</sup>ATP channel opener nicorandil (an anti-anginal drug with cardioprotective properties) are blocked by sulfonylureas that have a benzamido group. Although compounds with a benzamido group could theoretically interfere with ischemic preconditioning and increase vascular contractility at a time when this might be undesirable (e.g. severe myocardial ischemia), there is no clear evidence that therapeutic concentrations of sulfonylureas exert such an effect. Indeed, hyperglycemic states appear to obviate ischemic preconditioning; however, some authorities continue to advocate that use of sulfonylureas is kept to a minimum in patients with overt coronary artery disease [59].

**Meglitinides (short-acting prandial insulin releasers)**

Meglitinide analogs were evaluated as potential antidiabetic agents after an observation in the 1980s that meglitinide – the non-

**Figure 29.8** This illustrates the transmembrane complex of the SUR1 sulfonyleurea receptor and the ATP-sensitive Kir6.2 potassium efflux channel on the pancreatic β-cells (a). Each SUR1 has a cytosolic sulfonyleurea (S) binding site and a benzamido (B) binding site. SUR2A on cardiac muscle cells (and SUR2B on vascular smooth muscle cells) does not have a sulfonyleurea binding site (b).

The SUR1–Kir6.2 complex is a non-covalently bonded octamer comprising 4 × SUR1 and 4 × Kir6.2, illustrated from the cytosolic surface to show the sulfonyleurea and benzamido binding sites (c). The Kir6.2 molecules are located at the centre and form the K<sup>+</sup> efflux pore. The Kir6.2 channel has a cytosolic binding region for ADP/ATP.

sulfonyleurea moiety of glibenclamide which contains the benzamido group – could stimulate insulin secretion similarly to a sulfonyleurea [60]. The pharmacokinetic properties of these compounds favored a rapid but short-lived insulin secretory effect that suited administration with meals to promote prandial insulin release. By generating a prompt increase of insulin to coincide with meal digestion these agents help to restore partially the first phase glucose-induced insulin response that is lost in T2DM. Specifically targeting post-prandial hyperglycemia might also address the vascular risk attributed to prandial glucose excursions, and reduce the risk of interprandial hypoglycemia [61–63]. Two agents, the meglitinide derivative repaglinide and the structurally related phenylalanine derivative nateglinide, were introduced in 1998 and 2001, respectively, as “prandial insulin releasers” (Figure 29.9). Although acting mainly during the prandial and early post-prandial period, their effects extend sufficiently to produce some reduction of fasting hyperglycemia, particularly with repaglinide.

### Mode of action

Prandial insulin releasers bind to the benzamido site on the sulfonyleurea receptor SUR1 in the plasma membrane of the islet β-cells (Figure 29.8). This site is distinct from the sulfonyleurea site, but the response to binding is the same as for sulfonyleureas, causing closure of the K<sup>+</sup>ATP channel. Thus, there is no therapeutically additive advantage of the two types of agonists, but variations in their binding affinities and duration of action provide opportunities for the specialist to combine a meglitinide and a sulfonyleurea to fit with an unusual meal pattern.

### Pharmacokinetics

Repaglinide is almost completely and rapidly absorbed with peak plasma concentrations after about 1 hour. It is quickly metabolized in the liver to inactive metabolites, which are mostly excreted in the bile (Table 29.8). Taken about 15 minutes before a meal, repaglinide produces a prompt insulin response which lasts about 3 hours, coinciding with the duration of meal digestion. Nateglinide has a slightly faster onset and shorter duration of action [61–63].

### Indications and contraindications

Prandial insulin releasers can be used as monotherapy in patients inadequately controlled by non-pharmacologic measures. They are perhaps most suited for individuals who exhibit post-prandial glycemic excursions while retaining near-normal fasting glycemia. As rapid-acting insulin releasers they can be helpful to individuals with irregular lifestyles with unpredictable or missed meals. The lower risk of hypoglycemia also provides a useful option for some elderly patients, particularly if other agents are contraindicated, although the need for multiple daily dosages may be a disincentive.

Repaglinide is ideally taken 15–30 minutes before a meal. Introduce therapy with a low dose (e.g. 0.5 mg) and monitor glycemic control during titration every 2 weeks up to a maximum of 4 mg before each main meal. When a meal is not consumed, the corresponding dose of repaglinide should be omitted. With appropriate caution and monitoring, repaglinide can be given to patients with moderate renal impairment where some sulfonyleureas and metformin are contraindicated.

**Figure 29.9** Chemical structures of meglitinide, and the prandial insulin releasers repaglinide and nateglinide compared with glibenclamide (glyburide).

**Table 29.8** The meglitinides: repaglinide and nateglinide.

Agent	Dose range (mg/meal)	Max daily dose (mg)	Duration of action (h)	Metabolites	Elimination
Repaglinide	0.5–4.0	16	4–6	Inactive	Bile ~90%
Nateglinide	60–180	540	3–5	One slightly active	Urine ~80%

Nateglinide can be used as monotherapy in much the same way as repaglinide, although nateglinide tends to be faster and shorter acting and requires caution in patients with hepatic disease. Note that in some countries, such as the UK, nateglinide is not licensed for use as monotherapy, only for combination therapy.

If the desired glycemic target is not met with a prandial insulin releaser, consider early introduction of combination therapy (e.g. with an agent to reduce insulin resistance). Prandial insulin releasers can also be useful add-ons to monotherapy with metformin or a thiazolidinedione.

### Efficacy

Consistent with their use to boost prandial insulin secretion, repaglinide (0.5–4 mg) or nateglinide (60–180 mg) taken before meals produce dose-dependent increases in insulin concentrations and reduce post-prandial hyperglycemia. There is usually a small reduction in fasting hyperglycemia. Reductions in HbA<sub>1c</sub> are similar to or smaller than with sulfonylureas, as predicted by their shorter duration of action. As add-on to metformin, they can reduce HbA<sub>1c</sub> by an additional 0.5–1.5% (6–17 mmol/mol).

### Adverse effects

Hypoglycemic episodes are fewer and less severe with prandial insulin releasers than with sulfonylureas. Sensitivity reactions, usually transient, are uncommon. Plasma levels of repaglinide may be increased during co-administration with gemfibrozil. Prandial insulin releasers may cause a small increase in body weight when started as initial monotherapy, but body weight is little affected among patients switched from a sulfonylurea or when a prandial insulin releaser is combined with metformin.

### Thiazolidinediones

The antidiabetic activity of a thiazolidinedione (ciglitazone) was reported in the early 1980s. In the early 1990s the peroxisome proliferator-activated receptor (PPAR) family was identified as part of the nuclear receptor superfamily 1, and it became evident that thiazolidinediones were potent agonists of PPAR- $\gamma$  [64]. The PPAR- $\gamma$ -mediated transcriptional effects of thiazolidinediones were shown to improve whole-body insulin sensitivity, and troglitazone became the first thiazolidinedione to enter routine

**Figure 29.10** Chemical structures of thiazolidinediones rosiglitazone and pioglitazone.

clinical use, introduced in the USA in 1997. The drug, however, was associated with fatal cases of idiosyncratic hepatotoxicity and was withdrawn in 2000. Troglitazone was available for only a few weeks in 1997 in the UK. Two other thiazolidinediones, rosiglitazone and pioglitazone (Figure 29.10), which did not show hepatotoxicity, were introduced in the USA in 1999 and in Europe in 2000 [65]. Fixed-dose combinations of each agent with metformin are also available.

**Mode of action**

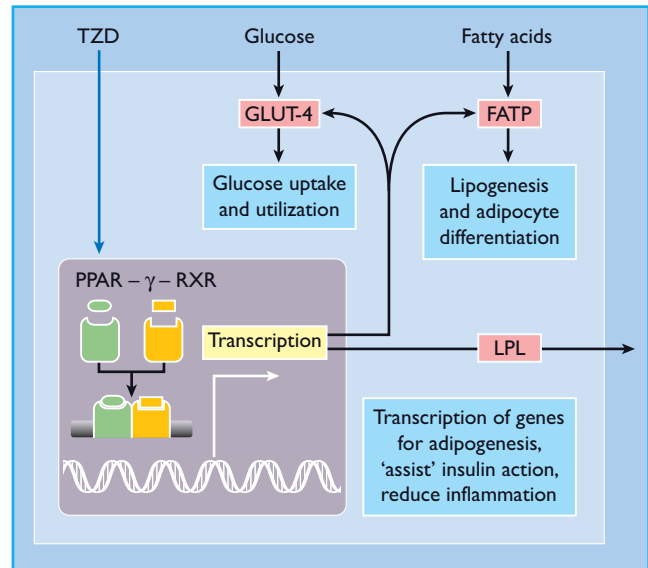

Most of the antidiabetic efficacy of thiazolidinediones appears to be achieved through stimulation of PPAR- $\gamma$  leading to increased insulin sensitivity [66,67]. PPAR- $\gamma$  is highly expressed in adipose tissue, and to a lesser extent in muscle and liver. When activated it forms a heterodimeric complex with the retinoid X receptor and binds to a nucleotide sequence (AGGTCAXAGGTCA) termed the peroxisome proliferator response element (PPRE) located in the promoter regions of PPAR-responsive genes. In conjunction with co-activators such as PGC-1, this alters the transcriptional activity of a range of insulin-sensitive and other genes (Table 29.9). Many of these genes participate in lipid and carbohydrate metabolism (Figure 29.11). Stimulation of PPAR- $\gamma$  by a thiazolidinedione promotes differentiation of pre-adipocytes into mature adipocytes: these new small adipocytes are particularly sensitive to insulin, and show increased uptake of fatty acids with increased lipogenesis. This in turn reduces circulating free fatty acids which rebalances the glucose–fatty acid (Randle) cycle, facilitating glucose utilization and restricting fatty acid availability as an energy source for hepatic gluconeogenesis. By reducing circulating fatty acids, ectopic lipid deposition in muscle and liver is reduced which further contributes to improvements of glucose metabolism.

Thiazolidinediones also increase glucose uptake into adipose tissue and skeletal muscle via increased availability of GLUT 4 glucose transporters. Improvements in insulin sensitivity are likely to be assisted by reduced production of several adipocyte-derived pro-inflammatory cytokines, notably tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), which has been implicated in muscle insulin resistance. Thiazolidinediones also increase production of adiponectin, which enhances insulin action and exerts potentially beneficial effects on vascular reactivity [68]. Because PPAR- $\gamma$  is

**Table 29.9** Examples of key genes activated by thiazolidinediones via stimulation of the peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ). Not all genes appear to be activated in all tissues. The main effects are in adipose tissue.

**Figure 29.11** Mechanism of action of thiazolidinediones. Most actions of a thiazolidinedione (TZD) are mediated via stimulation of the nuclear peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ), which is highly expressed in adipose tissue. When stimulated, PPAR- $\gamma$  forms a heterodimeric complex with the retinoid X receptor (RXR). The complex binds to the peroxisome proliferator response element (PPRE) nucleotide sequence (AGGTCAXAGGTCA) in the promoter regions of certain genes, recruits co-activators, and alters the transcriptional activity of these genes. This modifies nutrient uptake and metabolism, as well as the other functions of the cell.

expressed to a small extent in many tissues, thiazolidinediones can therefore affect responsive genes at these locations, and this has given rise to the tag “pleiotropic effects.”

Thiazolidinediones, like metformin, are antihyperglycemic agents and require the presence of sufficient insulin to generate their blood glucose-lowering effect. Plasma insulin concentrations are typically lowered by thiazolidinediones, and there is evidence that long-term viability of islet  $\beta$ -cells might be improved [69].

### Pharmacokinetics

Absorption of rosiglitazone and pioglitazone is rapid and almost complete, with peak concentrations at 1–2 hours, but slightly delayed when taken with food. Both drugs are metabolized extensively by the liver. Rosiglitazone is metabolized mainly by cytochrome P450 isoform CYP2C8 to inactive or only very weakly active metabolites with a plasma  $t_{1/2}$  of 100–160 hours; these are mostly eliminated in the urine. Pioglitazone is metabolized predominantly by CYP2C8 and CYP3A4 to active metabolites that are eliminated in the bile (Table 29.10). Rosiglitazone can interact with gemfibrozil. Pioglitazone does not appear to cause any clinically significant reductions in plasma concentrations of other drugs metabolized by CYP3A4 such as oral contraceptives. Both thiazolidinediones are almost completely bound to plasma proteins, but their concentrations are not sufficient to interfere with other protein-bound drugs.

### Indications and contraindications

Thiazolidinediones can be used as monotherapy in non-obese and obese patients with T2DM in whom lifestyle does not afford adequate glycemic control. Various treatment algorithms ascribe different positions for thiazolidinediones, but in general they are used as monotherapy if metformin is inappropriate or not tolerated, and for patients in whom an insulin secretagogue is less favored. They are often used to gain additive efficacy in combination with other antidiabetic drugs, particularly metformin [70]. Because of their slow onset of action it is not straightforward to substitute a thiazolidinedione for either a sulfonylurea or metformin without a temporary deterioration in glycemic control. Combination of a thiazolidinedione with insulin can improve glycemic control while reducing insulin dosages, especially in obese patients, but requires extra caution as peripheral edema is more common [71].

A particular issue with thiazolidinediones is their propensity for fluid retention with increased plasma volume of up to 500 mL,

a reduced hematocrit and a decrease in hemoglobin concentration of up to 1 g/dL. Thus, the use of thiazolidinediones is contraindicated in patients with evidence of heart failure. The exclusion criteria, based on cardiac status, vary between countries; for example, New York Heart Association classes I–IV are exclusions in Europe, while III and IV are exclusions in the USA [71]. Appropriate clinical monitoring is important, especially for patients considered at higher risk of cardiac failure and those showing marked initial weight gain. Current controversy has focused on a meta-analysis noting that rosiglitazone increased the risk of myocardial infarction during the first 6–12 months of therapy [72]. While this analysis has received much criticism, the labeling has been tightened to increase awareness of the issue. Despite an increased fluid volume, thiazolidinediones do not increase, and usually slightly decrease, blood pressure.

Although hepatotoxicity has not been a concern with either rosiglitazone or pioglitazone, the troglitazone experience prompted vigilance concerning liver function by measuring serum alanine aminotransferase (ALT) before starting therapy and periodically thereafter. Pre-existing liver disease, development of clinical hepatic dysfunction or elevated ALT levels  $>2.5$  times the upper limit of normal are contraindications to thiazolidinediones. Interestingly, because of the effects of thiazolidinediones on hepatic fat metabolism, recent studies have suggested that this class of drug might even be useful for the treatment of non-alcoholic steatohepatitis.

If there are no contraindications, rosiglitazone and pioglitazone can be used in the elderly. They can also be considered for patients with mild renal impairment, but appreciating the potential for edema. Use of a thiazolidinedione in women with anovulatory PCOS can cause ovulation to resume, but thiazolidinediones should not be continued in pregnancy.

### Efficacy

Thiazolidinediones produce a slowly generated antihyperglycemic effect which usually requires 2–3 months to reach maximum effect [65]. This tends to prolong the dose titration process, and because the therapeutic response can vary considerably between individuals, it is appropriate to consider the patient as a non-responder and to switch to another treatment if there is no clinically meaningful effect after 3 months. The two thiazolidinediones have similar blood glucose-lowering effects, reducing HbA<sub>1c</sub> by around 0.5–1.5% (6–17 mmol/mol). In a long-term monotherapy comparison with metformin or a sulfonylurea (the ADOPT study), rosiglitazone showed a slower onset but a more durable

**Table 29.10** The thiazolidinediones: pioglitazone and rosiglitazone.

Agent	Dose range (mg/day)	Duration of action (h)	Metabolites	Elimination
Pioglitazone	15–45	~24	Active	Bile > 60%
Rosiglitazone	4–8	~24	Inactive	Urine ~ 64%

glucose-lowering effect over more than 3 years [69]. Data from clinical trials suggest that the effect of thiazolidinediones may be better in patients with greater  $\beta$ -cell reserve and more overweight individuals, but a clear indicator of the best responders has not been established. Thiazolidinediones do not cause hypoglycemia as monotherapy.

Both thiazolidinediones substantially reduce circulating non-esterified (free) fatty acids, but effects on other components of the plasma lipid profile have been the subject of debate. Rosiglitazone tends to cause a small rise in the total cholesterol concentration, which stabilizes by about 3 months, although this may be mitigated by adequate statin therapy. The effect appears to reflect a rise in both LDL and HDL cholesterol, leaving the LDL:HDL cholesterol ratio and the total:HDL cholesterol ratio little changed or slightly improved. Pioglitazone generally appears to have little effect on total cholesterol, and has frequently reduced triglyceride concentrations in clinical trials. Both thiazolidinediones reduce the proportion of the smaller, more dense (more atherogenic) LDL particles [73].

Weight gain, similar in magnitude to sulfonylurea therapy (typically 1–4 kg) and stabilizing over 6–12 months, is usually observed after initiation of thiazolidinedione therapy. Several studies indicate that the distribution of body fat is altered. The visceral adipose depot is little changed or reduced, while the subcutaneous depot is increased as new small, insulin-sensitive adipocytes are formed [74].

Thiazolidinediones have been reported to exert beneficial effects on a selection of atherothrombotic risk markers, indices of vascular reactivity and components of the “metabolic syndrome” [69,75,76]. For example, thiazolidinediones downregulate PAI-1 expression, decrease urinary albumin excretion to a greater extent than expected for the improvement in glycemic control, reduce cIMT and coronary restenosis, and reduce circulating markers of chronic low-grade inflammation. Thiazolidinediones also reduce the occurrence of new onset diabetes in individuals with IGT or those with a history of gestational diabetes [77,78].

### Adverse effects

Despite improvements in several atherothrombotic risk factors, the main concerns over thiazolidinediones focus on the cardiovascular impact of edema, reduced hemoglobin levels and congestive heart disease. Additionally, a meta-analysis has suggested increased risk of myocardial infarction during the initial period of treatment with rosiglitazone, although this has not been confirmed by scrutiny of large treatment databases or by long-term prospective studies [75]. Nevertheless, in a large prospective study, pioglitazone reduced long-term vascular events [76,79,80].

Hypoglycemia may occur several weeks after adding a thiazolidinedione to a sulfonylurea; self-monitoring of blood glucose can be helpful to identify when the dosage of the sulfonylurea should be reduced. It has been suggested that rosiglitazone is initiated at half maximal dosage with a sulfonylurea. Recent studies have also noted an approximate doubling of the risk of a

bone fracture – notably at distal sites – amongst postmenopausal women receiving a thiazolidinedione, and possibly a slightly increased risk amongst men [81]. A check on bone density should exclude those at particular risk. Stimulation of PPAR- $\gamma$  in colonic cells has been reported to both increase and decrease the risk of tumors in animals and cell models; thus, familial polyposis coli is a contraindication to thiazolidinediones on theoretical grounds.

---

## Gliptins

Gliptins are DPP-4 inhibitors that enhance incretin levels. They act as selective inhibitors of the enzyme DPP-4 to enhance endogenous incretin activity by preventing the rapid degradation of the incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1). The history, structure and function of incretin hormones, and the therapeutic role of subcutaneously injected incretin mimetics such as exenatide and liraglutide are covered in Chapter 30. Briefly, incretin hormones are secreted from the intestine in response to meal digestion: one of their key actions is to increase glucose-induced insulin secretion by the pancreatic islet  $\beta$ -cells, thereby reducing prandial glucose excursions [82,83]. GLP-1 also suppresses glucagon secretion from the islet  $\alpha$ -cells.

It was noted in the 1980s that the incretin effect is reduced in T2DM, and this was attributed, at least in part, to reduced secretion of GLP-1 [84,85]. By contrast, the biologic actions of GLP-1 remained essentially intact in T2DM, suggesting that administration of extra GLP-1 might be useful therapeutically. This was not a straightforward option because the peptide is rapidly degraded ( $t_{1/2} < 2$  minutes). Studies dating from the early 1990s had shown that degradation was mainly by the enzyme DPP-4. Thus, DPP-4-resistant constructs and analogs of GLP-1 have been developed.

An alternative therapeutic approach is to inhibit the action of DPP-4. The first DPP-4 inhibitors were tested in the late 1990s but were not specific enough for clinical use [85]. Several specific inhibitors have subsequently been developed [86], and sitagliptin (2007) and vildagliptin (2008) were introduced in several countries (Figure 29.12). Another DPP-4 inhibitor, saxagliptin, has recently been introduced (2009) and other DPP-4 inhibitors are currently being developed.

### Mode of action

DPP-4 inhibitors act to prevent the aminopeptidase activity of DPP-4, an enzyme found free in the circulation and tethered to endothelia and other epithelial cells in most tissues, especially in the intestinal mucosa [87]. DPP-4 cleaves the N-terminal dipeptide from peptides that have either an alanine or a proline residue penultimate to the N-terminus. The incretins GLP-1 and GIP are prime targets for DPP-4, and DPP-4 inhibitors more than double their circulating concentrations, but this is not as high as the concentrations of subcutaneously administered incretin mimetic [88]. Raised endogenous incretin concentrations enhance nutrient-induced insulin secretion, and animal studies have demonstrated increased insulin biosynthesis and increased  $\beta$ -cell mass

**Figure 29.12** Chemical structures of the gliptins (DPP-4 inhibitors) sitagliptin and vildagliptin.

✓ yes, – no effect.  
\* Effect observed in animal studies but not confirmed by clinical studies in type 2 diabetes.

(Table 29.11). Increased GLP-1 concentrations also enhance suppression of glucagon secretion. Because these effects are glucose dependent, there is low risk of inducing significant hypoglycemia. The elevation of GLP-1 levels produced by DPP-4 inhibitors is not generally sufficient to create a measurable satiety effect or sufficient slowing of gastric emptying to cause any nausea, and body weight is usually little changed (Figure 29.13).

Because the incretin-mediated effect of DPP-4 inhibitors potentiates glucose-dependent insulin secretion, the activity period of these agents is mostly prandial. Although they are particularly effective in lowering post-prandial hyperglycemia, there is a substantial carry-over effect to benefit the control of interprandial glycemia [89]. By contrast, DPP-4 inhibitors do not initiate insulin secretion and so they do not increase basal insulin secretion. Also, they only suppress glucagon secretion in the hyperglycemic state, so there is low risk of interprandial “overshoot” into hypoglycemia.

### Pharmacokinetics

Sitagliptin and vildagliptin are selective, competitive and reversible inhibitors of DPP-4 (IC<sub>50</sub> approximately 18 and 3.5 nmol,

respectively). Sitagliptin (piperazine derivative) and vildagliptin (cyanopyrrolidine derivative) are each highly bioavailable (approximately 87% and 85%, respectively), rapidly absorbed ( $t_{\max}$  1–4 and <2 hours, respectively), and show relatively low (approximately 38% and 9%, respectively) plasma protein binding. Sitagliptin has a plasma  $t_{1/2}$  of 8–14 hours, and a small proportion is metabolized in the liver by CYP3A4 and CYP2C6. Most of a sitagliptin dose (approximately 79%) is eliminated unchanged in the urine through renal tubular secretion via the organic anion transporter OAT3. A single dose of 100 mg sitagliptin achieves near-complete inhibition of DPP-4 activity for about 12 hours and about 80% inhibition up to 24 hours. Vildagliptin has a shorter plasma  $t_{1/2}$  of 1.5–4.5 hours: the majority (approximately 69%) undergoes mainly renal metabolism to inactive metabolites with negligible involvement of CYP450 isoforms, and most (approximately 85%) is eliminated in the urine. A dose of 50–100 mg vildagliptin gives almost complete inhibition of DPP-4 for about 12 hours and about 40% inhibition by 24 hours (Table 29.12).

### Indications and contraindications

In principle, gliptins can be used as monotherapy in patients with T2DM who have responded inadequately to lifestyle measures, although this is not a licensed indication in all countries where available. Currently, as newly available agents, gliptins tend to be preferred as “add-on” therapy in patients inadequately controlled by metformin or a thiazolidinedione. Theoretically, they could be used with any other class of oral agent or insulin, as their mode of action on the  $\beta$ -cell is different from sulfonylureas and meglitinides, and their ability to reduce glucagon levels could be useful as add-on therapy to insulin even without  $\beta$ -cell function. In practice, however, full efficacy in T2DM requires adequate  $\beta$ -cell reserve. Lack of weight gain makes gliptins suitable for overweight and obese patients, and low risk of hypoglycemia when used as monotherapy (and when used with non-insulin releasing agents) favors their use in patients who have only slightly raised basal glycemia, are close to glycemic target or have unpredictable meal times [89,90].

Sitagliptin is taken once daily (100 mg) in the morning, and vildagliptin is usually twice daily (50 mg). The glucose-dependent mode of action reduces the risk of any significant glucose lowering effect unless there is hyperglycemia, lowering concern over

**Figure 29.13** Sites of action of gliptins (DPP-4 inhibitors). Incretin hormones such as GLP-1 are released in response to a meal. These hormones are normally degraded rapidly by the enzyme DPP-4. Gliptins act as inhibitors of DPP-4, allowing the normal effects of the incretin hormones to be enhanced. The main site of the enhanced incretin effect is on the pancreas to increase nutrient-induced insulin secretion. GLP-1 also reduces glucagon secretion. \* Potential effects to slow gastric emptying and increase satiety probably contribute little to the therapeutic efficacy of gliptins.

**Table 29.12** Gliptins: sitagliptin and vildagliptin.

Agent	Dose (mg/day)	Duration of action (h)	Metabolites	Elimination
Sitagliptin	100	18–24	Nominal metabolism	Urine ~ 79%*
Vildagliptin	2 × 50	12–24	Inactive	Urine ~ 85%

\* Unchanged drug.

missed meals. Thus, there is no dose titration, but it is recommended that fasting and post-prandial glycemia are reviewed after about 2 weeks of therapy, especially when added as a second agent.

Because sitagliptin is mostly eliminated unchanged in the urine, a reduced dose (50 mg once daily) is recommended for patients with moderate renal insufficiency (creatinine clearance  $\geq 30$  to  $< 50$  mL/min); for patients with severe renal insufficiency (creatinine clearance  $< 30$  mL/min) or with end-stage renal disease requiring hemodialysis or peritoneal dialysis, consider a dose of 25 mg once daily. Sitagliptin causes no apparent induction or inhibition of P450 isoforms, which allows its use in patients with mild or moderate impairment of liver function provided renal function is adequate.

In view of the renal metabolism and elimination of vildagliptin, this agent is not recommended in patients with moderate or severe renal impairment (e.g. creatinine clearance  $< 50$  mL/min). Some cases of reversibly raised ALT or aspartate aminotransferase (AST) have been observed in patients receiving vildagliptin,

therefore a liver function check should be made before starting treatment and periodically thereafter. A marked rise in liver enzymes (e.g. ALT or AST  $> 3\times$  upper limits of normal) or other signs of hepatic impairment contraindicate treatment.

No significant drug interactions have been noted with either gliptin. As clinical experience is limited it is advisable to use these drugs cautiously in patients with heart disease and to stop gliptin therapy in pregnancy.

### Efficacy

#### Sitagliptin

Administration of 100 mg/day sitagliptin as monotherapy or add-on therapy to other antidiabetic agents typically reduced HbA<sub>1c</sub> (from a baseline of approximately 8% [64 mmol/mol]) by about 0.7–0.8% (8–9 mmol/mol) after 24–52 weeks [89–92]. Individuals with a high baseline HbA<sub>1c</sub> usually showed reductions in HbA<sub>1c</sub> of  $> 1\%$  (11 mmol/mol). Fasting plasma glucose concentrations were reduced by about 1.0–1.5 mmol/L, and post-prandial glucose levels measured 2 hours after a standard mixed

meal were usually reduced by about 3 mmol/L. Sitagliptin therapy did not cause a clinically significant increase in the incidence of hypoglycemia, and a sitagliptin + metformin combination was associated with fewer hypoglycemic episodes than a combination of glipizide + metformin despite similar levels of HbA<sub>1c</sub> [93]. Sitagliptin did not increase body weight compared with placebo in any of the trials.

### Vildagliptin

In clinical trials a single daily dose of 50–100 mg/day vildagliptin showed similar efficacy and tolerability to sitagliptin when used as monotherapy or add-on to metformin or a thiazolidinedione [89–91,94]. Although several trials with vildagliptin produced slightly greater reductions in HbA<sub>1c</sub>, this was mostly associated with a slightly higher average baseline (starting) HbA<sub>1c</sub> (>8.5% [ $>69$  mmol/mol]). Again there was no effect on hypoglycemia or body weight.

### Adverse effects

Clinical experience to date with gliptins has not identified any serious adverse effects. In clinical trials (typically 6–12 months), measures of tolerability and adverse events were generally similar to placebo or comparator. There were some increases in liver enzymes with a 100 mg dose of vildagliptin, but not with the 50 mg dose that is marketed. Nominal increases in reported signs or symptoms of abdominal discomfort suggest that the potential to slow gastric emptying is unlikely to have a clinically significant impact.

Because there are many natural substrates for DPP-4 including bradykinin, enkephalins, neuropeptide Y, peptide YY1–36, gastrin releasing polypeptide, substance P, insulin-like growth factor I, vasostatin 1, the  $\alpha$  chains of thyrotropin, luteinizing hormone and chorionic gonadotropin and several chemokines such as monocyte chemoattractant protein 1 (MCP-1), gliptins have the potential to influence the hunger–satiety system, gastrointestinal motility, growth, vascular reactivity and immune mechanisms [88]. DPP-4 is also the CD26 T-cell activation antigen, but neither CD26 knockout mice nor the DPP-4-specific inhibitors used in animals or humans have yet shown any significant untoward immune-related effects. The importance of selective DPP-4 inhibition is also noted because inhibition of related enzymes such as DPP-8 and DPP-9 has produced blood dyscrasias and skin lesions in some species, but not in clinical use. Nevertheless, it is advisable to check for any evidence of skin lesions.

### $\alpha$ -Glucosidase inhibitors

Studies conducted in the late 1970s noted that inhibitors of intestinal  $\alpha$ -glucosidase enzymes could retard the final steps of carbohydrate digestion with consequent delay to the absorption of sugars. By the early 1980s it was demonstrated that this approach could reduce post-prandial hyperglycemia in diabetes [95]. Acarbose, the first  $\alpha$ -glucosidase inhibitor, was introduced in the early 1990s. Subsequently, two further agents, miglitol and voglibose, were introduced in some countries (Figure 29.14). In patients

**Figure 29.14** Chemical structures of the  $\alpha$ -glucosidase inhibitors acarbose, miglitol and voglibose.

who consume meals containing complex carbohydrate,  $\alpha$ -glucosidase inhibitors can effectively reduce post-prandial glucose excursions. These agents also have a good safety record but their application has been limited by gastrointestinal side effects.

**Mode of action**

$\alpha$ -Glucosidase inhibitors competitively inhibit the activity of  $\alpha$ -glucosidase enzymes in the brush border of enterocytes lining the intestinal villi (Figure 29.15). They bind to the enzymes with high affinity, preventing the enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays completion of carbohydrate digestion and can defer the process distally along the intestinal tract, leading to a delay in glucose absorption [95]. Different  $\alpha$ -glucosidase inhibitors have different affinities for the various  $\alpha$ -glucosidase enzymes. This gives slightly different activity profiles (e.g. acarbose has greatest affinity for glycoamylase > sucrase > maltase > dextrinases, whereas miglitol is a stronger inhibitor of sucrase). It is emphasized that  $\alpha$ -glucosidase inhibitors can only be effective if the patient is consuming complex digestible carbohydrate. These agents do not significantly affect the absorption of glucose per se. By moving glucose absorption more distally along the intestinal tract,  $\alpha$ -glucosidase inhibitors may alter the release of glucose-dependent intestinal hormones such as GIP and GLP-1 which enhance nutrient-induced insulin secretion. Thus, release of GIP, which occurs mainly from the jejunal mucosa, may be reduced by  $\alpha$ -glucosidase inhibitors, whereas secretion of GLP-1 (mostly from the ileal mucosa) is increased.  $\alpha$ -Glucosidase inhibitors probably reduce post-prandial insulin concentrations through the attenuated rise in post-prandial glucose levels [95].

**Pharmacokinetics**

Acarbose is degraded by amylases in the small intestine and by intestinal bacteria; less than 2% of the unchanged drug is absorbed

along with some of the intestinal degradation products. Absorbed material is mostly eliminated in the urine within 24 hours [95]. Miglitol is almost completely absorbed and eliminated unchanged in the urine.

**Indications and contraindications**

$\alpha$ -Glucosidase inhibitors can be used as monotherapy, usually for patients with T2DM with post-prandial hyperglycemia but only slightly raised fasting glycemia; however, they are more commonly used as add-on to other therapies, again to target post-prandial hyperglycemia [95].  $\alpha$ -Glucosidase inhibitors can also be used to extend the post-prandial period to reduce interprandial glycemic troughs or hypoglycemia in individuals receiving a sulfonylurea and/or insulin. Acarbose has also been shown to prevent progression of IGT to T2DM [96], although this is not a licensed use.

When starting an  $\alpha$ -glucosidase inhibitor the patient should be advised that a diet containing complex digestible carbohydrate is important.  $\alpha$ -Glucosidase inhibitors should be taken with meals, starting with a low dose (e.g. 50 mg/day acarbose) and slowly uptitrated over several weeks. Monitoring of post-prandial glycemia is often helpful. Hypoglycemia is unlikely when used as monotherapy, but gastrointestinal symptoms commonly limiting initial tolerability and dose titration. Symptoms tend to be reduced by slow titration and usually subside with time, possibly reflecting some adaptation of the intestinal tract, but tolerability is poor.

$\alpha$ -Glucosidase inhibitors are contraindicated for patients with a history of chronic intestinal disease, and high dosages of acarbose can occasionally increase liver enzyme concentrations; so it is recommended to measure transaminase concentrations periodically in patients receiving a maximum dosage (200 mg acarbose three times daily). Raised liver enzymes should remit as the dosage is reduced, otherwise alternative causes of hepatic dysfunction should be considered.

**Figure 29.15** Mode of action of  $\alpha$ -glucosidase inhibitors.  $\alpha$ -Glucosidase inhibitors competitively inhibit the activity of  $\alpha$ -glucosidase enzymes in the brush border of enterocytes lining the intestinal villi, preventing these enzymes from cleaving disaccharides and oligosaccharides into monosaccharides. This delays carbohydrate digestion.

**Efficacy**

Because  $\alpha$ -glucosidase inhibitors target post-prandial glucose excursions during meals that contain complex carbohydrate, their effectiveness is entirely dependent on dietary compliance. As monotherapy, these agents can reduce peak post-prandial glucose concentrations by 1–4 mmol/L. The incremental area under the post-prandial plasma glucose curve can be more than halved in some individuals, and there is usually some extended duration of effect to modestly lower basal glycemia up to about 1 mmol/L. The decrease in HbA<sub>1c</sub> is usually about 0.5–1.0% (6–11 mmol/mol), provided that a high dose of the drug is tolerated and dietary compliance is maintained [97].

Although overall reductions in HbA<sub>1c</sub> are modest,  $\alpha$ -glucosidase inhibitors offer several useful features: they do not cause weight gain or frank hypoglycemia and may reduce inter-prandial episodes of hypoglycemia. When combined with other antidiabetic agents,  $\alpha$ -glucosidase inhibitors can reduce post-prandial hyperinsulinemia, and they often lower plasma triglyceride concentrations. Use of an  $\alpha$ -glucosidase inhibitor can produce minor alterations to the intestinal absorption of other oral antidiabetic agents when used in combination therapy, but  $\alpha$ -glucosidase inhibitors usually provide additive efficacy gains when used in combination with any other class of antidiabetic agent [95]. There is preliminary evidence that acarbose might reduce major cardiac events, including myocardial infarction, but this requires confirmation, and it is unclear if this could be caused by the targeting of post-prandial hyperglycemia or an independent effect of the drug [98].

**Adverse effects**

Gastrointestinal side effects represent the main problem with  $\alpha$ -glucosidase inhibitors. For example, in the STOP-NIDDM trial, 31% of acarbose-treated patients compared with 19% on placebo discontinued treatment early [96]. If the dosage is too high (relative to the amount of complex carbohydrate in the meal), undigested oligosaccharides pass into the large bowel. These are fermented, causing flatulence, abdominal discomfort and sometimes diarrhea, but usually ameliorating with slower titration and time. Hypoglycemia is uncommon and there are no clinically significant drug interactions, although use in conjunction with agents affecting gut motility or cholestyramine is not recommended.

**Antiobesity therapies**

Obesity, especially excess visceral adiposity, predisposes to diabetes, complicates glycemic control and substantially increases the risk of vascular disease (see Chapter 14). The blood glucose-lowering efficacy of lifestyle measures to reduce adiposity in obese T2DM is well appreciated, although it is often very difficult to achieve and maintain significant weight loss in these patients. Interestingly, several studies have suggested that additional glucose-lowering can be attained with pharmacologic antiobesity

therapies. Whether this is entirely explained by greater weight loss and improved dietary compliance is unclear because it has been mooted that some antiobesity therapies could have some modest independent glucose-lowering effects.

In conjunction with a mildly hypocaloric and reduced fat diet, the intestinal lipase inhibitor orlistat (120 mg three times daily with meals) can reduce dietary fat absorption by up to 30%. In overweight and obese patients with T2DM this typically increases weight reduction by an extra 2–3 kg, and additional reductions in HbA<sub>1c</sub> of 0.28–1.1% (3–12 mmol/mol) have been reported [28]. Potential improvements in the glucose–fatty acid cycle might be envisaged. The satiety-inducing serotonin–norepinephrine reuptake inhibitor sibutramine often enables slightly greater reductions of body weight in overweight and obese patients with T2DM, with extra reductions in HbA<sub>1c</sub> of around 0.6% (7 mmol/mol)\*. Sibutramine metabolites might have useful metabolic effects. Antiobesity therapies carry their own contraindications, cautions and side effects, and orlistat could interfere with the absorption and activity of some oral antidiabetic agents, particularly  $\alpha$ -glucosidase inhibitors.

**Fixed-dose combinations**

As the target-driven early and intensified approach to management of hyperglycemia in T2DM gathers momentum, the use of combinations of two or more oral agents with *different* mechanisms of action has become commonplace [99]. To facilitate combination therapy, several fixed dose, single tablet combinations have been made available (Table 29.13). These are designed to provide bioequivalence and thereby similar efficacy, although minor adjustments to formulation may also enable some extra blood glucose-lowering efficacy. Fixed dose combinations can offer convenience, reduce the “pill burden,” simplify administration regimens and they may increase patient adherence compared with equivalent combinations of separate tablets. Lower doses of two different types of agents rather than a high dose of one agent may also provide a way to achieve efficacy while circumventing dose-related side effects. Current fixed dose combinations of antidiabetic agents include metformin combined with a sulfonylurea, thiazolidinedione, gliptin or meglitinide, as well as thiazolidinedione–sulfonylurea combinations. Although single tablets could reduce titration flexibility, most of the commonly used dosage combinations have been accommodated. It is reiterated that any form of combination therapy necessitates the same

\*The marketing authorization for sibutramine has recently been withdrawn in Europe following the publication of the SCOUT trial. In this trial which included 9,800 overweight or obese individuals at high risk of CVD events, treatment with sibutramine was associated with a 16% increased risk of non-fatal MI, non-fatal stroke, resuscitated cardiac arrest or CVD death. This result was driven by an increased incidence of non-fatal MI and stroke.

**Table 29.13** Fixed-dose single-tablet combinations of antidiabetic agents. Adapted from Bailey and Day [99].

Tablet	Components	Strengths (mg)
Glucovance	Metformin +glibenclamide	250:1.25, 500:2.5, 500:5.0
Metaglip	Metformin + glipizide	250:2.5, 500:2.5, 500:5.0
Avandamet	Metformin + rosiglitazone	500:1.0, 500:4.0, 500:2.0, 1000:2.0, 1000:4.0
Competact (Actoplusmet)	Metformin + pioglitazone	500:15, 850:15
Eucreas	Metformin + vildagliptin	850:50, 1000:50
Janumet	Metformin + sitagliptin	500:50, 1000:50
Prandimet	Metformin + repaglinide	500:1, 500:2
Avaglim (Avandaryl)	Rosiglitazone + glimepiride	4:1, 4:2, 4:4, 8:2, 8:4
Tandemact (Duetact)	Pioglitazone + glimepiride	30:, 45:4

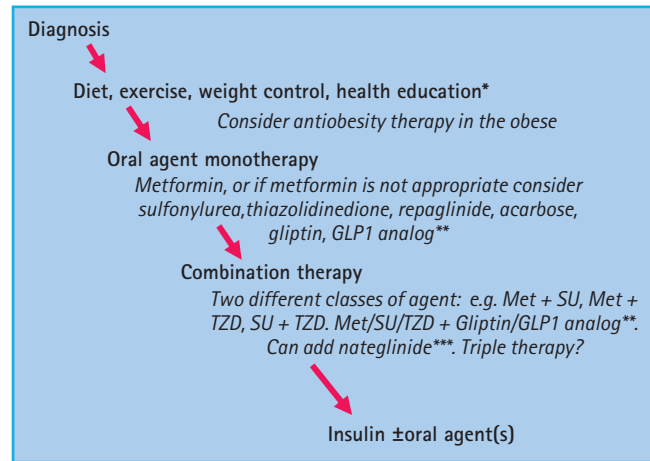

Availability of tablets and component strengths differ between countries. Names vary between Europe and USA. Alternative names are given in parentheses. Glibenclamide = glyburide

cautions and contraindications that apply to each active component.

### Conclusions

A minimalistic archetypal algorithm to treat hyperglycemia in T2DM is shown in Figure 29.16. This illustrates a typical stepped approach similar to that advocated in most current guidelines. Guidelines should be interpreted with flexibility, however, to ensure that the care plan, treatment targets and selection of therapies are individualized to suit the circumstances of the patient. The value of lifestyle intervention as initial and ongoing therapy in conjunction with pharmacologic agents should not be underestimated. In view of the progressive natural history of T2DM, the introduction of drug therapy, the need for periodic uptitration of dosage and the use of combination therapy can be expected for most patients (covered in further detail in Chapter 31).

A range of differently acting oral agents is available: metformin and thiazolidinediones counter insulin resistance; sulfonylureas, meglitinides and gliptins increase insulin secretion; and  $\alpha$ -glucosidase inhibitors slow carbohydrate digestion. Additionally, injected incretin analogs increase insulin secretion. All of these blood glucose-lowering agents can only provide glycemic control if there is sufficient  $\beta$ -cell reserve. When adequate control is not achieved or not maintained, it is important to proceed to the next stage without delay to avoid periods of hyperglycemia. Insulin should be considered when other therapies do not provide adequate glycemic control or are unsuitable. Integrated management

**Figure 29.16** Archetypal algorithm used in the treatment of hyperglycemia in type 2 diabetes (except patients presenting with severe hyperglycemia who may require immediate insulin therapy). Start with lifestyle measures (diet and exercise). If the individualized glycemic target for the patient is not achieved quickly using lifestyle measures, then add pharmacologic therapy without delay. The selected monotherapy is uptitrated to achieve the desired glycemic effect. If an uptitration step does not add benefit or is not tolerated revert back a step. When the desired glycemic effect is not achieved or adequate titration is not tolerated, move promptly to the addition of a second agent and uptitrate. If the desired glycemic control is not achieved or maintained consider triple therapy or introduce insulin while maintaining one or two of the existing therapies where appropriate. Respect drug cautions and contraindications at all times, monitor as required, and try to select glycemic targets that are realistic, safely achievable and avoid hypoglycemia. \* Lifestyle advice reinforced throughout. \*\* GLP1 analog given as subcutaneous injection. \*\*\* Nateglinide usually only as second agent.

to address cardiovascular risk and co-morbid conditions is essential. Monitoring, therapeutic adjustments for efficacy, safety, avoidance of hypoglycemia and contraindications require constant vigilance, but early, effective and sustained glycemic control is essential to minimize vulnerability to vascular complications later in life.

### Keypoints

- Incretins are gut hormones that enhance glucose-stimulated insulin secretion and have an important role in the regulation of post-prandial glucose levels.
- The major incretin hormones are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP).
- The physiologic actions of GLP-1 include potentiation of meal-induced insulin secretion, inhibition of glucagon secretion, delay in gastric emptying and suppression of food intake and appetite.
- Beneficial effects of parenteral administration of a synthetic GLP-1 receptor agonist (exenatide or liraglutide) in patients with type 2 diabetes include improved glycemic control and mild weight loss; nausea and vomiting are the most common adverse events.
- Amylin is a naturally occurring peptide that is co-secreted with insulin from the  $\beta$ -cells of the pancreatic islets.
- Physiologic actions of amylin include delayed gastric emptying, suppression of post-prandial glucagon secretion and increased satiety.
- Beneficial effects of parenteral administration of pramlintide, a synthetic amylin mimetic approved for use in insulin-treated subjects with either type 1 or type 2 diabetes, include improved glycemic control and mild weight loss; transient nausea and hypoglycemia are the most common adverse events.
- The non-insulin parenteral therapies include activators of the GLP-1 receptor, also called "incretin mimetics," as well as amylin mimetics.

### GLP-1 receptor activators

The actions of glucagon-like peptide 1 (GLP-1) include the potentiation of meal-induced insulin secretion and, in preclinical models, proliferation and/or neogenesis of the  $\beta$ -cell and prevention of  $\beta$ -cell apoptosis has been observed. GLP-1 also inhibits glucagon secretion, delays gastric emptying and suppresses food intake and appetite. Cardiovascular effects include protection of the ischemic heart, improved left ventricular ejection fraction, endothelial function and blood pressure lowering. In animal models, GLP-1 may also possess neurotropic effects. GLP-1 receptor agonists improve glycemic control to a degree that is similar to or greater than oral antidiabetic drugs. Furthermore, they induce weight loss of 2–3 kg, on average. It is unknown whether GLP-1 receptor agonists can delay the progression of type 2 diabetes mellitus (T2DM). The GLP-1 receptor mimetics are well tolerated and the most common adverse events are gastrointestinal, including nausea and vomiting. The available

GLP-1 receptor agonists require injection once or twice daily, but once-weekly GLP-1 receptor activators are in development.

### The incretin effect

"The incretin effect" designates the amplification of insulin secretion elicited by hormones secreted from the gastrointestinal tract. It is quantified by comparing insulin responses to oral and intravenous glucose administration, where the intravenous infusion is adjusted so as to result in the same (isoglycemic) peripheral plasma glucose concentrations [1,2]. In healthy subjects, the oral administration of glucose causes a two- to threefold larger insulin response than the intravenous route as a result of the actions of the "incretin hormones." Because of this, the incretin hormones are thought to have a particularly important role in the regulation of post-prandial glucose levels.

The two most important incretins are glucose-dependent insulinotropic polypeptide (GIP), previously designated gastric inhibitory polypeptide, and GLP-1. Both have been established as important incretin hormones in mimicry experiments in humans, where the hormones were infused together with intravenous glucose to concentrations approximately corresponding to those observed during oral glucose tolerance tests. Both hormones powerfully enhanced insulin secretion, to an extent that

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

could fully explain the insulin response [3,4], and recent experiments have documented that both are active with respect to enhancing insulin secretion from the beginning of a meal (even at fasting glucose levels), and that they contribute almost equally, but with the effect of GLP-1 predominating at higher glucose levels [5]. The effects of the two hormones with respect to insulin secretion have been shown to be additive in humans [6].

### The incretin effect in T2DM

Original studies by Nauck *et al.* [7] and several subsequent studies have indicated that the incretin effect is severely reduced or lost in patients with T2DM [8,9]. Thus, there is little doubt that a defective incretin effect contributes to the glucose intolerance of these patients.

Given that GLP-1 and GIP are the most important incretin hormones, it is possible to analyze their contribution to the defective incretin action in patients with diabetes. Such contributions could consist of defects with respect to secretion, action or metabolism. Detailed studies of the secretion of GIP and GLP-1 in response to mixed meals in patients with T2DM revealed a slightly impaired secretion of GIP, but a more pronounced impairment with respect to the secretion of GLP-1. The reduction was particularly prominent during the second and third hour of the meal test, while the initial response was unimpaired. The decreased response was related to both body mass index (BMI; the higher the BMI, the lower the incretin response) and to the actual diabetic state [10]. A decreased GLP-1 secretion in obese subjects has been observed repeatedly [11] and is related to an impaired incretin effect [12,13]. Insulin resistance is also independently related to a decreased GLP-1 meal response [13,14]. A decreased secretion of GLP-1 may not be seen in all obese or insulin-resistant subjects. Experience from the authors' laboratory suggests that in addition to insulin resistance and obesity, longer duration of diabetes and, in particular, influence of therapy is important. For instance, it is now clear that metformin enhances GLP-1 secretion [15]. When present, impaired secretion of GLP-1 is likely to contribute to the failing incretin effect.

The metabolism of GLP-1 and GIP was compared by Vilsbøll *et al.* [16,17] in patients with diabetes and controls; both hormones were metabolized at similar rates, suggesting that differences in their elimination do not explain the reduced plasma concentrations in diabetes.

With respect to the actions of the incretin hormones, it was discovered in 1993 that infusion of large amounts of GLP-1 resulted in near-normal insulin responses in patients with T2DM, whereas GIP had no significant effect [18]. However, infusions of GIP and GLP-1 at rates resulting in physiologic elevations of the incretin levels (as observed after mixed meal ingestion) while glucose was clamped at 15 mmol/L, failed to affect insulin secretion at all, despite these infusion rates greatly (and equally) increasing insulin secretion in healthy subjects [19]. These findings illustrate the dramatic loss of potency of both GIP and GLP-1 in T2DM. By contrast, when infused to supraphysiologic levels, GLP-1, but not GIP, was capable of restoring the  $\beta$ -cell sensitivity

to glucose to completely normal values [20]. The mechanisms whereby GLP-1, but not GIP, stimulates insulin secretion in T2DM remain unknown, but the observation suggested that GLP-1 in pharmacologic doses could be used clinically to enhance insulin secretion in T2DM.

Finally, one may ask whether the incretin defect is a primary event, perhaps a major etiologic contributor to the  $\beta$ -cell failure that characterizes T2DM. Several observations suggest that this is not the case [9], but may be related to insulin resistance and/or hyperglycemia [21], as reviewed recently [9]. Interestingly, there are now data to suggest that intensified treatment resulting in near-normal glucose levels may lead to a partial restoration of incretin action of GLP-1 and GIP [19,22] and induction of insulin resistance in healthy subjects is associated with a loss of the incretin effect [23].

### Actions of GLP-1

The acute insulinotropic effects of GLP-1 raised interest in the use of this peptide for the treatment of diabetes. In addition, the peptide possesses a number of other effects, which in the context of diabetes treatment must be considered favorable (Figure 30.1).

#### Effects on the islets

The insulinotropic activity of GLP-1, which represents a potentiation of glucose-induced insulin secretion and therefore is strictly glucose-dependent, is, at least partly (see below), exerted via interaction with the GLP-1 receptor located on the cell membrane of the  $\beta$ -cells [24]. Binding of GLP-1 to the receptor causes activation of adenylate cyclase resulting in the formation of cyclic AMP (cAMP), via a stimulatory G-protein. Most of the actions of GLP-1 are secondary to the formation of cAMP and results in a plethora of events including altered ion channel activity, intracellular calcium handling and enhanced exocytosis of insulin-containing granules [25]. The effects of glucose and GLP-1 may converge at the level of the  $K_{ATP}$  channels of the  $\beta$ -cells. These channels are sensitive to the intracellular ATP levels and, thereby, to glucose metabolism of the  $\beta$ -cells, but may also be closed by protein kinase A activated by GLP-1, resulting in subsequent depolarization of the plasma membrane and opening of voltage-sensitive calcium channels [26–28]. This has clinical importance because sulfonylurea drugs, which bind to and close the  $K_{ATP}$  channels and thereby cause membrane depolarization and calcium influx, may uncouple the glucose dependency of GLP-1 [29]. Indeed, 30–40% of patients treated with both sulfonylurea compounds and a GLP-1 agonist (see below) experience, usually mild, hypoglycemia.

The transcription factor PDX-1, a key regulator of islet growth and insulin gene transcription, appears to be essential for most of the glucoregulatory, proliferative and cytoprotective actions of GLP-1 [30]. In addition, GLP-1 upregulates the genes for the cellular machinery involved in insulin secretion, such as the glucokinase and GLUT-2 genes [31]. For further discussion of the insulinotropic effects of GLP-1, see Holst [32].

Importantly, GLP-1 also has trophic effects on  $\beta$ -cells [33]. Not only does it stimulate  $\beta$ -cell proliferation [34,35], but it also

**Figure 30.1** Effects of glucagon-like peptide 1 (GLP-1) receptor agonists on glucose metabolism.

enhances the differentiation of new  $\beta$ -cells from progenitor cells in the pancreatic duct epithelium [30,36] and inhibits apoptosis of  $\beta$ -cells including human  $\beta$ -cells [37,38]. Because the normal number of  $\beta$ -cells is maintained in a balance between apoptosis and proliferation [39], this observation is of considerable interest, and also raises the possibility that GLP-1 could be useful in conditions with increased  $\beta$ -cell apoptosis.

The complicated mechanisms whereby GLP-1 may exert trophic effects on the  $\beta$ -cells were reviewed recently by Drucker [40].

#### **Reflex activation of the $\beta$ -cell**

GLP-1 is extensively degraded by the enzyme dipeptidyl peptidase 4 (DPP-4) and it has been demonstrated that only about one-quarter of the amount of GLP-1 leaving the gut (the endocrine organ) is still in the intact active form, and only about 8% of what is secreted actually reaches the pancreas as the intact peptide [41–43]. This has given rise to speculation that the actions of GLP-1 on the  $\beta$ -cells might be exerted indirectly via activation of long vagovagal reflexes [42]. Indeed, the GLP-1 receptor is expressed in cell bodies in the nodose ganglion from which the sensory afferents from the gastrointestinal tract emanate [44], and it has been demonstrated that blockade of the autonomic ganglia also blocked the effects of intraportally injected GLP-1 on insulin secretion [45]. Thus, it may be that under physiologic conditions the majority of the effects of GLP-1 on insulin secretion are transmitted via autonomic nerves.

#### **Effects on glucagon secretion**

GLP-1 also strongly inhibits glucagon secretion. Because in patients with T2DM there is fasting hyperglucagonemia as well

as exaggerated glucagon responses to meal ingestion [46], and because it has been demonstrated that the hyperglucagonemia contributes to the hyperglycemia of patients [47], this effect may be as important as the insulinotropic effects. The mechanism whereby GLP-1 inhibits glucagon secretion remains unsettled but there is evidence that the somatostatin-producing D-cells of the islets transmit the effects of GLP-1 by paracrine inhibition of the  $\alpha$ -cells [48].

#### **Effects on the gastrointestinal tract**

Further important effects of GLP-1 include inhibition of gastrointestinal secretion and motility, notably gastric emptying [49,50]. By this mechanism, GLP-1 may curtail post-prandial glucose excursions [51], and thereby reduce the number of episodes with high post-prandial glucose levels. There has been concern that the powerful inhibitory effect could represent a problem in patients with gastroparesis, but so far there have been no reported cases.

#### **Effects on appetite and food intake**

GLP-1 inhibits appetite and food intake in normal subjects [52] as well as in obese subjects with T2DM [53,54], and it is thought that GLP-1 is one of the gastrointestinal hormones that normally regulate food intake [32]. Clinical studies have shown that the effects on food intake are maintained for several years and lead to a sustained or progressive weight loss.

#### **Cardiovascular effects**

It has been known for some time that there are GLP-1 receptors in the heart [55]. A physiologic function for these receptors was indicated in recent studies in mice lacking the GLP-1 receptor,

**Figure 30.2** Cardioprotective effect of the GLP-1 receptor agonist, exendin-4. Post-conditioning with the GLP-1 receptor agonist, exendin-4 (i.e. addition of the agonist to the perfusate *after* the ischemia period) reduces infarct size in an isolated rat heart model of ischemia-reperfusion injury. Adapted from Sonne *et al.* [60]

which exhibit impaired left ventricular contractility and diastolic functions as well as impaired responses to exogenous epinephrine [56]. GLP-1 also increases left ventricular pressure and coronary blood flow in isolated mouse hearts [57], although in normal rat hearts, it reduces contractility [58]. However, further studies in rats showed that GLP-1 protects the ischemic and reperfused myocardium in rats by mechanisms independent of insulin [58,59]. Protective effects may be demonstrated by administration of GLP-1 or GLP-1 receptor agonists both before and after ischemia (Figure 30.2) [57,60], and may involve the p70s6 kinase [61]. Surprisingly, some of the cardiac effects may also be elicited by the metabolite GLP-1 9-36 amide, which is formed rapidly in the circulation, but which has a strongly reduced activity on the classic GLP-1 receptor of the  $\beta$ -cells [57,60,62]. It has therefore been suggested that a different receptor mediates at least some of the cardiovascular effects, although not all studies support this [61]. Whatever the mechanism, these findings may have important clinical implications. Nikolaidis *et al.* [63] studied patients treated with angioplasty after acute myocardial infarction, but with postoperative left ventricular ejection fractions as low as 29%. In these patients, GLP-1 administration significantly improved the ejection fraction to 39% and improved both global and regional wall motion indices [63]. In studies of dogs with induced dilated cardiomyopathy, GLP-1 was reported to improve left ventricular and systemic hemodynamics dramatically, and it was suggested that GLP-1 may be a useful metabolic adjuvant in decompensated heart failure [64]. Indeed, addition of GLP-1 to standard therapy in patients with heart failure significantly improved left ventricular ejection fraction, myocardial oxygen uptake, 6-minute walking distance and quality of life [65]. In another study in which patients undergoing coronary artery bypass grafting were randomized to receive GLP-1 or conventional treatment, there was less use of inotropic and vasoactive drugs and fewer arrhythmias, as well as better glycemic control, in the GLP-1 group [66]. The cardioprotective actions of GLP-1 were recently reviewed by Fields *et al.* [67].

Furthermore, GLP-1 has been found to improve endothelial dysfunction in patients with T2DM and coronary heart disease, again a finding with interesting therapeutic perspectives [68]. An effect on endothelial dependent vasodilation was confirmed in healthy subjects [69], and functional receptors for GLP-1 have

been identified on endothelial cells [57]. Chronic administration of GLP-1 agonists for clinical use is generally associated with small but significant decreases in blood pressure [70,71]. This may reflect the vasodilatory actions of GLP-1 as observed in various animal experimental models [57,72].

#### Neurotropic effects

Intracerebroventricular GLP-1 administration was associated with improved learning in rats and also displayed neuroprotective effects [73,74]. GLP-1 has also been proposed as a new therapeutic agent for neurodegenerative diseases, including Alzheimer disease [75], supported by observations that GLP-1 can modify processing of amyloid precursor protein and protect against oxidative injury [76]. Very recently, it was reported that the GLP-1 receptor agonist, exendin 4, promoted adult neurogenesis, normalized dopamine imbalance and increased the number of dopaminergic neurons in the substantia nigra in animal models of Parkinson disease [77].

#### Actions of GLP-1 in T2DM

In agreement with the findings of preserved insulinotropic actions of GLP-1 in T2DM [18], intravenous infusion of GLP-1 at 1.2 pmol/kg/minute was demonstrated to be capable of completely normalizing plasma glucose in patients with long-standing severe disease admitted to hospital for insulin treatment [78]. Subsequent studies in patients with moderate disease showed that plasma glucose concentrations could be near-normalized by an intravenous GLP-1 infusion covering the night-time and the next day, including two meals [79]. Continuous intravenous infusion of GLP-1 is not clinically practical and the effect of subcutaneous injections of GLP-1, given to both patients and healthy subjects [80], on plasma glucose and insulin concentrations turned out to be very short-lasting, because of an extremely rapid and extensive metabolism of GLP-1 in the body [81,82]. The intact peptide has an apparent intravenous half-life of 1–2 minutes and a plasma clearance amounting to 2–3 times the cardiac plasma output [16]. GLP-1 degradation is brought about by the actions of the ubiquitous enzyme, DPP-4, which catalyzes the removal of the two N-terminal amino acids of the molecule, thereby rendering it inactive [81] with respect to insulin secretion (but it may have cardiovascular effects, see above). The metabolic instability of

GLP-1 clearly restricts its clinical usefulness, but Zander *et al.* [83] carried out a clinical study in which GLP-1 or saline was administered as a continuous subcutaneous infusion (using insulin pumps) for 6 weeks to a group of patients with T2DM. The patients were evaluated before, after 1 week and after 6 weeks of treatment. No changes were observed in the saline-treated control group, whereas in the GLP-1 group, fasting and average plasma glucose concentrations were lowered by approximately 4–6 mmol/L, HbA<sub>1c</sub> decreased by 1.2% (13 mmol/mol), free fatty acids were significantly lowered and the patients had a gradual weight loss of approximately 2 kg. In addition, insulin sensitivity, determined by a hyperinsulinemic euglycemic clamp, almost doubled, and insulin secretion capacity (measured using a 30 mmol/L glucose clamp + arginine) greatly improved. There was no significant difference between results obtained after treatment for 1 or 6 weeks, but there was a tendency towards further improvement of plasma glucose as well as insulin secretion. There were very few side effects and no differences between saline and GLP-1 treated patients in this respect. This study therefore provided “proof of concept” for the principle of GLP-based therapy of T2DM, and further attempts to utilize the therapeutic potential of GLP-1 have included, on one hand, the development of stable, DPP-4 resistant analogs [84] and, on the other hand, inhibitors of DPP-4 demonstrated to be capable of protecting the peptide from degradation and thereby augmenting its insulinotropic activity (see Chapter 29) [85].

## GLP-1 receptor agonists

None of the per oral antidiabetics or insulin have been shown to stop the progressive decline of  $\beta$ -cell function, and none address the elevated glucagon secretion [86]. Some oral antidiabetics are associated with weight gain (sulfonylureas, glinides and glitazones), hypoglycemia (sulfonylureas and glinides), lactate acidosis (metformin), intestinal side effects (metformin and  $\alpha$ -glucosidase inhibitors) or peripheral edema and fractures (glitazones) [86].

In contrast, GLP-1 receptor agonists regulate glucose metabolism and promote weight loss with a low risk of hypoglycemia. At present two GLP-1 receptor agonists are approved. Exenatide (Byetta®) was approved by the US Food and Drug Administration (FDA) in April 2005 and released in Europe in 2007 for the treatment of T2DM. Liraglutide (Victoza®), a once-daily human GLP-1 analog, was approved in Europe in May 2009 and by the FDA in January 2010.

### Exenatide (Byetta)

Exendin-4, originally isolated from the saliva of the Gila monster, has 53% sequence homology with human GLP-1 in its first 30 amino acids [87]. Synthetic exendin-4, referred to as exenatide (1-39), is resistant to DPP-4 cleavage, and has a subcutaneous half-life in humans of approximately 2.5 hours after injection and a peak action 2–3 hours after injection [88], as reviewed in [89].

Exenatide is not recommended for patients with severe kidney failure (creatinine clearance <30 mL/minute), because it is predominantly eliminated by glomerular filtration with subsequent proteolytic degradation. Exenatide, administered twice daily within 60 minutes of morning and evening meals, lowers glucose for 5–7 hours and predominately affects post-prandial glycemic excursion, with only modest effects on lunch hyperglycemia and on fasting blood glucose [89–90]. The main side effect, nausea, is dose-dependent after subcutaneous injection, but may show some tachyphylaxis [88]. Therefore, it is recommended to start therapy with 5  $\mu$ g twice daily for 1 month and subsequently to increase to 10  $\mu$ g twice daily.

In clinical studies, exenatide exhibited actions that are similar to those of GLP-1, but the *in vivo* glucoregulatory potency of exenatide is significantly greater than that of native GLP-1 [91]. Increased insulin secretion, inhibition of glucagon secretion and delayed gastric emptying are the main mechanisms by which exenatide improves glucose metabolism (Figure 30.1) [88,89,92].

### Clinical efficacy of exenatide

In the three so-called AMIGO (Diabetes Management for Improving Glucose Outcome) trials, the efficacy of exenatide in combination with metformin, sulfonylurea or a combination of the two was studied for 30 weeks [93–95]. Basal mean HbA<sub>1c</sub> in the three studies was 8.3–8.6% (67–70 mmol/mol). The placebo-corrected reduction in HbA<sub>1c</sub> with 10  $\mu$ g b.i.d. was 0.9–1.0% (10–11 mmol/mol), and the weight loss was 1.6–2.6 kg after 30 weeks [94–95]. Body weight reductions were directly proportional to baseline BMI, with about 80% of subjects losing weight [93–95]. Improvements were observed in some cardiovascular risk factors and hepatic biomarkers [71]. Thus, increases in high density lipoprotein (HDL) cholesterol (+0.12 mmol/L), decreases in triglycerides (–0.43 mmol/L) and diastolic blood pressure (–2.7 mmHg) were achieved [71]. Two weeks’ treatment with exenatide was associated with significantly decreased post-prandial triglycerides excursions [96].

In patients with T2DM treated with a glitazone and metformin, exenatide reduced HbA<sub>1c</sub> (baseline mean HbA<sub>1c</sub> 7.9%, 63 mmol/mol) by 1.0% (11 mmol/mol) and weight by 1.6 kg compared with placebo [97]. No clinically significant episodes of hypoglycemia were reported [97]. As in most of the other studies, the drop-out rate in the exenatide group was twice that in the placebo group (29% vs 14%) [97].

In an open-label trial, insulin glargine once daily or exenatide twice daily were added for patients inadequately controlled by metformin and sulfonylurea [98]. HbA<sub>1c</sub> fell by 1.1% (12 mmol/mol) points in both groups (baseline mean HbA<sub>1c</sub> 8.2%, 66 mmol/mol) [98]. Body weight increased by 1.8 kg with insulin glargine while a 2.3-kg weight loss was obtained with exenatide. Frequencies of hypoglycemia did not differ between treatments, but nocturnal hypoglycemia was less frequent with exenatide. Approximately 19% and 10% of the patients withdrew from the study in the exenatide and glargine groups, respectively [98]. In a 52-week trial, exenatide was compared with twice daily biphasic

insulin aspart (baseline mean HbA<sub>1c</sub> 8.6%, 70 mmol/mol) [99]. A greater proportion of exenatide-treated patients reached HbA<sub>1c</sub> <7.0% (<53 mmol/mol, 32% vs 24%) [99]. Body weight changes (−2.5 kg vs +2.9 kg) also favored exenatide over insulin. Systolic (−5 mmHg) and diastolic (−2 mm Hg) blood pressures were significantly reduced with exenatide, but remained unchanged with insulin. No difference with respect to hypoglycemia was found between the two groups [99].

In obese subjects with T2DM treated with insulin plus oral antidiabetic drugs, addition of exenatide induced a 6.5-kg weight loss and lowered HbA<sub>1c</sub> by 0.6% (7 mmol/mol) points over a 26-week follow-up period [100]. Rapid acting and premix insulin doses were reduced by 28% and 60%, respectively, while the dose of basal insulin was unchanged. In contrast, substitution of exenatide for insulin in insulin-treated patients with T2DM appears to be less successful, because such a switch resulted in a slight increase in HbA<sub>1c</sub> (+0.3%, 3 mmol/mol) [101].

Other studies have shown that exenatide improved first-phase insulin responses to intravenous glucose and decreased the proinsulin:insulin ratio, indicating a beneficial effect of exenatide treatment on  $\beta$ -cell function [94,102]. Nevertheless, no human data indicate that exenatide can protect or restore the  $\beta$ -cell mass. Thus, the  $\beta$ -cell function did not change from before start of treatment when tested after 1 year treatment with exenatide followed by 1 month wash-out of exenatide [103].

#### **Adverse effects with exenatide**

Exenatide has generally been well tolerated and rarely causes treatment discontinuation because of side effects, but in the phase 3 studies drop-out rates in the exenatide groups were twice those in the placebo-treated groups [93–95]. Hypoglycemia is not a problem when exenatide is used in monotherapy or in combination with metformin [94], but mild hypoglycemia was observed in 15–36% of subjects receiving sulfonylurea in combination with exenatide [93,95]. Appropriate glucagon responses have been demonstrated during treatment with GLP-1 or exenatide, which may protect against severe hypoglycemia [104,105]. Mild to moderate nausea has been reported in up to 57% of patients treated with exenatide compared to about 7–23% on placebo in combination with oral antidiabetic drugs [93–95]. Nausea generally occurs during the first days of treatment and, in most patients, decreases with time. Vomiting and headache have also been observed in some patients. Other adverse effects reported include diarrhoea, dizziness and constipation [106]. About 40–50% of treated subjects develop antibodies to exenatide [93–95]; the importance of these is unknown, but they do not seem to influence efficacy on glucose control, except in some subjects with very high titers. Exenatide treatment has been associated with acute pancreatitis, and clinicians should be alert to this potential adverse effect [107]; however, it is not evident that the incidence of acute pancreatitis is higher in those receiving exenatide than in the background diabetic population. It has been recommended that exenatide should not be used in subjects at risk of pancreatitis (e.g. with alcoholism, cholecystolithiasis or hypertriglyceri-

demia), and if pancreatitis is suspected the drug should be discontinued.

#### **Liraglutide**

Liraglutide is a once daily human GLP-1 analog, with a half-life of about 13 hours following subcutaneous injection. Liraglutide is based on the structure of native GLP-1 with an amino acid substitution (lysine with arginine at position 34) and attachment of a C16 acyl chain via a glutamoyl spacer to lysine at position 26 [108]. Liraglutide is relatively stable towards DPP-4 degradation both intrinsically (because it may form heptameric aggregates) and as a consequence of binding to albumin [108]. After initiation of treatment, steady-state concentrations are obtained after 3–4 days [108].

#### **Studies with liraglutide**

In the clinical Liraglutide Effect and Action in Diabetes (LEAD) development program the initial dose of liraglutide was escalated weekly in a stepwise fashion from 0.6 mg/day to 1.2 mg/day, and in some patients to 1.8 mg/day. In monotherapy (basal mean HbA<sub>1c</sub> 8.3%, 67 mmol/mol) liraglutide 1.2 and 1.8 mg reduced HbA<sub>1c</sub> more than glimepiride (LEAD-3) over 52 weeks (0.84%, 1.14% [12 mmol/mol] and 0.5% [5 mmol/mol], respectively) [109]. The decrease in HbA<sub>1c</sub> with 1.8 mg liraglutide was significantly greater than with 1.2 mg liraglutide, and the decrease was most pronounced in the group previously treated with only lifestyle changes (1.2 mg liraglutide, 1.2% [13 mmol/mol]; 1.8 mg liraglutide, 1.6% [17 mmol/mol]; and glimepiride, 0.9% [10 mmol/mol]) [109]. A weight decrease occurred in the liraglutide groups, compared to weight gain in the glimepiride group, resulting in a weight difference of 3.2–3.6 kg [109]. Nausea, mostly transient, occurred in 29% of the participants in the liraglutide groups compared with 9% in the glimepiride group. The rates of minor hypoglycemic episodes were significantly lower for the liraglutide groups versus glimepiride (12, 8 and 24 events/subjects/year) [109]. Two-year data showed that liraglutide had a long-lasting beneficial effect on glycemic control with a reduction in HbA<sub>1c</sub> of −0.9% (10 mmol/mol), −1.1% (12 mmol/mol) and −0.6% (7 mmol/mol) in the 1.2 mg liraglutide, 1.8 mg liraglutide and glimepiride groups, respectively [110]. The weight loss was −2.1 kg, −2.7 kg and +1.1 kg in the three groups [110].

Liraglutide, when added to glimepiride (LEAD-1) reduced HbA<sub>1c</sub> more than rosiglitazone over 26 weeks (1.1% vs 0.4%, 12 vs 4 mmol/mol) [111]. The changes in weight were superior for liraglutide compared with rosiglitazone [111].

Liraglutide was compared with 4 mg glimepiride when added to metformin (baseline mean HbA<sub>1c</sub> 8.4%, 68 mmol/mol) in LEAD-2 [112]. The reduction in HbA<sub>1c</sub> did not differ between glimepiride and liraglutide over 26 weeks (1.0% vs 1.0%, 11 mmol/mol). The reduction in weight in the two groups treated with 1.2 or 1.8 mg/day liraglutide was 2.6 and 2.8 kg, compared with an increase in weight of 1.0 kg in group the treated with glimepiride [112]. Mild hypoglycemic events were reported in up to 2.5% of the patients treated with metformin and liraglutide compared

with 17% in the glimepiride group [112]. In LEAD-4, liraglutide, when added to metformin and rosiglitazone, reduced HbA<sub>1c</sub> (-1.5% vs +0.5%, -16 vs +5 mmol/mol) and weight (-2.0 vs +0.6 kg) more than placebo [113].

In LEAD-5, patients treated with metformin plus a sulfonylurea were randomized to treatment with liraglutide (1.8 mg) or insulin glargine [114]. Mean reduction in HbA<sub>1c</sub> was significantly greater with liraglutide than in insulin glargine treated groups (1.1% vs 0.9%, 12 vs 10 mmol/mol), and more than half of the patients treated with liraglutide reached the American Diabetes Association (ADA) target of HbA<sub>1c</sub> <7.0% (<53 mmol/mol), and 36% reached HbA<sub>1c</sub> <6.5% (<48 mmol/mol) [114]. With respect to body weight, liraglutide resulted in a weight difference of 3.5 kg compared to the insulin glargine treated group [114]. Five patients (2.2%) experienced major hypoglycemic episodes in the liraglutide treated group; there were no major episodes in the insulin glargine treatment group. It is well described that the combination of a sulfonylurea with a GLP-1 receptor agonist increases the risk of hypoglycemia. The mechanism behind this reflects an uncoupling of the glucose-dependent insulin secretion of GLP-1 when combined with a sulfonylurea [29]. Incidence of minor hypoglycemic events did not differ between the groups [114].

In LEAD-6, a head-to-head comparison of 1.8 mg liraglutide once daily with exenatide 10 µg twice daily, the reduction in HbA<sub>1c</sub> was 1.1% (12 mmol/mol), compared to 0.8% (9 mmol/mol), respectively [115]. Both groups lost around 3 kg in weight. The most frequent reported adverse events for both liraglutide and exenatide treated groups were nausea at a level of around 25% when initiating therapy [115]. After week 8–10 the percentage of patients reporting nausea with liraglutide was well below 10%, while in the exenatide group the level remained at about

10%. The rate of minor hypoglycemia was significantly lower in the liraglutide group. After 30 weeks the patients treatment with exenatide were shifted to liraglutide, which resulted in a further 0.3% (3 mmol/mol) reduction in HbA<sub>1c</sub>.

Treatment with liraglutide has been associated with improvement of several cardiovascular risk factors: C-reactive protein (CRP), tumor necrosis factor α (TNF-α) induced plasminogen activator inhibitor 1 (PAI-1), vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule 1 (ICAM-1) and B-type natriuretic peptide (BNP) [116]. The weight reduction in the clinical studies depend on basal BMI, and was in subjects with BMI <25 kg/m<sup>2</sup> from 0–2 kg increasing to 1–4.5 kg in subjects with a BMI >35 kg/m<sup>2</sup> [117]. The greatest weight loss was observed with the combination of liraglutide and metformin, which may reflect that metformin is weight neutral while sulfonylureas such as glimepiride and rosiglitazone are associated with weight gain [117]. The highest dose of liraglutide (1.8 mg/day) reduces systolic blood pressure by 2.7–4.5 mmHg versus comparator treatment, but in patients with a systolic blood pressure greater than 140 mmHg the reduction was about 11 mmHg [118]. Lastly, liraglutide improved β-cell function evaluated by homeostasis model assessment (HOMA) and the proinsulin:insulin ratio [119]. The thyroid C-cell neoplastic changes, which have been observed in rodents and mice, have not been observed in humans [120]. Five cases of pancreatitis were described during the phase 3 program with liraglutide.

**Comparison of GLP-1 receptor agonists with DPP-4 inhibitors**

The GLP-1 receptor agonist and DPP-4 inhibitors differ in route of administration and may have differing side effect and tolerability profiles (Figure 30.3). Two head-to-head studies have

**Figure 30.3** Dose-response relationships for the effects of GLP-1. The figure illustrates the relationship between the plasma concentrations of GLP-1 or GLP-1 mimetics and their clinical effects and side effects as observed during treatment with GLP-1 mimetics or incretin enhancers (DPP-4 inhibitors, see Chapter 29). With modestly elevated GLP-1 levels, as obtained with both mimetics and enhancers, there are significant effects on the pancreatic islets. Higher concentrations (which may not be reached during therapy with enhancers) are needed to slow down gastric emptying and to reduce appetite and food intake. At even higher concentrations, which may be reached with GLP-1 mimetics, side effects such as nausea, diarrhea and vomiting might result. Adapted from Holst JJ, Deacon CF, Vilsbøll T, Krarup T, Madsbad S: Glucagon-like peptide-1, glucose homeostasis and diabetes. *Trends Mol Med* 2008; 14: 161–168.

compared the efficacy of a GLP-1 receptor agonist and the DPP-4 inhibitor sitagliptin. Liraglutide reduced HbA<sub>1c</sub> by 1.4% vs 0.9% (14 vs 10 mmol/mol) and weight by -3.5 vs -0.9 kg compared with sitagliptin. In another study, exenatide once weekly reduced HbA<sub>1c</sub> by 1.7% vs 1.0% (19 vs 11 mmol/mol), and the weight by 2.8 vs 0.9 kg compared with sitagliptin [121].

### Future GLP-1 receptor agonists

#### Exenatide once weekly

Exenatide once weekly, a preparation containing a polylactide-glycolide microsphere suspension, leads to a sustained release for up to 28 days after single subcutaneous injection and is currently in phase 3 clinical development [122]. Exenatide 10 µg twice daily and 2 mg once weekly reduced HbA<sub>1c</sub> after 30 weeks' treatment by 1.9% vs 1.5% (21 vs 16 mmol/mol) from a baseline of 8.3% (67 mmol/mol) 77% vs 61% of patients reached an HbA<sub>1c</sub> of 7.0% or less (<53 mmol/mol) without any reports of severe hypoglycemia [122]. Notably, 29% of once weekly treated patients taking exenatide with a baseline HbA<sub>1c</sub> >9.0% (>75 mmol/mol) achieved levels <6.5% (<48 mmol/mol). About 26% vs 35% of the patients reported nausea with once weekly exenatide. Both groups lost about 4 kg in weight [123]. After 30 weeks the patients treated with exenatide twice daily were changed to treatment with exenatide once weekly [122]. After 1 year, the reduction in HbA<sub>1c</sub> was about 2% (22 mmol/mol) in both groups and the mean HbA<sub>1c</sub> was 6.6% (49 mmol/mol). Of the participants, 77% obtained a HbA<sub>1c</sub> <7.0% (<53 mmol/mol). Weight loss was 4.5 kg, and one-third of the patients lost more than 5% in weight. In a group of participants with a HbA<sub>1c</sub> >9.0% (>75 mmol/mol), the reduction in HbA<sub>1c</sub> was 2.8% (31 mmol/mol). Systolic blood pressure was reduced by 6 mmHg in the whole group, and 11 mmHg in subjects with hypertension at baseline. About 74% developed antibodies to exenatide, and a small group of participants with high-titer antibodies showed attenuated glycemic response [122].

#### Albiglutide

Albiglutide is a long-acting GLP-1 receptor agonist, developed by fusion of two recombinant human GLP-1 molecules (with an ALA8→GLY amino acid substitution) to recombinant human albumin [124]. Despite the large size of the molecule, albiglutide inhibits gastric emptying and appetite, although it is unclear whether the anorectic effect is weaker than that of native GLP-1 because of an impaired blood-brain barrier permeability [125]. The circulating half-life is 6–7 days, and in phase 2 studies it has been administered weekly, biweekly or monthly [126]. The optimal dose seems to be 30 mg weekly in relation to reduction in HbA<sub>1c</sub> and side effects, and this dose has been shown to be more potent than exenatide twice daily in reducing HbA<sub>1c</sub> with less nausea [126]. Albiglutide is currently in phase 3 clinical development.

#### Taspoglutide

This a modified human GLP-1 receptor agonist resistant to DPP-4 degradation with a release profile extending up to 26 days,

which make it suitable for once weekly administration [127]. The reduction in HbA<sub>1c</sub> was 1.4–1.5% (15–16 mmol/mol) after 8 weeks' treatment with 10 and 20 mg once weekly. About 80% reached the goal of 7.0% (53 mmol/mol) from mean baseline of 7.9% (63 mmol/mol) [127]. The reduction in body weight after 8 weeks was about 2.1–2.8 kg. Taspoglutide is in phase 3 clinical development.

#### Other GLP-1 receptor agonists

Lixisenatide is a modified exendin 4 molecule which in phase 2 studies has been administered once or twice daily, and now is in phase 3 clinical development [128].

Other GLP-1 receptor agonists in development are CJC1134, which is a exendin 4 molecule linked covalently to serum albumin. Its half-life is similar to circulating albumin, approximately 10–15 days [129]. NN9535 from Novo Nordisk Pharmaceutical is a once weekly GLP-1 receptor agonist. Orally administered GLP-1 receptor agonists are in development, and also intranasal and pulmonary administration of GLP-1 is under investigation.

#### Comments on GLP-1 receptor agonists

The GLP-1 analog are attractive for treatment of people with T2DM because their effects on both insulin and glucagon secretion are glucose dependent, which reduces the risk of hypoglycemia. When GLP-1 analogs are combined with metformin or a glitazone the risk of hypoglycemia is minimal. GLP-1 receptor agonists induce weight loss, which is important because many people with T2DM are obese. The need for self-monitoring of blood glucose is minimal, especially when compared with insulin treatment. Whether the GLP-1 analogs can prevent the progression of the disease by preventing β-cell failure is yet unknown. The durability and magnitude of the weight loss induced by the GLP-1 analogs need to be established.

The observation that GLP-1 improves myocardial function in human patients after myocardial infarction, improves endothelial function and reduces blood pressure highlights the need for studies with cardiovascular endpoints [130]. GLP-1 analogs may be attractive to use in subjects with T2DM and heart failure because GLP-1 promotes renal sodium and water excretion and lowers blood pressure [70,131,132]. Long-term studies are also needed to obtain more data on the safety of the GLP-1 analogs. Lastly, studies in patients with newly diagnosed type 1 diabetes mellitus (T1DM) and in patients with T1DM of long duration and no residual β-cell function are needed to evaluate the ability of GLP-1 to prolong the remission, to reduce the insulin requirements and possibly the risk of hypoglycemia.

---

#### Amylin and amylin analogs

Amylin is a 37 amino acid peptide co-secreted with insulin. It delays gastric emptying, suppresses post-prandial glucagon secretion and increases satiety. Human amylin has an inherent

**Figure 30.4** Human amylin, naturally occurring in  $\beta$ -cells. On the right-hand side is depicted the structure of the pramlintide molecule specifically engineered by three proline substitutions at amino acids 25, 28 and 29.

tendency to self-aggregate, forming fibrils and adhering to surfaces. Amylin Pharmaceuticals Inc. has developed an analog named pramlintide where the amino acid residues at positions 25, 28 and 29 are replaced with proline (Figure 30.4). Pramlintide was approved by the FDA in 2005 for use in insulin-treated subjects with either T1DM or T2DM. The results have been quite promising in that, when measured over a period of 6–12 months, treatment resulted in a decrease in HbA<sub>1c</sub> of 0.4–0.6% (4–7 mmol/mol) compared with placebo. A small, but clinically significant, weight loss was observed (0.8–1.4 kg compared with placebo). Main side effects are nausea (often transient) and hypoglycemia but, when titrated, especially with a reduction in insulin dose, both have been reduced significantly.

Although amyloid deposits in the pancreas were first described more than a century ago as a major constituent in the islet of Langerhans of patients with T2DM, the primary component of these deposits was not identified until two decades ago by Cooper *et al.* [133] and Westermark *et al.* [134]. It is a 37 amino acid peptide, denoted islet amyloid polypeptide (IAPP) or amylin. Amylin has approximately 50% sequence identity to calcitonin gene-related peptide (CGRP) and is also structurally related to calcitonin, and belongs to the family of peptides, which also includes adrenomedullin. The amylin precursor, proamylin, is primarily co-localized in the secretory granules together with insulin and is processed by the same processing enzyme before being released from the pancreatic  $\beta$ -cells, co-secreted with insulin (Figure 30.5). Interestingly, similar to insulin and many other hormones, amylin is released in a high frequency pulsatile manner [135]. The peptide circulates in both a non-glycosylated form (approximately 50%) and a glycosylated form [136]. In contrast to insulin, amylin is mainly eliminated through renal metabolism. In healthy people its plasma concentrations are within the range of 4–25 pmol/L, and amylin is distributed, like insulin, in plasma and interstitial fluids. Smaller amounts of amylin are also present in the central nervous system, especially the caudal trigeminal nucleus and the amygdala area, and also in the gastric antrum and fundus, as well as being expressed in the entire gastrointestinal tract. The gene encoding the 89 amino acid prepolamylin precursor protein is located to chromosome 12 and consists of three exons and two introns. Functional amylin receptors can be generated by co-expression of the G-protein coupled calcitonin receptor gene and receptor activity modifying proteins.

## Amylin effects

### *In vitro* and animal studies

Most studies have been performed in rodents, and have demonstrated effects of amylin on glucose metabolism. In the rat skeletal muscle, amylin leads to insulin resistance in pharmacologic doses by inhibiting glycogen synthase activity and enhancing glycogen breakdown and subsequently lactate release. The influence of amylin *per se* on insulin secretion is controversial.

Amylin inhibits glucagon secretion in rats following an arginine infusion in a dose-dependent manner [137], but it does not suppress glucagon release in the isolated perfused pancreas, implying that its ability to inhibit glucagon secretion depends on extrapancreatic pathways. Amylin also delays gastric emptying. Dose-response studies have demonstrated that amylin is more potent in this respect than other gastrointestinal hormones. The ability of amylin to slowing down the gastric emptying process has, however, been shown to be overridden by hypoglycemia [138]. Finally, amylin reduces food intake and body weight in rodents. The inhibitory effect on food intake is present after both intracerebral and peripheral administration of amylin. These effects appear to be mediated mainly via central pathways that include high affinity binding sites in the area postrema in the hindbrain.

### Amylin in human studies

Two studies, both from Bloom's group [139,140], have examined the possible impact of acute administration of native amylin on *in vivo* glucose metabolism in healthy humans. Despite using high pharmacologic doses of the hormone, resulting in circulating amylin levels 50–100 times above normal post-prandial concentrations, no effect of native amylin could be demonstrated on glucose uptake, neither as assessed by a hyperinsulinemic euglycemic clamp nor during an intravenous glucose tolerance test.

## Effects of the amylin analog pramlintide in human studies

### Acute and short-term studies

Human amylin has inappropriate physicochemical properties. It has an inherent tendency to self-aggregate, to form fibrils and to adhere to surfaces. Particularly, the amino residues in positions 20–29 are responsible for self-aggregation. Amylin Pharmaceuticals Inc. tested a number of different analogs of the human amylin

**Figure 30.5** Plasma amylin concentrations in healthy subjects and patients with diabetes. (a) Mean 24-hour plasma profiles of insulin and amylin in six healthy males without diabetes. (b) Mean ( $\pm$ SE) amylin plasma concentrations following ingestion of a liquid Sustacal® meal. Similar to insulin secretion, amylin secretion is impaired in patients with type 2 diabetes ( $n = 12$ ) and absent in patients with type 1 diabetes ( $n = 190$ ) compared with healthy subjects ( $n = 27$ ).

molecule including the originally designated peptide AC137 (pramlintide) in which the amino acid residues at positions 25, 28 and 29 were replaced with proline (Figure 30.2). Pramlintide was approved by the FDA in March 2005 for use in insulin-treated patients with T1DM and T2DM. At the time of writing, pramlintide has only been approved in the USA, where it has the tradename Symlin®. The plasma half-life of pramlintide is approximately 48 minutes [141] when given subcutaneously into the abdominal area or the thigh. The peptide is primarily eliminated by the kidneys. Normal dosing in patients with T1DM during gradual titration is often 60–90  $\mu$ g three to four times per day prior to meals. In those with T2DM, doses may be somewhat higher and often administered subcutaneously twice per day. In order to optimize efficacy and also to minimize the often transient nausea, it is also important to titrate pramlintide dosing.

In the mid 1990s, Kolterman [142] performed a series of acute and short time studies with pramlintide given prior to a Sustacal meal (350 kcal, 24% protein, 21% fat and 55% carbohydrate). A considerable reduction in the glycemic levels after oral intake before the meal was observed in both patients with T1DM and T2DM in the acute studies as well as during the studies lasting 14–28 days. The efficacy of the acute and short-term pramlintide

administration is probably because of the decreased gastric emptying and reduced glucagon response. The effect on gastric emptying in diabetes is well-documented [143]. The suppression of glucagon in subjects with diabetes and the ensuing decrease in endogenous glucose production as reported by Shah *et al.* [144] is considered important in view of the post-prandial glucagon excess characterizing T2DM. Fineman *et al.* [141] have convincingly described a significant, and probably clinically relevant, reduction in post-prandial circulation glucagon in patients with either T1DM or T2DM after pramlintide exposure together with a liquid Sustacal meal (Figure 30.4). It has been estimated that the influence of pramlintide on post-prandial glucagon is responsible for an approximately 25% reduction in plasma glucose which has also been confirmed by others. In a cross-over study during a stepwise hypoglycemic clamp in subjects with T1DM it was demonstrated that insulin sensitivity during euglycemia was normal (as shown in many other studies). During the hypoglycemic clamp with nadir of plasma glucose at 2.8 mmol, plasma adrenalin and noradrenalin did not differ between pramlintide and placebo. Plasma glucagon tended to be higher during pramlintide administration ( $P = 0.10$ ) as did cortisol. Growth hormone was significantly increased during hypoglycemia after

pramlintide exposure. Recovery time after hypoglycemia did not differ [145].

### Long-term studies

Several studies in the phase 3 program and many other interesting studies have subsequently been performed. The conclusion is that pramlintide, in double-blinded studies in insulin-treated patients with T1DM or T2DM, after 6–12 months leads to a decrease in HbA<sub>1c</sub> of 0.4–0.6% (4–7 mmol/mol) compared with placebo. In patients with T2DM, a small but clinically significant weight loss was observed (0.8–1.4 kg compared to controls).

Other interesting findings have been made regarding lipid profile, combination of pramlintide with thiazolidinediones regarding weight, and the lowering of post-prandial glycemia during pramlintide administration. Previous exposure to pramlintide in humans significantly reduces the enthusiasm to eat a second meal [146]. In a recent study in very obese subjects without diabetes treated over a 12-month period with a high pramlintide dose as an adjunct to lifestyle intervention, a weight loss of approximately 8 kg was observed compared with the placebo group [147]. Recently, Roth *et al.* [148] demonstrated, in a proof of concept study, that pramlintide in humans acts synergistically with recombinant human leptin to reduce body weight in non-leptin deficient subjects and suggested that amylin agonism may restore leptin responsiveness in diet-induced obesity.

### Side effects and drawbacks of pramlintide treatment

The most common side effects are gastrointestinal, but these are generally transient and can be minimized by starting with a low dose of the compound. Another side effect is hypoglycemia, which is rare in T2DM. It should be noted that in the primary studies pramlintide and insulin doses were fixed, increasing the risk of hypoglycemia. Current recommendations suggest that titration is performed both with respect to both pramlintide dosing and reduction of insulin dose.

In spite of the availability of advanced injection devices, some patients feel it a burden to take these additional injections 2–4 times a day. For reasons of biochemical compatibility, it is unfortunately not possible to mix insulin and pramlintide in the same pen. It was demonstrated recently, however, that adjunctive pramlintide administration to individuals with T1DM, intensively treated with either multiple daily injection or pump therapy, in a double-blind non-inferiority trial, resulted in greater treatment satisfaction compared with placebo treatment, despite similar reductions in HbA<sub>1c</sub> [149].

### Conclusions and perspectives

Overall, pramlintide has proven effective in terms of reducing glycemia and weight, but must now prove efficacy against new drugs such as incretin mimetics. Conversely, pramlintide appears to be a safe antidiabetic drug, which can be used in combination with classic antidiabetic agents.

## How to Use Type 2 Diabetes Treatments in Clinical Practice: Combination Therapies

**Joseph A. Aloï & Anthony L. McCall**

Division of Endocrinology, University of Virginia Health System, Charlottesville, VA, USA

### Keypoints

- Managing type 2 diabetes has become more complex as pharmacotherapy has expanded. Clinicians have more pharmaceutical agents targeted to hyperglycemia and obesity than before, but a relentlessly progressive disorder to overcome.
- Clinical trials continue to show that glycemic control is critical to reduce microvascular complications and in the long-term also cardiovascular events. Nonetheless, poor glycemic control, hypoglycemia and obesity remain stubborn barriers for clinicians.
- Few comparative data direct us in the best use of multiple drug therapies for the management of type 2 diabetes and its co-morbidities. One is guided by good clinical studies, the potential of therapeutic agents to reverse pathophysiology and ultimately the proper use of insulin which is eventually needed in most patients to replace the loss of  $\beta$ -cell function.

### Introduction

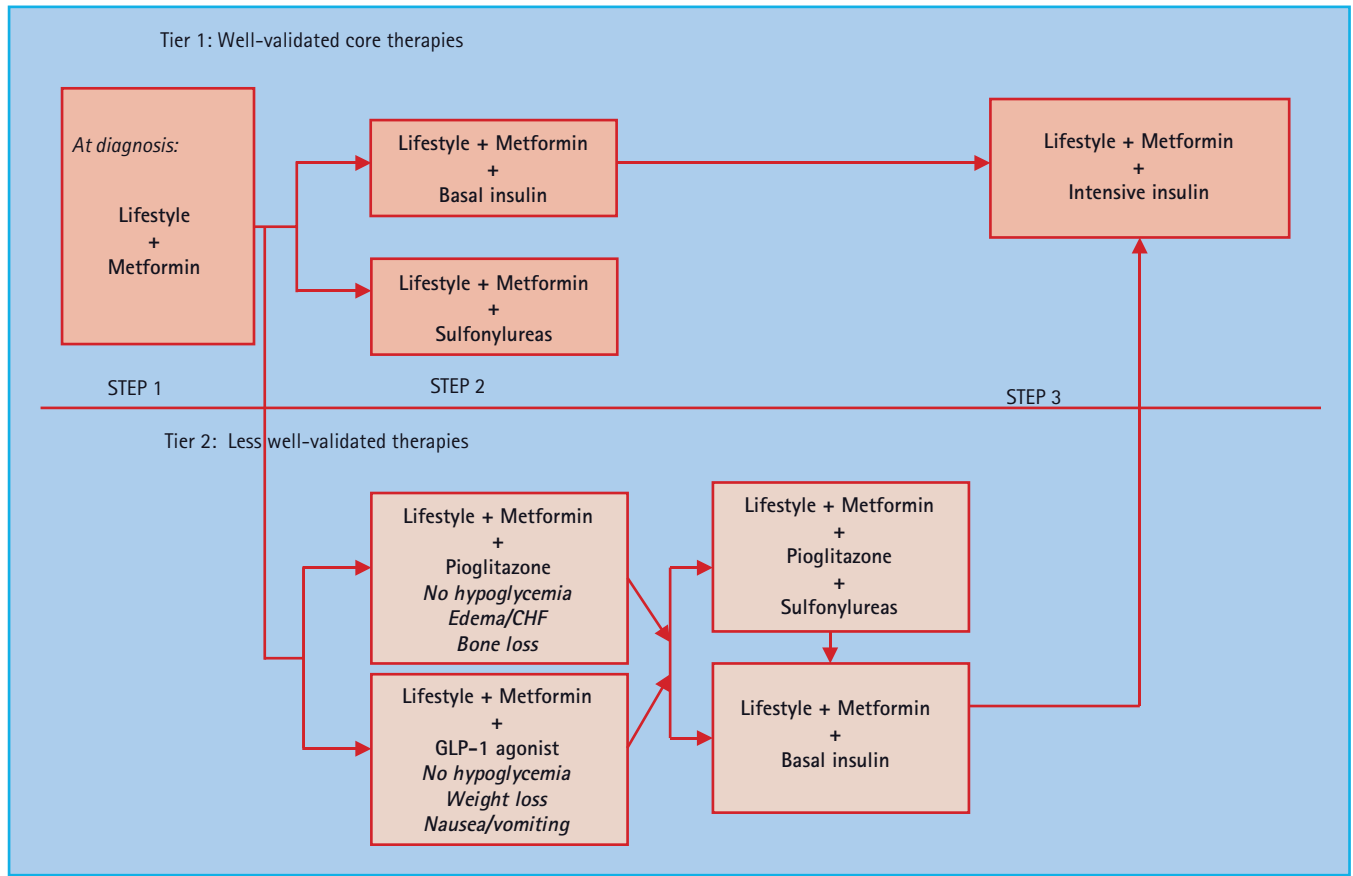

The epidemic of type 2 diabetes mellitus (T2DM) presents the clinician as well as society with complex challenges in designing both prevention and treatment strategies for T2DM. T2DM is a worldwide epidemic with a global prevalence in 2009 of 285 million people, expected to increase to 435 million by 2030 [1]. The Centers for Disease Control and Prevention (CDC) estimates that in 2007 nearly 24 million people in the USA have diabetes [2], mostly T2DM. At least 57 million people have pre-diabetes (impaired fasting glucose or impaired glucose tolerance), providing an expanding pool of new patients with T2DM. Current prevalence represents a 90% increase in the new diagnosis of diabetes over the last decade [3] and more rapid increases in many parts of the world. This increasing prevalence of diabetes relates both to environmental and genetic factors, each of which may influence insulin sensitivity (e.g. insulin resistance) and insulin secretion capacity. Insulin resistance begins in early life and is fueled by obesity and a sedentary lifestyle which contribute to alterations in glucose homeostasis and to abnormal lipid and protein metabolism.

Relative insulin deficiency is the defining metabolic difference between obesity and the development of hyperglycemia with pro-

gression to T2DM. An inexorable progression of diabetes appears related to worsening insulin deficiency [4,5]. Most people therefore have gradually increasing needs for additional therapy. Combinations of therapy such as adopting a therapeutic lifestyle change, as well as oral and injectable medicines, are required to keep the glycemia under control. The failure to advance therapy at an early sign of therapeutic failure and, in particular, a reluctance to advance to insulin underlies the less than optimum control for many patients with diabetes.

### Algorithms for management

Several approaches to the best management of T2DM have been proposed. All algorithms begin with therapeutic lifestyle change and are generally focused primarily upon controlling hyperglycemia. Consensus statements from the American Diabetes Association (ADA) have been recently revised in conjunction with the European Association for the Study of Diabetes (EASD) [6]. The most recent algorithm (Figure 31.1) moves away from the focus on glucose as the sole goal of therapy and tries to develop evidence-directed therapy to treating diabetes by normalizing hyperglycemia and minimizing cardiometabolic risk. The US Food and Drug Administration (FDA) has recently advised that new medicines for glycemic control in diabetes be routinely evaluated early for their effects upon cardiovascular disease. By doing so, they recognize atherosclerosis as the primary cause of cost and mortality in diabetes.

**Figure 31.1** The ADA/EASD consensus statement on the recommended strategy to advance therapies to control hyperglycemia in diabetes. The top portion focuses on traditional well-validated therapies buttressed by large studies and long experience (metformin, sulfonylureas, insulin). The lower portion focuses on more recent emerging therapies that have less follow-up and validation in clinical trials (thiazolidinediones or glitazones as they are often called; e.g. pioglitazone, GLP-1 agonists such as exenatide). According to the authors, the amylin agonists,  $\alpha$ -glucosidase inhibitors, glinides and DPP-4 inhibitors were not included in the two

The current consensus algorithm (Figure 31.1) moves quickly from metformin treatment failure to the addition of sulfonylurea or insulin. Newer classes of drugs (e.g. incretin mimetics, pioglitazone) are recommended later or as a secondary consideration because of the lack of compelling data to suggest their superiority compared to existing treatments and associated concerns for unintentional ill effects such as long bone fractures or increase in congestive heart failure (glitazones) or pancreatitis (exenatide). Ultimately, the treatment pathway must incorporate patient individualization, clinical acumen, and the broad experience gained from clinical trials.

## Goals of treatment

Treatment goals for patients with diabetes have changed considerably over the past two decades. The Diabetes Control and Complications Trial (DCCT) [7] confirmed the concept of the

tiers of preferred agents in this algorithm, owing to their lower or equivalent overall glucose-lowering effectiveness compared with the first- and second-tier agents and/or to their limited clinical data or relative expense. However, they may be appropriate choices in selected patients. Similarly, colesevelam is not mentioned in this algorithm but may be appropriate for selected patients. Rosiglitazone is omitted from the algorithm because of unsettled concerns raised about cardiovascular side effects. Reproduced from the updated American Diabetes Association/European Association for the Study of Diabetes consensus statement [6].

relationship of glyemic control to microvascular complications in type 1 diabetes. Similar results were found for T2DM in the landmark UK Prospective Diabetes Study (UKPDS) [8,9]. Long-term analysis of subjects participating in these trials at 10 years following a period of improved glyemic control found cardiovascular risk reduction with insulin, metformin and sulfonylureas [10,11] and for T2DM also a mortality advantage.

In assigning patients to a treatment plan, consideration must be given to treatment goals. The ADA continues to recommend HbA<sub>1c</sub> of <7% (<53 mmol/mol) as a general glyemic goal and individualization is recommended. For properly selected patients, either less tight control or alternatively more rigorous normalization of glycemia down to 6% (42 mmol/mol) HbA<sub>1c</sub> can be recommended, if the latter can be achieved without hypoglycemia problems. Using similar data sources, the International Diabetes Federation (IDF) and American Association of Clinical Endocrinologists (AACE) suggest  $\leq 6.5\%$  (48 mmol/mol) as a general goal. All authorities recommend the need for individuali-

zation of goals based on co-morbidities and vulnerability to hypoglycemia among other criteria. The ACCORD trial hypothesized that close to normal glucose control (HbA<sub>1c</sub> 6% or less [ $<42$  mmol/mol]) would improve cardiovascular endpoints. Recent analysis of the ACCORD trial [12] cautions the provider against attempting to normalize glycemia in those with characteristics similar to this patient cohort (e.g. older and those with existing cardiovascular disease), as the intensively treated group had a 22% increase in mortality primarily from fatal cardiovascular events; very possibly, although unproven, this may have been as a result of hypoglycemia. This poses a dilemma to the practitioner: how best to normalize glycemia but avoid hypoglycemia. This practical consideration suggests newer therapies with a relatively low hypoglycemia risk should be considered for certain patient groups. Additionally, strategies to recognize and prevent hypoglycemia risk in patients at high risk should be adopted routinely. These include the need for self-monitored blood glucose (SMBG) tests, good communication and education about how to treat and adjust therapy should hypoglycemia become frequent or severe, especially if hypoglycemia unawareness occurs.

Ultimately, patients with T2DM require progression of therapy from combination oral therapy to combination injectable therapy (basal bolus insulin regimens, incretin insulin combinations). Initiating combination therapy early minimizes side effects while maximizing clinical effectiveness, decreasing pill counts and cost while facilitating compliance. New ACCE guidelines use all drugs and tailor their number and starting insulin to the baseline HbA<sub>1c</sub> [13].

---

## Lifestyle advice for diabetes and pre-diabetes

Lifestyle management is one of the most challenging barriers to successful diabetes control. Deriving recommendations for eating, physical activity and minimizing psychologic stressors is frequently frustrating for both the provider and patient [14]. The assumption that complex patterns of lifestyle behavior can be altered by dispensing general advice in the course of a busy medical visit is flawed, but unfortunately a reality for many providers. It should be replaced by an agreement that the patient is responsible for assisting in their disease management and is the only source of key information needed to manage their illness [15]. One strategy is to make patients more aware of their own lifestyle patterns. Developing a baseline for eating and exercise (type, frequency, duration, barriers) is as integral as obtaining initial laboratory testing in patients with T2DM to compile a treatment plan based on physiology as well as the psychology of the patient. Obtaining a narrow focus on a few behavioral objectives can increase success. Approaches we often use for patients are:

- Keep an eating behavior diary over the next week; and
- Wear a pedometer and keep track of your baseline steps for the next week.

The information almost always contains some surprises for patients but it helps them to identify personal behaviors and to

focus and motivate them to take the lead in setting meaningful objectives.

The role of the physician is critical in emphasizing the importance of lifestyle change to the patient, initiating a process of working on lifestyle change, and reinforcing, and refining the education to achieve incremental obtainable objectives. Use of motivational interviewing and assessment of readiness to change are important aspects of evaluation of the patient by both the medical provider and diabetes educator. It is our practice to recommend strongly diabetes education for every patient who is willing to do so and to reinforce the recommendation for lifestyle change at any point when additional therapy needs occur. A useful acronym that we have used to help trainees remember how to assist patients in making lifestyle change is FIRM [15]. This stands for negotiating Few changes, typically 1–3 at any clinical visit; those changes should be Individualized by the patient's selection of what aspects of behavior change to embark on; the changes should be Realistic and therefore likely to succeed by setting moderate, achievable goals within a specific timeframe; and be Measureable and monitored through patient record-keeping to be shared with the provider or diabetes educator at the next visit.

---

## Therapy for obesity as a treatment for T2DM

Because the vast majority of people with T2DM are overweight or obese, a serious consideration is the use of weight loss and increasing physical activity strategies as a useful treatment to gain control of glycemia and favorably influence multiple cardiovascular risk factors as well [16,17]. Prevention and/or treatment plans for T2DM could also legitimately consider use of pharmacotherapy for obesity. Successful weight loss of 10% or less has repeatedly been shown to improve glycemic control (HbA<sub>1c</sub> reductions 0.3–0.5% [3–6 mmol/mol] and sometimes much more) as well as favorable improvements in lipids, hypertension as well as other cardiac risk factors. Currently, three drugs (phentermine, orlistat and sibutramine) are approved for management of obesity in the USA. Rimonabant was approved for use in several countries outside the USA, but recent withdrawal of support by the European Medicines Agency has ended its possibility of wider use. Other drugs of the endocannabinoid receptor blocker class have also been discontinued from clinical development. Phentermine is only approved for short-term use and is the least well-studied and is less commonly used and not generally recommended.

Orlistat is currently approved for use in the management of obesity. Orlistat functions as a gastric and pancreatic lipase inhibitor. When given at a dosage of 120 mg three times daily with meals, approximately 20–30% of ingested fat is passed into the feces. Large amounts of fat in the gastrointestinal tract result in the most difficult side effect to manage, namely anal leakage of oil to post-prandial diarrhea which may be abrupt. Attention to this expected effect as well as dietary counseling or use of daily or twice daily dosing can minimize patient's gastrointestinal accidents and may enhance patient adherence to low fat dietary regimens. No long-term malabsorption of fat-soluble vitamins

has been seen but replacement with a multivitamin including vitamin D is recommended during therapy. A lower dosage (60 mg) over-the-counter form is now available.

Orlistat has been critically studied both in the prevention [18] and in the treatment of T2DM in patients receiving metformin or insulin [19,20]. In the XENDOS trial, 3305 obese subjects at risk for T2DM were randomized to therapeutic lifestyle change or therapeutic lifestyle change plus orlistat 120 mg three times daily over a study period of 4 years. The subset of subjects with impaired glucose tolerance at entry receiving orlistat enjoyed a 37% relative risk reduction in development of T2DM at study end. Favorable lipid effects were also seen.

In obese subjects with T2DM failing metformin monotherapy [19], the addition of orlistat to the treatment plan lowered HbA<sub>1c</sub> by 0.35% (4 mmol/mol) and improved lipid as well as blood pressure control. Similarly, benefits were also seen in insulin-treated patients given orlistat for 1 year [20] with improved glycemia (HbA<sub>1c</sub>  $-0.62 \pm 0.08$  for orlistat-treated vs  $-0.27 \pm 0.08\%$  given placebo;  $P < 0.002$ , 7 vs 3 mmol/mol) and improved lipids despite lowered diabetes medicine doses.

Sibutramine enhances satiety and diminishes appetite primarily through central pathways, involving the inhibition of synaptic reuptake of norepinephrine, serotonin and to a lesser extent dopamine.\* Doses approved for use in the management of obesity range 5–15 mg, with greatest efficacy at the cost of highest frequency of side effects seen at the 15 mg dosage. Doses up to 20 mg have been used in the clinical trial setting with a similar observation. A recent meta-analysis studied eight of 30 available clinical trials using sibutramine in the management of diabetes [21]. The authors included studies using sibutramine in combinations with sulfonylureas, metformin or a hypo-caloric diet. In general, treatment effects were associated with a 5.5-kg loss in body weight versus an approximate 1-kg weight gain in comparator groups. On average, HbA<sub>1c</sub> improved 0.28% (3 mmol/mol) with variability among the different studies included. Additional positive effects were noted in reducing triglycerides and raising high density lipoprotein (HDL) without any adverse effects on blood pressure. Small increases in heart rate were noted. The presence of hypertension, especially if not ideally controlled, should be considered a contraindication to use of sibutramine, especially given how sensitive patients with diabetes are to the adverse impact of modest blood pressure changes and the effects of blood pressure upon diabetes complications.

Rimonabant, an endocannabinoid CB1 receptor blocker, has recently been removed from the European market because of concerns over exacerbating mood disorders (depression). Ongoing clinical trials using rimonabant have also been halted,

\*The marketing authorization for sibutramine has recently been withdrawn in Europe following the publication of the SCOUT trial. In this trial which included 9,800 overweight or obese individuals at high risk of CVD events, treatment with sibutramine was associated with a 16% increased risk of non-fatal MI, non-fatal stroke, resuscitated cardiac arrest or CVD death. This result was driven by an increased incidence of non-fatal MI and stroke.

raising questions over both the utility and availability of drugs acting on the endocannabinoid system. Despite its removal from studies and failure to stay widely marketed, there are studies finding a substantial antihyperglycemia effect similar to that of some approved diabetes pills. Such work validates the notion that treatment directed toward obesity have glycemic effects that are similar to some of the already approved pharmacotherapy choices for diabetes. Safety concerns regarding depression appear unlikely to allow this type of medication to be marketed in the future.

Bariatric surgery for appropriate patients (typically BMI  $>40 \text{ kg/m}^2$  or  $>35 \text{ kg/m}^2$  with co-morbidities) who have failed successful lifestyle interventions and/or pharmacotherapy for obesity is an increasingly utilized option. Improved safety and standardization combined with expanding data for the surgical management of obesity with favorable effects including long-standing remissions of T2DM in most patients make this an increasingly employed procedure [22,23]. The physiology behind such benefits remains poorly understood. Paradigms for identifying patients best suited for surgical treatment of cardiometabolic risk are evolving. Typically, many patients who are candidates for bariatric surgery are already on a combination of therapies. Following surgery, most patients who have been on insulin will be able to stop unless there is a very long history of diabetes. During the hypocaloric diet employed in preparation for such surgery, significant decreases in the need for insulin and sometimes other diabetes medications occur. For those who undergo Roux-en-Y procedures it is common to have a rapid reduction of insulin requirements within days to weeks. Decreasing insulin dosage by half or more is frequently necessary to avoid hypoglycemia.

---

## Combination pharmacotherapy for T2DM

Therapies for T2DM can be divided into drugs facilitating supply of endogenous insulin (secretagogues, incretins) or those enhancing insulin actions (biguanides, thiazolidinediones, incretins,  $\alpha$ -glucosidase inhibitors, amylin analogs, colesevelam). Successful treatment of T2DM combines approaches to lifestyle modification frequently in conjunction with use of pharmacologic therapy.

We conclude from data found in the UKPDS that insulin secretory loss starts on average 10 years before the formal diagnosis of T2DM, followed by insulin deficiency on average 10–12 years after diagnosis [8]. The dual aspects of T2DM, insulin resistance and insulin deficiency, are important factors in therapy selection and the subsequent response to therapy. This chapter provides an update on combinations of therapies for T2DM, presents evidence and opinions on sequences of medications, reviews new insights into diabetes and obesity treatments, and briefly describes some new medications emerging for the treatment of T2DM.

---

## Need for combination therapy

The management of T2DM, as with any chronic illness, requires individual assessment and involvement of patient with their care

**Figure 31.2** This figure, which is adapted from the UK Prospective Diabetes Study comparing conventional policy to intensive policy with sulfonylureas or insulin, shows the progressive rise of median HbA<sub>1c</sub> that presumably is related to the progressive insulin secretory defect present in type 2 diabetes mellitus. A noteworthy aspect of this figure is the decline in HbA<sub>1c</sub> from nearly 9% (75 mmol/mol) to around 7% (53 mmol/mol) in the first 3 months after initial evaluation. During this period, subjects in this study had visits with educators and dietitians helping them to improve lifestyle.

plans. Perhaps the original “combination therapy” for T2DM remains advice on flexible approaches to healthy eating styles coupled with encouragement and support to improve physical activity with consideration of the use of early pharmacologic treatment interventions in most patients. Most patients with T2DM eventually require combination pharmacologic therapy; some at the time of initial diagnosis, especially if they have a markedly elevated HbA<sub>1c</sub>. Data from the UKPDS [5] showed that about 50% of patients required combination therapy within 3 years of diagnosis, and approximately 75% at 9 years after diagnosis (Figure 31.2).

**Choice of initial therapy**

No therapy has rigorously been proven to alter the natural history of progressive β-cell decline and the ultimate need for combination treatment. Nonetheless, randomization to rosiglitazone in the ADOPT trial [24] was associated with longer monotherapy success for a new diagnosis of T2DM (60 months) versus metformin (45 months) or glyburide (glibenclamide) (33 months). The data from this study (Figure 31.3) found that at the 4-year evaluation, 40% of the 1456 patients in the rosiglitazone group had a glycated hemoglobin level of less than 7% (<53 mmol/mol), compared with 36% of the 1454 patients in the metformin group (*P* = 0.03) and 26% of the 1441 patients in the glyburide group (*P* < 0.001). Thus, even with some superior durability of treatment-related glycemic response, it is clear that most patients with T2DM will require combination therapy within the first 3–6 years after medication is begun.

**Rationale for combination therapy**

In the context of at least two major physiologic defects in T2DM, insulin resistance and progressive insulin secretory failure, com-

**Figure 31.3** The ADOPT study examined the duration of maintenance of fasting glycemia in patients with diabetes on three monotherapies: glyburide (glibenclamide), metformin and rosiglitazone. As shown in this figure, rosiglitazone was superior to metformin which was in turn superior to glyburide in efficacy of maintenance of HbA<sub>1c</sub>. Nonetheless, at 4 years most patients in each of the three groups did not maintain their HbA<sub>1c</sub> goals and needed to progress to combination therapy. The analysis shown reflects time until mean HbA<sub>1c</sub> within treatment group exceeds 7% (>53 mmol/mol) based on a repeated measures mixed model. Reproduced from Kahn *et al. N Engl J Med* 2006; **355**:2427–2443.

binning treatments with complementary actions can be a logical approach. Several distinct advantages of combining agents can be distinguished.

**Efficacy**

The first rationale for combination therapy (either with oral agents alone, with oral agents and insulin or oral agents with other injectable medicine such as incretin mimetics) is its superior efficacy. One principle that emerges from randomized controlled trials of antidiabetic therapies is that switching from one medication to another does not work as well as adding on or combining therapies. Figure 31.4 shows a classic study of combination oral agent therapy that illustrates this point [25]. Patients with inadequate glycemic control on maximal doses of glyburide were randomized to continuation of that monotherapy, to metformin monotherapy gradually titrated to maximal doses (850 mg orally three times a day), or to a combination of glyburide and metformin. Neither monotherapy resulted in any significant improvement in fasting plasma glucose (FPG), but combination therapy with an insulin secretagogue and metformin showed a dramatic improvement. Similarly, studies with other combination therapies showed no benefit of switching to a new agent class, but greater glucose-lowering efficacy through combining it with an agent with a different mechanism. A final benefit of combination treatment may add efficacy by using some agents that treat preprandial hyperglycemia and others that treat post-prandial hyperglycemia. As with basal and bolus insulin, it may be important to use both approaches in balance.

**Tolerability and convenience**

Most side effects of glycemic medications are dose-related. For example, hypoglycemia is a side effect of insulin or insulin secretagogues, gastrointestinal side effects are common with met-

**Figure 31.4** As shown by DeFronzo *et al.* [25] in subjects failing maximal dose glyburide (dotted line), continuation of the “failing” secretagogue led to gradually worse hyperglycemia. Likewise, a switch from glyburide to metformin (dashed line) showed little glycemic improvement. A worsening of hyperglycemia with increased fasting plasma glucose (FPG) was seen in the metformin group

after glyburide had been stopped and before full dose titration of metformin had occurred. This study exemplifies the general principle that switching makes little sense as the combination of therapy (solid line) substantially improves FPG which is not observed with either monotherapy.

formin, incretin mimetics and  $\alpha$ -glucosidase inhibitors, and fluid retention or weight gain may occur with the thiazolidinediones. In contrast to some of the adverse effects of diabetes agents noted above, the efficacy of oral agents in glucose lowering is often not linear with increasing dose. Thus, with dose escalation one may increase undesirable side effects while gaining little in efficacy. One option is to utilize lower doses of two complementary medications, which can minimize side effects while achieving equal or better glycemic control. This principle has been tested directly for the combination of glyburide and metformin [25].

Using combinations of oral agents may seem more complex than monotherapy, but in some cases their convenience can be enhanced. Combining a single dose of a long-acting sulfonylurea, such as glimepiride, with one or two tablets of metformin, may have greater benefit than three or four tablets of metformin alone. Metformin–secretagogue (metformin–glyburide, metformin–glipizide, metformin–repaglinide) combination pills, have been introduced. Similarly, metformin–thiazolidinedione (metformin–rosiglitazone, metformin–pioglitazone) combination pills are also available. Recently, thiazolidinediones–secretagogue (rosiglitazone–glimepiride, pioglitazone–glimepiride) combination pills have become available. Some newer agents such as sitagliptin have been approved for use when combined with metformin and are also available as a combination pill.

The trend to use combination pills will likely increase in the future. Formulations of two agents in a single pill with dual actions may appeal to many patients and practitioners. While separate titration of agents may be desirable for many patients, for others a case can be made for combination preparations. Side effects are often characteristic of a particular agent (e.g. sulfonylureas with hypoglycemia, metformin with gastrointestinal side effects, glitazones with fluid retention) and thus can be com-

monly attributed correctly to the specific agent in a combination pill. Occasionally, rarer or idiosyncratic side effects could be less readily attributed to the specific agent. This tactic may prove especially attractive for patients who must take not only two or more agents for glycemic control, but also other medications for manage blood pressure, lipid abnormalities, heart disease and other problems.

## Secretagogues

Whether rapid or longer-acting, secretagogues work well with both metformin [25] and thiazolidinediones [26]. Their use with basal insulin therapy, such as evening NPH or glargine [27] is also evidence-based. Use of secretagogues with a mixture of evening basal plus mealtime insulin reduces insulin requirements and prevents interim hyperglycemia during insulin dose titration [28], however, their use with two or more mealtime insulin doses is considered superfluous, and might increase the risk of hypoglycemia. Insulin secretagogues work by binding to sulfonylurea receptors (SUR), which in the pancreas are of the SUR1A subtype. SUR are linked to potassium inward rectifier (Kir 6.2) channels. When Kir channels are closed by secretagogue binding to SUR, calcium channels are opened and insulin is released. The Diabetes mellitus, Insulin Glucose infusion in Acute Myocardial Infarction 1 (DIGAMI-1) study [29] showed that, compared with usual care, insulin treatment reduced mortality from acute myocardial infarction in diabetes mellitus; thus, it seems reasonable to avoid secretagogues, particularly glyburide, in patients with active ischemic heart disease (acute coronary syndromes or the presence of stable angina). DIGAMI-2 [30] did not confirm the mortality differential found in DIGAMI-1. The DIGAMI-2 study was

limited by the inability to achieve targeted glycemic goals (5–7 mmol/L) and a small separation of glycemic control between treatment groups. Nevertheless, the investigators confirmed the epidemiologic relationship between hyperglycemia and cardiac mortality. Taken together, this information suggests cardiac ischemia with hyperglycemia may still be best managed with insulin.

The primary side effect of secretagogues, used alone or in combination, is hypoglycemia. Avoidance of hypoglycemia, particularly in older patients or patients with cardiovascular disease as recently highlighted by the ACCORD trial [12], restricts overuse of this class. For a few patients hypoglycemia occurs overnight. Chlorpropamide and glyburide are the secretagogues most likely to cause hypoglycemia although it may occur with any of the sulfonylureas. Nonetheless, daytime hypoglycemia, most commonly in the mid afternoon, with once daily morning dosing is a more common timing of hypoglycemia. It should lead to advice not to skip or delay lunch and may occasionally require a snack when patients are physically active in the middle of the day.

Loss of early prandial insulin release is thought to be an early event in the development of T2DM [31]. Epidemiologic studies suggest that post-prandial hyperglycemia or impaired glucose tolerance independently predicts risk for cardiovascular disease in patients with diabetes mellitus and normal fasting glycemia [32,33]. Several antidiabetes agents specifically target post-prandial hyperglycemia. These agents include the rapid-acting insulin analogs aspart, lispro and glulisine;  $\alpha$ -glucosidase inhibitors; rapid-acting insulin secretagogues and incretins. Table 31.1 lists commonly used medication, their efficacy and their preprandial and post-prandial effects and side effects of different agents.

### Rapid-acting secretagogues (glinides)

The meglitinide repaglinide and the phenylalanine derivative nateglinide have theoretical advantages, with rapid prandial

insulin release potentially mimicking normal physiology. Some facilitation of prandial insulin release, however, does occur with long-acting secretagogues. The differential effect on early insulin secretion with rapid-acting secretagogues compared to sulfonylureas has not been consistently seen in all studies. Carroll *et al.* [34] failed to identify a substantial and consistent prandial glycemic benefit of rapid-acting secretagogues in comparison to extended- or immediate-release glipizide. Rapid-acting secretagogues are considered most appropriate for sulfonylurea-intolerant patients, patients with erratic food intake and patients in whom there is a demonstrated individual benefit. The absence of data showing improved clinical outcome, greater cost, more frequent dosing and no superiority in HbA<sub>1c</sub> reduction limits enthusiasm for their wider use. Moreover, the rapid kinetics of nateglinide may explain its somewhat reduced overall antihyperglycemic efficacy. Secretagogues will retain their role in restoring insulin secretory deficits, especially in leaner patients, alone and in combination.

### Biguanides

The antihyperglycemic effect of metformin is largely brought about by suppression of hepatic glucose release, thus reducing insulin resistance in the liver. Metformin may accomplish this by activation of the enzyme adenosine 5'-monophosphate-activated protein kinase (AMPK), which acts as a "fuel sensor." Although not approved by the FDA for the treatment of the metabolic syndrome or intermediate hyperglycemia, some clinicians have taken advantage of the insights from the Diabetes Prevention Program (DPP) [35]; in patients with impaired glucose tolerance, there was a delay in the onset of T2DM through the use of intensive lifestyle modification (58% reduction), metformin (31% reduction) and troglitazone (early DPP data suggest a benefit, but this study arm was discontinued because of the

**Table 31.1** Diabetes drugs with efficacy, preprandial and post-prandial effects and side effects.

Drug type	HbA <sub>1c</sub> lowering	Pre-prandial effect	Post-prandial effect	Actions	Side effects
Sulfonylureas and non-SU rapid secretagogues	1.0–2.0%	++	+	Direct/indirect secretagogue	Hypoglycemia, wt gain
Biguanides	1.0–2.0%	+++	–	↓ Hepatic glucose output	GI, lactic acidosis, wt neutral
Thiazolidinediones	0.5–1.6%	+++	–	↑ Muscle insulin sensitivity	Edema, CHF
Incretin agonists	0.9–1.1%	+	++	Strong GLP-1 effects ↑ insulin ↓ glucagon	Nausea, vomiting, wt loss
DPP-4 inhibitors	0.6–0.8%	+	++	Moderate GLP-1 effects ↑ Insulin ↓ glucagon	Nausea, wt neutral
Insulin Basal (NPH, glargine and detemir)	1.5–2.5%	+++	– Depends upon type	↓ Hepatic glucose output, ↑ muscle glucose disposal	Hypoglycemia, wt gain
Insulin Meal (analog and regular)	1.0–2.0%	–/+	++ Depends upon type	↓ Hepatic glucose output, ↑ muscle glucose disposal	Hypoglycemia, wt gain
Pramlintide	0.5–0.7%	–/+	++	↑ Insulin ↓ glucagon	Nausea, vomiting

CHF, congestive heart failure; DPP-4, dipeptidyl peptidase 4; GI, gastrointestinal; GLP-1, glucagon-like receptor 1; SU, sulfonylurea; wt, weight. HbA<sub>1c</sub> 1% = 11 mmol/mol.

hepatotoxicity observed). Thus, in patients with pre-diabetes or the metabolic syndrome, metformin is sometimes used in combination with intensive lifestyle modification for prevention of T2DM.

Metformin is usually the preferred initial treatment selection in most T2DM. Data, again from the UKPDS, demonstrate that metformin as monotherapy in overweight patients reduced mortality, myocardial infarction and weight gain [9]. Long-term follow-up from the UKPDS suggests this cardiovascular and mortality benefit persists [11]. The use of metformin in combination with secretagogues in T2DM is very common and two combination pills are available. One formulation combines metformin with glyburide, and the other combines metformin with glipizide. Combination medications are also available for metformin with thiazolidinediones, repaglinide and sitagliptin. The combination medications do not include the extended-release versions of metformin, and this may limit gastrointestinal tolerance for a few patients.

### Thiazolidinediones

Thiazolidinediones (TZDs) are insulin-sensitizing agents that act as ligands of the nuclear transcription factor peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ) [36]. In so doing, they improve not only glycemia but may ameliorate dyslipidemia, inflammation and hypercoagulability associated with insulin resistance [37]. As a result, there is particular interest in their potential cardiovascular benefits in T2DM. The pleiotropic effects of TZDs beyond glycemic control lie in the role of their ligand, PPAR- $\gamma$ , on lipid metabolism and inflammatory pathways. PPARs are members of a nuclear receptor superfamily that regulates gene expression in response to ligand binding. There are three known PPARs:  $\alpha$ ,  $\delta$  (sometimes called  $\beta$ ) and  $\gamma$ . PPAR- $\alpha$  is found in the liver, the heart, muscle and vascular walls, and binds fibrates, with subsequent free fatty acid oxidation, reduced triglycerides, improved high-density lipoprotein (HDL) cholesterol and a decrease in inflammation [37]. PPAR- $\gamma$  is most abundant in adipose tissue, but also is in  $\beta$ -cells of pancreatic islets, vascular endothelium and macrophages. It regulates gene expression, influencing adipocyte differentiation, fatty acid uptake and storage, and glucose uptake [36,37].

Rosiglitazone and pioglitazone are both FDA approved for monotherapy and in combination with metformin and sulfonylureas [38–41]. Because of concerns about cardiovascular risk, rosiglitazone is no longer recommended with insulin or nitrate therapy. Pioglitazone is approved for use with insulin. A TZD predecessor, troglitazone, was FDA approved in 1997 but withdrawn in 2000 because of reports of fatal hepatotoxicity, which is not seen with current TZDs. In a meta-analysis of 13 randomized clinical trials, less than 0.3% of patients on pioglitazone or rosiglitazone had alanine aminotransferase (ALT) levels greater than three times the upper limit of normal, compared to nearly 2% of patients on troglitazone [42]. Nonetheless, it is

recommended that liver function tests be performed prior to initiation of therapy and periodically thereafter. Of interest, recent reports suggest that TZD therapy may improve elevated transaminase values and even liver histology in patients with T2DM and non-alcoholic fatty liver disease or non-alcoholic steatohepatitis [43].

Both pioglitazone and rosiglitazone effectively lower HbA<sub>1c</sub>, up to about 1–1.5% (11–16 mmol/mol), with maximum doses in monotherapy [44] but less on average. Glycemic control is improved on average more than with nateglinide or  $\alpha$ -glucosidase inhibitors, but less than with sulfonylureas or metformin in unselected patients, partly because of a heterogeneous response; some patients have a small response, but others have a robust response. When TZDs are added to sulfonylureas, metformin or insulin, an additional 0.8–1.5% (9–16 mmol/mol) HbA<sub>1c</sub> decline can generally be achieved [45]. A combination form of metformin and rosiglitazone is currently available. A combination pill of pioglitazone and metformin is now marketed. As with the sulfonylurea combination pills, the immediate-release form of metformin is used in these formulations. For very insulin-resistant patients (usually with high BMI, marked central obesity and hypertriglyceridemia) with preserved insulin secretion (shorter duration of diabetes), use of metformin with a TZD can be very effective. These same characteristics probably identify good TZD monotherapy responders. Combination pills of metformin and rosiglitazone or pioglitazone may be preferable for some patients because there are fewer pills to take or there is lower co-payment from insurance in some countries. TZD–secretagogue combinations are effective in insulin-resistant patients with moderate insulin secretory reserve. Combination pills are available, both for pioglitazone (with glimepiride) and rosiglitazone (with glimepiride).

As described above, the ADOPT (A Diabetes Outcome Progression Trial) trial (Figure 31.3) [24] assessed the durability of glycemic efficacy of glyburide, metformin and rosiglitazone as a monotherapy. It used as a primary endpoint the ability to maintain fasting plasma glucose less than 180 mg/dL. Secondary outcomes included time from randomization to FPG >140 mg/dL. Other prespecified outcomes included levels of FPG and glycated hemoglobin, weight and measures of insulin sensitivity and  $\beta$ -cell function as determined by homeostasis model assessment using the HOMA 2 method (Figure 31.5). The primary study endpoint, the proportion of those who failed to keep the FPG less than 180 mg/dL was achieved by 143 patients on rosiglitazone (2.9 per 100 patient-years), 207 on metformin (4.3 per 100 patient-years) and 311 on glyburide (7.5 per 100 patient-years). The percentages of patients HbA<sub>1c</sub> achieving <7.0% (<53 mmol/mol) while on assigned therapy at study end were 26% for glyburide, 36% for metformin and 40% for rosiglitazone. Weight gain was greater with rosiglitazone than glyburide (2.5 kg) and greater still than metformin (6.9 kg) while hypoglycemia was more common with glyburide and gastrointestinal side effects with metformin as would be expected. Cardiovascular events were reduced with glyburide but not with the other two therapies.

**Figure 31.5** Based upon a homeostasis (HOMA) model, residual maximal insulin secretory reserve is depicted at the time of diagnosis and yearly for 6 years in subjects receiving diet only in the UK Prospective Diabetes Study. This figure illustrates that nearly half of insulin secretion is lost at diagnosis. It also shows the progressive loss of insulin secretory reserve, which predicts essentially complete insulin deficiency in about a dozen years if further loss were linear.

**Figure 31.6** The natural history of type 2 diabetes mellitus. Long before diagnosis  $\beta$ -cell function begins a gradual and inexorable decline (solid red line at top of figure). Insulin resistance (solid orange line) begins to increase during early adulthood in conjunction with cardiovascular risks. The dashed green line depicts the initial compensatory increase in insulin secretion in response to increasing insulin resistance, which initially maintains euglycemia but which eventually fails and causes progression from euglycemia to prediabetes to diabetes. At the bottom of the figure post-prandial glucose levels rise (solid pink line) initially as insulin secretion fails to keep pace with insulin resistance. Later (dotted purple line) fasting glucose will also begin to rise progressively as

insulin secretion wanes further. Progressive insulin deficiency requires progressive therapy combinations. After about 10 years of diagnosed diabetes frank insulin deficiency leads to the need for basal and then basal and meal insulin treatment in most people with type 2 diabetes. Microvascular complications occur only after several years of hyperglycemia. Macrovascular complications may precede or arrive simultaneously with diagnosis of diabetes because of the long prodrome of insulin resistance-related cardiovascular risks. Adapted from Holman RR. *Diabetes Res Clin Pract* 1998; **40**(suppl):S21–S25; Ramlo-Halsted BA, Edelman SV. *Prim Care* 1999; **26**:771–789; Nathan DM. *N Engl J Med* 2002; **347**:1342–1349; UKPDS Group. *Diabetes* 1995; **44**:1249–1258.

Overall, most editorialists have concluded that glitazones remain in the balance less attractive as initial therapy than metformin [46].

TZDs also stimulate the production and circulation of adiponectin [47], a fat-cell-derived hormone (or adipokine) that increases AMPK activity in the liver, adipose tissue and skeletal muscle. Low adiponectin levels are seen in patients with T2DM and are thought to contribute to insulin resistance and subsequent hyperglycemia [48]. The stimulation of adiponectin

production, in addition to direct activation of AMPK, may explain some of the beneficial lipid effects of TZDs as well as their ability to increase insulin sensitivity [48]. Low adiponectin levels may predict a therapeutic response to TZDs, and polymorphisms in the PPAR- $\gamma$  gene could potentially help to explain the variability of therapeutic response to TZDs and progression of diabetes (see Chapter 12) [48].

A recent meta-analysis raised the question of cardiac safety with rosiglitazone with findings of a 43% relative increased risk

in ischemic heart disease events [49]. Some studies using the same data have confirmed this increase in risk while others have failed to do so. Further analysis, including interim safety analysis of the RECORD trial, failed to show increased rates of major adverse cardiac events (see below) [50]. Results from recently published prospective randomized controlled clinical trials (VADT, ADVANCE, ACCORD) [12,51,52] which had high rates of TZD usage failed to show reduction in major adverse cardiovascular events (MACE) with tighter glycemic control and did not suggest increases in MACE associated with TZD use. Nevertheless, the ADA/EASD algorithm has taken a conservative stance and has not included rosiglitazone in its standard alternative recommendations.

What does become clear in review of the available safety data for this class is their propensity for promoting fluid retention in some patients, who may be difficult to predict in advance. Close tracking of patient weight and reviewing medication dose or diuretic use may need to be performed when patients gain more than 5–7 lb (3 kg). This has led to a re-emphasis on their potential for exacerbation of congestive heart failure particularly in patients with class III or IV heart failure [53].

Subsequent analysis of clinical trial data, both old and new, with an emphasis on analysis of those patients at risk for MACE lead to significant changes in the labeling for use of TZDs. In particular, concomitant usage of insulin or nitrates was associated with increased risk for congestive heart failure and other cardiovascular events, and combination therapy of insulin and/or nitrates with rosiglitazone is no longer indicated. Currently, neither pioglitazone nor rosiglitazone are indicated in patients with class III or IV heart failure.

The link between TZD usage and possible adverse cardiovascular events or potential cardiovascular risk reduction remains unanswered. Rosiglitazone was used in large numbers of patients in both the ACCORD [12] and VADT trial [52] without a clear MACE signal, suggesting the drug does not promote cardiovascular events. Pioglitazone was studied in the Prospective Pioglitazone Clinical Trial in Macrovascular Events (PROactive) to examine its effects on morbidity and cardiovascular mortality and the secondary cardiovascular endpoints of myocardial infarction, death and stroke were favorably affected [54]. This study of 2600 actively treated patients showed no increase in mortality or MACE. Future studies may assist the practitioner to reach a clearer answer to this important but unresolved question.

Two recent studies tend to affirm the cardiovascular safety of rosiglitazone. They are the RECORD trial [55] and the BARI 2D trial [56]. These studies compared the cardiovascular benefits of rosiglitazone to other monotherapy (RECORD) in a non-inferiority analysis, while an insulin sensitizing approach was compared with an insulin providing approach in the BARI 2D trial. In the BARI 2D trial [56], 2368 patients with both T2DM and heart disease were randomly assigned to either prompt revascularization with intensive medical therapy or intensive medical therapy alone. They were also assigned to either insulin-sensitization or insulin-provision therapy, with either insulin or secreta-

gogues. The primary endpoints were the rate of death and a composite of death, myocardial infarction or stroke (major cardiovascular events). At 5 years, survival rates were similar with revascularization (88.3%) and medical therapy (87.8%;  $P = 0.97$ ) or with insulin-sensitization (88.2%) and insulin-provision (87.9%;  $P = 0.89$ ). Similarly, freedom from major cardiovascular events did not differ significantly among the groups: 77.2% with revascularization and 75.9% with medical treatment ( $P = 0.70$ ) and 77.7% with insulin-sensitization and 75.4% with insulin-provision group ( $P = 0.13$ ). Severe hypoglycemia was more common with insulin provision (9.2%) than with an insulin-sensitization strategy (5.9%;  $P = 0.003$ ).

In the RECORD study [55], 4447 patients with T2DM on metformin or sulfonylurea monotherapy with mean HbA<sub>1c</sub> of 7.9% (63 mmol/mol) were randomly assigned to added rosiglitazone ( $n = 2220$ ) or to metformin and sulfonylurea ( $n = 2227$ ). The primary endpoint was cardiovascular hospitalization or cardiovascular death, with a hazard ratio (HR) non-inferiority margin of 1:20; 321 people offered added rosiglitazone and 323 in the control group experienced the primary outcome during 5.5-year follow-up, meeting the criterion of non-inferiority (HR 0.99; 95% CI 0.85–1.16). HR was 0.84 (0.59–1.18) for cardiovascular death, 1.14 (0.80–1.63) for myocardial infarction, and 0.72 (0.49–1.06) for stroke. Although these cardiovascular endpoints did not differ significantly, heart failure leading to hospitalization or death occurred in 61 people with rosiglitazone and 29 in the control group (HR 2.10, 1.35–3.27). Limb fracture rates were increased (about double), mainly in women randomly assigned to rosiglitazone. Mean HbA<sub>1c</sub> was lower (approximately 0.25% [3 mmol/mol]) in the rosiglitazone group than in the control group at 5 years. Although the preponderance of this evidence now appears to exculpate rosiglitazone from the concern regarding ischemic heart disease, it does not indicate a clear benefit in this regard either.

Lastly, an unanticipated complication seen with both TZDs is an increase in observed long bone fractures in woman participating in PROactive [54] and rosiglitazone trials (ADOPT) [24]. In both cases, the fracture rates were approximately double (5.1% vs 2.5%: PROactive) that of comparator groups, were seen early and were unrelated to diabetic control. A potential mechanism may relate to PPAR involvement in osteoblast cell differentiation [57], but this remains incompletely understood. Consideration should be given to screening for fracture risk including at the wrist to assess cortical bone in patients on TZD therapy at initiation and periodically thereafter until further information regarding the mechanism of the increased fracture rate associated with TZD usage is provided.

Taken together, the adverse event profile for the rosiglitazone without compelling evidence for specific cardiovascular benefit suggests use of this agent be reserved for patients unable to tolerate alternative drug regimens. This is in concordance with the current ADA/EASD recommendations. It should be acknowledged that this recommendation is controversial and we may see revision of this in due course.

## Incretin therapy combinations

The recent availability of incretin mimetics, either glucagon-like peptide 1 (GLP-1) receptor agonists, such as exenatide and liraglutide, or dipeptidyl peptidase 4 (DPP-4) inhibitors, such as sitagliptin, saxagliptin, alogliptin and vildagliptin, has opened up new possibilities in combination therapy [58]. Exenatide is an injectable synthetic analog of the Gila monster (*Heloderma suspectum*) salivary protein exendin 4. This compound has substantial homology with GLP-1 and tightly binds to GLP-1 receptors and thereby mimics the actions of native GLP-1 when given in doses of 5 or 10 µg twice daily. Three registration trials of similar design show the use of exenatide in 30-week long studies in patients with oral agent failure with sulfonylureas [59], metformin [60] or both [61]. After a 4-week placebo run in, subjects were randomized to blinded placebo versus exenatide 5 µg twice daily for 1 month and then continued this dose or increased to 10 µg twice daily. All subjects continued their prior oral agents.

When exenatide versus placebo was added to metformin, 272 patients completed the study [60]. They were middle-aged (53 ± 10 years), obese (34.2 ± 5.9 kg/m<sup>2</sup> BMI) and with inadequate glycemic control (HbA<sub>1c</sub> 8.2 ± 1.1% [66 mmol/mol]). At 30 weeks, the HbA<sub>1c</sub> change from baseline was -0.78 ± 0.1% (10 µg), -0.4 ± 0.11% (5 µg) and 0.08 ± 0.1% for placebo; *P* < 0.002, (8, 4 and 1 mmol/mol, respectively). Exenatide was associated with weight loss: -2.8 ± 0.5 kg (10 µg), -1.6 ± 0.4 kg (5 µg); *P* < 0.001 versus placebo. Gastrointestinal side effects including nausea, vomiting and diarrhea were more common with exenatide but lessened toward the end of the trial. In the 5 and 10 µg groups, exenatide resulted in a placebo subtracted percentage for nausea of 11% and 22%, for vomiting 7% and 8%, and for diarrhea 4% and 8% overall during the study.

In the sulfonylurea failure study [59], the study population was similar with obese middle-aged subjects with slightly higher baseline glycemia (HbA<sub>1c</sub> 8.6 ± 1.2% [70 mmol/mol]). The change from baseline HbA<sub>1c</sub> at 30 weeks was -0.86 ± 0.11 (10 µg), -0.46 ± 0.12 (5 µg) and 0.12 ± 0.09% (placebo); *P* < 0.001, (9, 5 and 1 mmol/mol, respectively). Weight loss was somewhat less with 10 µg than in the metformin alone study (-1.6 kg). The third trial was for patients inadequately controlled on the combination of effective doses of sulfonylurea and metformin. Similar subjects were studied with middle-aged, obese, poorly controlled subjects (baseline HbA<sub>1c</sub> 8.5 ± 1.0% [69 mmol/mol]). The change from baseline HbA<sub>1c</sub> occurred at 30 weeks was -0.8 ± 0.1% (10 µg), -0.6 ± 0.1% (5 µg) and 0.2 ± 0.1% (placebo); *P* < 0.0001, (9, 7 and 2 mmol/mol, respectively). Weight loss in this study averaged 1.6 kg for the 10 µg dose group and was similar to the sulfonylurea alone study.

A similar study has been conducted showing comparable glycemic benefit in patients in a thiazolidinedione alone or with metformin to which 5 and then 10 µg doses of exenatide were added for 16 weeks [62]. Again, approximately 1% (11 mmol/mol) reduction in HbA<sub>1c</sub> occurred from a baseline of 7.9% (63 mmol/mol) in comparison to placebo controls and approxi-

mately a 30 mg/dL (1.7 mmol/L) decline in fasting glucose occurred with a greater weight loss in the exenatide group (~1.5 kg). Nausea was more common with exenatide (40 vs 15% for placebo) and the drop-out rate was also higher.

Is it reasonable to choose exenatide as an alternative to basal insulin therapy? Perhaps if patients are not very far from glycemic goal the answer may be yes. Heine *et al.* [63] reported a study of 551 subjects with T2DM who were inadequately controlled. They were randomized to either insulin glargine once a day at bedtime or 5 µg for 1 month then 10 µg exenatide for the duration of this 26-week long trial. Baseline HbA<sub>1c</sub> was 8.2% (66 mmol/mol) for patients receiving exenatide and 8.3% for those on insulin glargine. By study end, exenatide and insulin glargine therapies resulted in equal reduction of HbA<sub>1c</sub> levels by 1.11% (12 mmol/mol). Exenatide reduced post-prandial plasma glucose levels more than insulin glargine, while insulin glargine reduced FPG levels more than exenatide. This is well illustrated in the seven-point self-monitored glucose levels before and after meals and at 3 AM performed at study beginning and end. Body weight decreased 2.3 kg with exenatide and increased 1.8 kg with insulin glargine. Rates of symptomatic hypoglycemia were similar, but nocturnal hypoglycemia occurred less frequently with exenatide (0.9 vs 2.4 events/patient-year). Gastrointestinal symptoms were more common in the exenatide group than in the insulin glargine group, including nausea (57.1% vs 8.6%), vomiting (17.4% vs 3.7%) and diarrhea (8.5% vs 3.0%). Despite similar lowering of HbA<sub>1c</sub>, there were marked differences in prandial versus preprandial control, suggesting these interventions had different patterns of benefit.

In all of the studies of exenatide in which sulfonylureas were used, an increased risk of hypoglycemia occurred that sometimes required a reduction in sulfonylurea dose to reduce the risk of hypoglycemia symptoms. In patients on sulfonylureas treated with exenatide (and likely also with DPP-4 inhibitors), it may be appropriate to pre-emptively reduce sulfonylurea doses by half if patients' lowest blood sugars are less than 100 mg/dL because the glucose-dependent insulin secretion with this combination is lost as a result of the sulfonylurea. Taken together, these studies suggest that exenatide may represent a desirable alternative for overweight patients for whom lifestyle intervention alone is insufficient in improving weight and who also need improved glycemia control but are reluctant to use insulin.

One study by Nauck *et al.* [64] studied exenatide twice daily (n = 253) vs biphasic insulin aspart (70/30, n = 248) in patients poorly controlled on metformin and sulfonylureas in a non-inferiority analysis. Exenatide was found to be non-inferior with a mean ± SEM decrease in HbA<sub>1c</sub> from baseline of -1.04 ± 0.07% (11 mmol/mol), and for biphasic insulin aspart it was -0.89 ± 0.06% (10 mmol/mol); the difference was -0.15% ((5% CI -0.32 to 0.01%). Exenatide-treated patients lost weight and had nausea in 35%, while patients treated with biphasic insulin aspart gained weight (between-group difference -5.4 kg; 95% CI -5.9 to 5.0 kg). Both treatments reduced fasting glucose (exenatide -1.8 ± 0.2 mmol/L, *P* < 0.001; biphasic insulin aspart -1.7 ± 0.2 mmol/L, *P* < 0.001). Greater reductions in post-

prandial glucose excursions at all meals were observed with exenatide. The withdrawal rate was 21.3% (54/253) for exenatide and 10.1% (25/248) for biphasic insulin aspart.

In a second study which compared 70/30 insulin aspart analog mixture, as alternatives for patients failing oral agent therapy, Bergenstal *et al.* [65] found that more patients responded to the biphasic insulin than to exenatide. The higher baseline HbA<sub>1c</sub> (10.2% [88 mmol/mol]) was thought to reflect more advanced disease and thus would be associated with less  $\beta$ -cell function, which is a requirement for full clinical response to exenatide.

Although not approved for use together, exenatide with insulin therapy is reportedly used in patients with T2DM. The rationale is based upon the potential insulin sparing effects of exenatide presumably through its multiple effects to augment insulin and reduce glucagon at meals as well as its effects upon gastric emptying, appetite and weight loss. Sheffield *et al.* [66] described a series of 134 patients initiating exenatide in combination with insulin in private endocrine practice with a 1-year follow-up. Exenatide use resulted in a 0.87% (9 mmol/mol) reduction of HbA<sub>1c</sub>, despite a 45% discontinuation of premeal insulin, reduction in insulin injection number and discontinuation of sulfonylureas. Its use resulted in reduced weight slightly over 5 kg, although some weight loss was observed in 72% of patients. Slightly over one-third of patients (36%) discontinued the exenatide primarily because of gastrointestinal side effects, while 10% of patients had hypoglycemia. The authors have some experience with the use of exenatide with a basal insulin as an alternative for selected patients who have difficulty with accurate dosing of meal insulin in combination with basal insulin, which mirrors the experience reported in this case series.

Liraglutide is a GLP-1 analog with 97% homology to human GLP-1 which has now had several clinical trials, and has now been approved by the US FDA and European Medicines Agency. Phase 3 trials have included monotherapy and trials in combination with either metformin, with sulfonylureas or the combination of the two oral agents. In a 52-week study [67], doses of 1.2 and 1.8 mg were given once daily to 746 patients with early T2DM. The subjects in this study were randomly assigned to once daily liraglutide (1.2 mg [n = 251] or 1.8 mg [n = 247]) or glimepiride 8 mg (n = 248). The primary outcome was change in HbA<sub>1c</sub> from baseline. The analysis was by intention-to-treat. At 52 weeks, the HbA<sub>1c</sub> was decreased by 0.51% (SD 1.20%) with glimepiride, compared with 0.84% (1.23%) with liraglutide 1.2 mg (difference -0.33%; 95% CI -0.53 to -0.13;  $P = 0.0014$ ) and 1.14% (1.24%) with liraglutide 1.8 mg (-0.62; -0.83 to -0.42;  $P < 0.0001$ ). Five patients in the 1.2 mg liraglutide, and one in 1.8 mg groups discontinued the treatment because of vomiting, but none in the glimepiride group did so. The frequently self-monitored blood glucose profiles appear to show very good fasting glucose control, although interestingly a bit less marked blunting of post meal glucose than in some of the exenatide studies. There is no direct comparison with exenatide in this study.

In a multiple-arm study [68] of 1041 adults with T2DM with an average age of  $56 \pm 10$  years (mean  $\pm$  SD) over 26 weeks, liraglutide (0.6, 1.2 or 1.8 mg/day) or rosiglitazone (4 mg/day) or

placebo was added to glimepiride monotherapy. Liraglutide (1.2 or 1.8 mg) reduced HbA<sub>1c</sub> from baseline more (-1.1% [12 mmol/mol]; baseline 8.5% [69 mmol/mol]) when compared with placebo (+0.2% [2 mmol/mol];  $P < 0.0001$ ; baseline 8.4% [68 mmol/mol]) or rosiglitazone (-0.4% [4 mmol/mol];  $P < 0.0001$ ; baseline 8.4% [68 mmol/mol]). A lower dose of liraglutide was less effective and only reduced HbA<sub>1c</sub> by 0.6% (7 mmol/mol). Fasting plasma glucose decreased by week 2, with a 1.6 mmol/L decrease from baseline at 26 weeks with liraglutide 1.2 mg (baseline 9.8 mmol/L) or 1.8 mg (baseline 9.7 mmol/L) compared with a 0.9 mmol/L increase with placebo ( $P < 0.0001$ ; baseline 9.5 mmol/L) or 1.0 mmol/L decrease with rosiglitazone ( $P < 0.006$ ; baseline 9.9 mmol/L). Post-prandial plasma glucose decreased more from baseline with liraglutide 1.2 or 1.8 mg (-2.5 to -2.7 mmol/L [baseline 12.9 mmol/L for both]) compared with placebo (-0.4 mmol/L;  $P < 0.0001$ ; baseline 12.7 mmol/L) or rosiglitazone (-1.8 mmol/L;  $P < 0.05$ ; baseline 13.0 mmol/L). Changes in body weight with liraglutide 1.8 mg (-0.2 kg; baseline 83.0 kg), 1.2 mg (+0.3 kg; baseline 80.0 kg) or placebo (-0.1 kg; baseline 81.9 kg) were less than with rosiglitazone (+2.1 kg;  $P < 0.0001$ ; baseline 80.6 kg). The adverse events for all treatments were minor hypoglycemia (<10%), nausea (<11%), vomiting (<5%) and diarrhea (<8%).

A recently published article studied the addition of liraglutide [69] in 533 patients with diabetes failing on oral agents, randomizing them in a 1:1:1 ratio to liraglutide 1.2 or 1.8 mg daily or placebo in addition to rosiglitazone 4 mg twice daily and metformin 1 g twice daily for 26 weeks. HbA<sub>1c</sub> values decreased significantly more in the liraglutide groups vs placebo ( $1.5 \pm 0.1\%$  for both liraglutide 1.2 and 1.8 mg and  $-0.5 \pm 0.1\%$  for placebo [mean  $\pm$  SE]). FPG decreased by 40, 44 and 8 mg/dL for liraglutide 1.2, 1.8 and placebo, respectively, and 90 minutes post meal post-prandial plasma glucose (PPG) decreased by 47, 49 and 14 mg/dL, respectively ( $P < 0.001$  for all liraglutide groups vs placebo). Dose-dependent weight loss occurred with liraglutide 1.2 and 1.8 mg ( $1.0 \pm 0.3$  and  $2.0 \pm 0.3$  kg, respectively;  $P < 0.0001$ ) as compared to weight gain with placebo ( $0.6 \pm 0.3$  kg). Interestingly systolic blood pressure decreased by 6.7, 5.6 and 1.1 mmHg with liraglutide 1.2, 1.8 mg, and placebo, respectively. These data, dissimilar to some with exenatide, suggest a greater effect on fasting glucose control and a more commensurate change in fasting with post-prandial control. A 26-week head-to-head comparison of exenatide 10  $\mu$ g twice daily with liraglutide 1.8 mg daily showed a 0.3% (3 mmol/mol) greater reduction in HbA<sub>1c</sub> with liraglutide in a population of adults with inadequately controlled T2DM on maximally tolerated doses of metformin, sulphonylurea, or both [70]. Furthermore, more patients receiving liraglutide achieved an HbA<sub>1c</sub> of less than 7% (54% vs 43%). Liraglutide also reduced mean fasting plasma glucose more than did exenatide. Both drugs promoted similar weight losses but nausea was less persistent and minor hypoglycaemia was less frequent with liraglutide.

Drucker *et al.* [71] have compared exenatide with a longer acting preparation given once weekly of the same agent. This randomized non-inferiority study compared long-acting release

exenatide 2 mg once weekly with 10 µg exenatide administered twice daily, in 295 patients with T2DM (HbA<sub>1c</sub> 8.3% ± 1.0 SD [67 mmol/mol]), mean fasting glucose 9 ± 2 mmol/L, weight 102 ± 20 kg and diabetes duration of 6.7 ± 5.0 years. The patients were either naive to drug therapy or on one or more oral antidiabetic agents. The primary endpoint was change in HbA<sub>1c</sub> at 30 weeks. At study endpoint the patients given exenatide once a week had lower HbA<sub>1c</sub> than those on exenatide twice daily (−1.9 ± 0.1%; SE vs −1.5 ± 0.1%; (95% CI −0.54% to −0.12%; *P* = 0.0023). More patients receiving treatment once weekly vs twice daily achieved HbA<sub>1c</sub> levels of 7.0% (53 mmol/mol) or less (77% vs 61%; *P* = 0.0039). Again, in this trial as in the liraglutide studies there appears to be more effect upon fasting glycemic control than with twice daily exenatide. It is a little difficult to know if in this study differences were to be attributed mostly to kinetics differences or changes in the achieved levels of the incretin mimetic in the blood at the end of the study. However, the ability to lower fasting control to a greater degree than currently available with exenatide seems an important observation and may relate to overall antihyperglycemic efficacy.

## DPP-4 inhibitors

Incretin action can also be provided by inhibiting the rapid degradation of GLP-1 and glucose-dependent insulinotropic peptide (GIP). Although with DPP-4 inhibition the level of circulating GLP-1 agonist activity probably does not rise to a degree similar to that seen with receptor agonists such as exenatide and liraglutide, the glycemic lowering efficacy of sitagliptin and vildagliptin is close to that seen with injectable receptor agonists. Vildagliptin 50 mg once daily added to patients inadequately controlled on metformin (baseline HbA<sub>1c</sub> 7.7% [61 mmol/mol]) resulted in a placebo subtracted difference in HbA<sub>1c</sub> at 52 weeks of −1.0 ± 0.2% (11 mmol/mol, *P* < 0.001) [72].

Vildagliptin combined with a sulfonylurea or a thiazolidinedione also improved glycemia in patients with T2DM in trials of 24–52 weeks. In patients inadequately controlled with metformin, added vildagliptin 100 mg/day was non-inferior to add on therapy with pioglitazone; each treatment reducing HbA<sub>1c</sub> an additional 1% (11 mmol/mol) [73]. Vildagliptin is also available as a fixed-dose formulation with metformin. Vildagliptin has also been studied by Fonseca *et al.* [74] added to insulin treatment and has a small additional effect (approximately 0.3% [3 mmol/mol] HbA<sub>1c</sub> lowering) when compared with placebo. In an interested recent physiologic study, Ahren *et al.* [75] have found that glucagon responsiveness is not only suppressed with a glucose challenge with vildagliptin, but there is also a slight improvement in glucagon increment to insulin hypoglycemia.

DPP-4 inhibitors do not cause nausea and vomiting and are weight neutral, lacking the weight-reduction effects of the GLP-1 agonists observed at 1 year. This is likely because of lower levels of GLP-1 activity. Sitagliptin has been studied as monotherapy [76,77] and as additional treatment for those not meeting gly-

**Figure 31.7** The relative contribution of fasting plasma glucose (FPG; shown in the open bars) and the post-prandial plasma glucose (PPG; shown in the shaded bars) to overall hyperglycemia. An area-under-the-curve analysis suggests that as HbA<sub>1c</sub> approaches the ADA goal for minimum desirable glycemic control (<7.0% [53 mmol/mol]), the PPG makes a greater contribution to overall hyperglycemia. Conversely, as the HbA<sub>1c</sub> rises far from goal, the contribution of FPG to overall hyperglycemia is greater. For patients with poor hyperglycemia a focus on the fasting glucose thus becomes an important priority. As patient approach targeted glycemic goals a greater attention should be directed to post-prandial hyperglycemia. The equivalent IFCC units for the quintiles are: <56 mmol/mol, 56–58 mmol/mol, 69–77 mmol/mol, 78–88 mmol/mol, >88 mmol/mol,

emic goals on either metformin [78] or a thiazolidinedione [79]. In doses of 100 mg for patients with normal renal function in two monotherapy studies of 18 and 24 weeks' duration, sitagliptin reduced HbA<sub>1c</sub> by 0.6% (7 mmol/mol) and 0.8% (9 mmol/mol), respectively. Added to either metformin or pioglitazone, it further reduced HbA<sub>1c</sub> by 0.7% (8 mmol/mol) in 24-week duration studies. DPP-4 inhibitors are weight neutral, probably because of an appetite effect of raising endogenous GLP-1 levels. Their glycemic effects on peak prandial control appear superior to effects on preprandial control. This should complement the primarily preprandial effects of metformin or thiazolidinediones. Incretin drugs appear especially favorable for prandial glycemic control and may be favored also because of positive effects of weight loss or minimal weight gain. Prandial control has been observed by Monnier *et al.* [80,81] to be important particularly as HbA<sub>1c</sub> nears goal (Figure 31.7). Also, if prandial euglycemia contributes to decreased cardiovascular risk through reducing oxidative stress then incretins could have an additional favorable action.

## Colesevelam

After a pilot trial of 12 weeks' duration, 65 subjects with T2DM showed that the addition of the bile acid sequestrant colesevelam reduced HbA<sub>1c</sub> by 0.5% (5 mmol/mol, *P* < 0.007) as well as the expected lipid benefit [82]. Further studies have examined combination therapy in several different groups. Bays *et al.* [83] looked at its effects in doses of 3.75 g/day (*n* = 159) compared with matched placebo (*n* = 157) in subjects with T2DM on met-

formin and other diabetes oral agents, confirming the early pilot with a reduction of HbA<sub>1c</sub> of 0.54% (6 mmol/mol,  $P < 0.001$ ). Those on metformin alone were reduced by 0.47% compared with placebo; those on combined therapy (mostly sulfonylureas, or glitazones and a few other agents) were reduced by 0.62% (7 mmol/mol). Goldberg *et al.* [84] found that patients who were on insulin therapy but not adequately controlled also show the similar level of glycemic benefit after 16 weeks when compared with placebo (−0.41% HbA<sub>1c</sub> for colesevelam vs +0.09% for the placebo group;  $P < 0.001$ ). Fonseca *et al.* [85] found that patients on sulfonylureas given colesevelam 3.75 g/day for 26 weeks showed a placebo corrected difference of −0.54% (6 mmol/mol) HbA<sub>1c</sub>. Overall, these data suggest a modest consistent benefit of colesevelam, on average of 0.5% (6 mmol/mol) reduction in HbA<sub>1c</sub>, in people with T2DM on a variety of combination regimens. The drug is well known and may certainly cause hypertriglyceridemia in those who have pre-existing high levels of triglycerides (usually >250 mg/dL would be high risk). In addition, like other bile acid sequestrants it may cause constipation. With absent high triglycerides at baseline, it is both safe and likely in patients on statins to reduce low density lipoprotein (LDL) cholesterol significantly and contribute to achieving cardiovascular risk reduction.

## Transition to insulin

Current consensus guidelines endorse early adoption of insulin therapy. In general, insulin is an underutilized therapy as a result of both patient and provider hesitance to adopt an injectable therapy associated with weight gain and potential severe life-threatening hypoglycemia. Attention to patient reluctance and provider barriers can maximize successful initiation of insulin therapy. Providing simple patient titration schemes

enhance practitioner and patient acceptance [86]. Combination insulin (parenteral) and sulfonylurea (oral) therapy has been widely studied and provides a basis for many later basal insulin studies. Twice daily (bedtime insulin, daytime sulfonylurea) therapy [87–90] was shown to be an effective therapy prior to the widespread use of metformin in the USA. The use of bedtime insulin suppressed hepatic glucose output and facilitated the use of sulfonylurea for prandial insulin support.

Initiation of insulin therapy can be performed safely and efficiently with the addition of a basal insulin (NPH, glargine, detemir) with titration of dosage to desired target blood glucose. Several studies and reviews support the safety and effectiveness of this approach [6,91–95].

An alternative to a single dose of basal insulin, which has similar overall efficacy but a different pattern of control, is prandial dosing. The APOLLO trial (Figure 31.8) [93] examined basal once daily insulin glargine in comparison to three times a day insulin lispro at meals in 418 subjects with inadequate glycemic control while on oral diabetes agents. In this study, which was 44 weeks in duration, the HbA<sub>1c</sub> drop was similar (−1.7% [19 mmol/mol] for glargine −8.7% [72 mmol/mol] to 7% [53 mmol/mol], −1.9% [21 mmol/mol] for lispro – from 8.7% [72 mmol/mol] to 6.8% [51 mmol/mol]), and as might be expected from the kinetics and timing of the insulin preparations showed superior fasting glycemic control with insulin glargine (−4.3 vs −1.8 mmol/L; 77 vs 32 mg/dL) and better nocturnal control but less effective daytime control (each by about 0.5 or 10 mg/dL). Not surprisingly in this open label study, patients found it preferable to use once daily injection. Subjects taking glargine had fewer hypoglycemia episodes than those on lispro. This study suggests that either meal insulin or basal can be used to achieve improved control although patient preference suggests a basal insulin strategy.

**Figure 31.8** From the APOLLO study, nine-point self-monitored blood glucose profiles in the APOLLO trial. This open labeled study compared the effects of once daily insulin glargine in comparison to lispro three times daily at meals. Average glycemia and HbA<sub>1c</sub> were similar, although hypoglycemia was increased with lispro while weight gain was similar in the two groups. The pattern of glycemia reveals that fasting glucose control improved to a greater degree with

glargine and that as one would expect prandial control is better with lispro. These two strategies are complementary in the glycemic patterns suggesting that using basal insulin and some meal analog insulin may be a useful strategy for many patients. The highest increase in prandial glycemia occurred at breakfast and dinner [94].

## Combining insulin and oral agent therapy

Insulin therapy is eventually needed for most patients with T2DM. An evening insulin strategy is a simple way to begin insulin therapy that will achieve glycemic goals and is easily understood by patients. The rationale for evening insulin has previously been reviewed [86,91,92]. In brief, an evening injection of intermediate- or long-acting insulin addresses a fundamental need in management of T2DM by suppressing overnight endogenous glucose production and thereby preventing hyperglycemia prior to the first meal of the day. This approach is useful for most patients with T2DM, with the notable exception of patients taking morning glucocorticoid therapy.

There are several versions of this strategy, including the use of intermediate-acting insulin at bedtime, intermediate and quick-acting insulin mixed in a single injection at dinnertime, and insulin glargine or insulin detemir at bedtime. For some patients, an alternate timing of glargine may be used earlier in the day; for those using large doses (0.8 units/kg) of detemir use early in the day may also be possible. Most of the evidence for these regimens comes from trials of insulin combined with oral agents, such as a sulfonylurea alone or with metformin, with the oral agents continued while the insulin dosage is gradually increased until control is re-established.

### NPH at bedtime

Addition of an injection of NPH insulin within an hour of bedtime is usually able to restore adequate fasting glycemic control for patients who are no longer well-controlled with one or more oral agents alone. This tactic may be best employed in patients who do not eat a very large meal toward the end of the day and thus do not need short-acting insulin at suppertime. A multicenter trial has shown bedtime NPH insulin plus daytime oral agents achieves glycemic control as effectively as insulin taken in the morning with oral agents, or mixed intermediate and regular insulin twice daily without oral agents; however, there is less weight gain with evening NPH [89]. Other trials show better glycemic control with bedtime NPH plus a sulfonylurea than with a single injection of insulin alone [87,88]. Evening NPH insulin also reduces free fatty acids to a greater degree than use of daytime insulin. Patients can begin with a low dose of NPH insulin, usually about 10 units. They are instructed to self-titrate the dose up by 2–4 units every 3–7 days based upon the stability of their fasting glycemic response [86]. Stable patients may titrate more quickly, based upon the pattern of response, but there is little reason to hurry because glucose control will steadily improve at any rate of titration so long as the oral agents are continued. The insulin dosage required is frequently in the range of 30–50 units daily [91], or about 0.4–0.5 units/kg body weight. The target for fasting glucose should be individualized and adjusted when hypoglycemia occurs, but often can be ADA recommended 90–130 mg/dL (5–7.2 mmol/L) value in plasma-referenced home glucose-monitoring systems. Patients need to wake at a reason-

ably consistent time and eat breakfast consistently. Oral agents are continued, although sulfonylureas are usually given only with the first meal of the day. A randomized trial has examined the choice of daytime therapy accompanying bedtime NPH insulin [89]. This study compared four different regimens in a prospective 1-year randomized controlled trial. The four regimens included bedtime insulin combined with morning insulin, glyburide alone, metformin alone or glyburide combined with metformin. The least weight gain occurred when metformin was the only oral agent, and hypoglycemia was a limiting factor when glyburide was used.

### Pre-mixed insulin with the evening meal

A second form of evening insulin that appears to work better for more obese patients (BMI >30 kg/m<sup>2</sup>) is the combination of morning sulfonylureas and suppertime mixed insulin, the latter commonly offered as 70/30 (70% NPH with 30% Regular) insulin. In a multicenter study using the long-acting sulfonylurea glimepiride [90], patients achieved a more rapid restoration of glycemic control with self-titration of 70/30 insulin while continuing the oral agent, rather than with insulin alone. Insulin was started at 10 units and titrated weekly, seeking FPG equivalent to 140 mg/dL (7.8 mmol/L, plasma-referenced). Nearly all subjects using the combination regimen reached the titration target rapidly, but 15% of the subjects in the placebo plus insulin group dropped out, mainly because of hyperglycemia during the transition to insulin. The mean HbA<sub>1c</sub> declined from almost 10% (86 mmol/mol) to 7.6% (60 mmol/mol) for subjects completing the trial in both groups. The mean dose in the insulin alone group was 78 units and for the glimepiride plus insulin combination was 49 units. More subjects in this study who were on insulin alone needed doses higher than 100 units daily, and so had to take more than one injection. A smaller study with a more aggressive titration scheme found better glycemic control using 70/30 insulin with the evening meal plus glyburide once daily than with evening insulin alone [83]. Premixed rapid analog mixes [e.g. lispro–neutral protamine lispro (25/75%) and aspart–neutral protamine aspart (30/70%)] similarly may achieve control with somewhat more convenient meal timing of insulin. It is critical for safety that patients understand the appropriate timing of meals and do not skip meals. Garber *et al.* [96] have reported a small observational study using either once, twice or three times daily administration at meal time of the 70/30 aspart mixture in patients inadequately controlled on oral agents with or without basal insulin treatment. In this study, once daily administration at dinner of 70/30 reduced HbA<sub>1c</sub> by 1.4% (15 mmol/mol), twice daily at breakfast and supper by 1.9% (21 mmol/mol) and thrice daily with an added lunch dose by 1.8% (20 mmol/mol). Use of insulin pens at meal times is often desirable especially for those who eat outside the home frequently. Pre-mixed insulins are commonly given twice a day, sometimes more or less frequently. When given more frequently they may become somewhat non-intuitive as to which dose to adjust and this may confuse some patients.

**Figure 31.9** Improved metabolic control with patient titration of insulin. Metabolic control (FPG and HbA<sub>1c</sub>) improved in all insulin-treated patients in the treat to target study. Based upon a forced titration strategy of increases between 2 and 8 units each week based upon average fasting plasma glucose (FPG; an average of 2 days) after starting with 10 units, the course of FPG (solid line) and HbA<sub>1c</sub> (dotted line) are depicted on the left and right of the above figure. By week 18, FPG decreased from 206 mg/dL to 116 mg/dL ( $P = 0.0001$ ) and HbA<sub>1c</sub> decreased from 8.6% to 6.9%. To convert to mmol/L divide FPG values by 18. DCCT result (%) =  $(0.0915 \times \text{IFCC result in mmol/mol}) + 2.15$ .

### Insulin glargine at bedtime

A study using insulin glargine [97] suggested this agent offers another option for starting insulin with an evening injection. In this 1-year European study, 426 subjects were randomly assigned to either insulin glargine or NPH insulin at bedtime, while continuing previous oral therapy. The therapeutic target was a fasting blood glucose  $<120$  mg/dL (6.7 mmol/L), using a method that was probably not plasma-referenced. The insulin dosages used (23 units for glargine and 21 for NPH) and HbA<sub>1c</sub> values achieved (8.3% and 8.2%, 67 mmol/mol and 66 mmol/mol) were similar with the two insulins, but the rates of hypoglycemia were significantly less for the group using glargine (33% vs 51% for all symptomatic hypoglycemia), despite similar average insulin doses. Nocturnal hypoglycemia occurred in less than half as many subjects using glargine (13% vs 28%). Moreover, glucose control was better in the afternoon and evening with glargine, presumably because of its longer duration of action than NPH.

The Treat to Target Trial (Figure 31.9) [91], also compared insulin glargine with NPH insulin at bedtime. Subjects in this study averaged a baseline HbA<sub>1c</sub> of 8.6% (70 mmol/mol). Both NPH and glargine study groups were instructed to initiate doses of 10 units of insulin at bedtime and each week the dose was raised between 0 and 8 units based upon how close the subjects were to the glycemic goal ( $<5.5$  mmol/L; 100 mg/dL). This forced weekly titration of dose based upon fasting glucose concentration with patient self-adjustment according to the pattern of therapy response was a key concept in reaching the targeted goal of HbA<sub>1c</sub>  $<7\%$  ( $<53$  mmol/mol) in about 60% of patients in this study on both NPH and glargine insulin. Subjects in this study did not need to achieve the targeted FPG because hypoglycemia would have been too frequent. Hypoglycemia overnight was more common with NPH insulin as might be expected based upon the differences in kinetics of NPH versus glargine with the former

having a greater peak effect usually within the first 4–8 hours after subcutaneous administration.

### Insulin detemir

Insulin detemir is a newer formulation of intermediate- to long-acting insulin with a duration of effect in type 1 diabetes single-dose studies that is dose-dependent. Based upon a common dosage of 0.4 units/kg, an average duration of action of about 20 hours is predicted. With higher doses a longer duration approaching 24 hours is achieved [98]. In one study [99], twice daily insulin therapy with NPH versus detemir was compared in subjects with T2DM inadequately controlled (HbA<sub>1c</sub> 8.5% [69 mmol/mol] and 8.6% [70 mmol/mol] for NPH and detemir, respectively) on therapy (mostly metformin plus secretagogues with some use of  $\alpha$ -glucosidase inhibitors and about 30% of subjects not on oral agents when insulin was used). A total of 475 subjects were randomized to participate in a 24-week study comparing twice daily administration of these two insulins at breakfast and bedtime. Starting with 10 units per injection subjects were instructed to titrate doses every 3 days based upon pre-dinner and pre-breakfast self-monitored glucose averages from 2 up to 10 units per injection. At 24 weeks, subjects with insulin detemir decreased HbA<sub>1c</sub> by 1.8% (20 mmol/mol) to an average value of 6.8% (51 mmol/mol), while subjects on NPH decreased the HbA<sub>1c</sub> by 1.9% (21 mmol/mol) to an average value of 6.6% (49 mmol/mol). Most subjects (about 70%) achieved HbA<sub>1c</sub> less than 7% ( $<53$  mmol/mol) but more subjects on detemir achieved the goal without hypoglycemia. Overall hypoglycemia was significantly less on detemir, which by non-inferiority analysis was comparable in overall glycemic lowering efficacy to NPH. Doses of insulin were a bit higher than might have been expected (36.1 units in the morning and 29.5 units in the afternoon for detemir; and 25.3 units in the morning and 19.7 units in the afternoon for

NPH) given that the average BMI of these patients was a little over 29 kg/m<sup>2</sup>. Detemir can be administered once in the evening or twice daily. Its desirable features include a lower rate of hypoglycemia, somewhat greater consistency in glycemic response from day to day, and possibly a reduced tendency for weight gain.

### Optimal manner of initiating insulin and progressive insulin treatment

Recent studies have tried to readdress the issue of whether there is a best way to initiate insulin treatment. The strategy of basal insulin only vs the alternative of basal and prandial insulin combined continues to be addressed. The 4-T Study, which is a multicenter multiyear trial of insulin therapy carried out in an open-label manner is one such study [100]. In this study, 708 patients with HbA<sub>1c</sub> of 7–10% (53–86 mmol/mol) while on maximally tolerated doses of metformin and sulfonylureas were randomized to receive biphasic insulin aspart (70/30) twice daily at breakfast and supper, prandial insulin aspart three times daily, or basal insulin detemir once daily or twice if required. The outcomes of this study included mean glycated hemoglobin level, the proportion of patients with a glycated hemoglobin level of 6.5% or less (<48 mmol/mol), the rate of hypoglycemia, and weight gain. At 1 year, mean HbA<sub>1c</sub> levels were similar in the biphasic group (7.3%, 56 mmol/mol) and the prandial group (7.2% [55 mmol/mol];  $P = 0.08$ ) but higher in the basal group (7.6% [60 mmol/mol];  $P < 0.001$ ) for both comparisons. The proportions of patients with HbA<sub>1c</sub> level of 6.5% or less were 17.0%, 23.9% and 8.1% in mixed insulin, prandial insulin and basal insulin, respectively. The average of hypoglycemic events per patient-year was 5.7, 12.0 and 2.3, respectively. The mean weight gains were 4.7, 5.7 and 1.9 kg, respectively. Rates of adverse events were similar among the three groups. After 3-years of treatment, the median HbA<sub>1c</sub> ranged from 6.8–7.1% (51–54 mmol/mol) and did not differ between groups [101]; however, there were important differences between the regimens. Fewer participants receiving biphasic insulin reached a target of either of 6.5% (48 mmol/mol) or 7.0% (53 mmol/mol) than the other groups. Hypoglycemia rates were lowest in those who began with basal insulin while weight gain was highest in those who began with prandial insulin. The authors concluded that this study provides evidence to support the addition of basal insulin to oral therapy with subsequent intensification to a basal-bolus regimen as the preferred method of insulin initiation in people with type 2 diabetes. A subsequent editorial, however, felt that while it was clear that insulin initiation with basal insulin is preferred to prandial insulin, biphasic insulin may still provide an effective means of obtaining glycemia control for patients and clinicians wanting a less intensive insulin regimen [102].

In general, the authors' practice is to begin patients on either a weight-based dose (e.g. 0.2 unit/kg) or an arbitrary starting dose and titrate basal insulin weekly or every 3 days if quite stable with the dose, increase by 2–4 units if on low doses or by 10–20% of basal dose if higher insulin doses are needed or if the patient is

poorly controlled. Patient self-titration is clearly more effective than waiting until the next physician visit and involves the patient in their own care.

When patients no longer can continue adequate glycemic control despite fasting glycemia in a desirable range or if erratic fasting control exists, the authors often add meal insulin at dinner or at the largest meal of the day based on weight (0.1 units/kg) or an arbitrary low dose and titrate upward by assessing 2-hour post-prandial glucose levels [93]. The overuse of basal insulin alone can lead to serious hypoglycemia overnight. When there is a history of overnight or early morning hypoglycemia, testing of post-prandial control is very important. Commonly, one needs to make at least a unit for unit trade-off between meal insulin and basal insulin; as the former increases, an equal decrease in basal insulin helps to minimize nocturnal hypoglycemia.

## In-Hospital Treatment and Surgery in Patients with Diabetes

**Maggie Sinclair Hammersley<sup>1</sup> & June James<sup>2</sup>**

<sup>1</sup>Nuffield Department of Medicine, University of Oxford, Oxford, UK

<sup>2</sup>University Hospitals of Leicester, Leicester, UK

### Keypoints

- The diabetes epidemic is not sparing hospital practice. Approximately 12–24% of all hospital inpatients have diabetes.
- A significant proportion of hospital inpatients with hyperglycemia have undiagnosed diabetes and stress hyperglycemia.
- Hospitalization frequently presents a missed opportunity to diagnose diabetes and to identify those at risk for diabetes.
- In-hospital hyperglycemia and hypoglycemia are associated with poor outcomes in a broad range of specialties.
- There are few randomized controlled trials demonstrating benefit from interventions in the inpatient care setting.
- Hospital inpatients with diabetes frequently have multiple comorbidities and complex medical and nursing requirements.
- Ward-based staff are frequently poorly trained and therefore ill-equipped to manage diabetes care safely and effectively.
- Care of the critically ill patient with diabetes and hyperglycemia requires highly skilled and appropriately trained staff.
- Insulin and diabetes management errors continue to compromise patient safety.
- Structured diabetes care delivered by appropriately trained staff and supported by a dedicated specialist inpatient team in partnership with the patient improves the patient experience, reduces diabetes prescribing and management errors and length of stay in many clinical settings in hospital.
- Patients with diabetes are more likely to undergo in-hospital procedures and should be individually managed by agreed and audited protocols.
- Patients undergoing surgery should have a preoperative assessment, a robust risk assessment and an individualized care plan including a safe and effective discharge plan.
- Standards of care for hospital inpatients have been defined by professional organizations but are not globally implemented.
- Audit of inpatient care reveals poor standards of care and patient experience and demonstrates the inadequacy of present systems and processes.

### Introduction

#### Known diabetes in hospital

The global burden of diagnosed diabetes has reached epidemic proportions. The International Diabetes Federation predicts that by the year 2030 prevalence rates of type 2 diabetes will have increased by approximately 20% in Europe and by 65–98% in less economically developed countries [1]. Disproportionate numbers of people admitted to hospital have diabetes. The prevalence of diabetes in the inpatient population is almost certainly underestimated because of poor coding of diabetes as a co-morbidity. This applies equally to both planned and emergency care. Conservative estimates of diagnosed diabetes are between 12% and 24% of all inpatients in the USA [2]. Every year people with diabetes spend approximately 1.34 million days in hospital and it

is estimated that in the UK there are 80 000 excess bed days per year. The cost of caring for inpatients with diabetes is around £485 million per year [3].

#### Undiagnosed diabetes and stress hyperglycemia in hospital

The number of hospital inpatients with diabetes has increased and is rising inexorably. This only represents the tip of the iceberg, however, as it takes no account of those patients with a raised plasma glucose level without a diagnosis of diabetes. In addition to those with diagnosed diabetes, there are two other groups of patients with hyperglycemia in hospital. First, there are those with unrecognized diabetes occurring during hospitalization and subsequently confirmed after discharge and, secondly, those with so-called “hospital-related” hyperglycemia (fasting plasma glucose >126 mg/dL (7 mmol/L) or random >198 mg/dL (11 mmol/L), occurring during hospitalization, which reverts to normal after discharge (also known as “stress hyperglycemia”). Recent studies suggest that these two groups may add a further 30% to the total numbers with raised plasma glucose levels [4].

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

So when the burden of “in-hospital hyperglycemia” is considered to include all three groups, then the prevalence is approximately 40% of all hospital inpatients.

---

### **Evidence of harm from in-hospital hyperglycemia and benefit of glucose lowering**

There is compelling evidence that poorly controlled blood glucose levels are associated with a higher in-hospital morbidity and mortality, prolonged length of stay, unfavorable post-discharge outcomes and significant excess health care costs [5–9]. Umpierrez *et al.* [4] showed that patients with new hyperglycemia had an 18-fold increased in-hospital mortality and patients with known diabetes had a 2.7-fold increased in-hospital mortality when compared with normoglycemic patients [4]. In 2004, a joint position statement from the American College of Endocrinology (ACE) and the American Association of Clinical Endocrinologists (AACE) on inpatient diabetes and metabolic control concluded that hyperglycemia in hospitalized patients is a common, serious and costly health care problem [10]. There was a strong recommendation for early detection of hyperglycemia and an aggressive management approach to improve outcomes.

Randomized trials have demonstrated improved outcomes resulting from more aggressive management of hyperglycemia in the following areas.

#### **Acute coronary syndromes**

It is not clear whether high glucose is a marker or mediator of poor outcomes in acute coronary syndromes (ACS). In the management of myocardial infarction a meta-analysis of 15 studies showed that blood glucose (BG) >120 mg/dL (6.1 mmol/L), with or without a prior diagnosis of diabetes, was associated with an increased in-hospital mortality and subsequent heart failure [11]. Current evidence supports the use of intravenous insulin in the first 24 hours and intensified subcutaneous insulin for 3 months in the setting of ST-segment elevation myocardial infarction (STEMI) where the DIGAMI 1 study showed a 29% reduction in mortality at 1 year [12]. Other randomized controlled trials such as DIGAMI-2 and CREATE-ECLAT have failed to reproduce these findings [13,14].

Observational data from the UK Myocardial Infarction National Audit Programme (MINAP) of patients with troponin-positive ACS demonstrated poorer outcomes in those with an elevated BG on admission, with 30-day mortality of 20.2% in those with BG >170 mg/dL (9.4 mmol/L) compared with 3.3% in those with BG <170 mg/dL (9.4 mmol/L). Of 38 864 patients recorded on the MINAP database, around 10% (of those with no prior diagnosis of diabetes) had an admission BG >250 mg/dL (14 mmol/L). Patients who did not receive treatment with intravenous insulin had a relative increased risk of death of 56% at 7 days and 51% at 30 days [15].

#### **Cardiac surgery**

Most of the outcome data for patients undergoing cardiac surgery relates to the Portland Diabetic Project, which was a non-randomized observational study of 5510 patients undergoing cardiac surgery during 1987–2005. This has shown that patients with hyperglycemia managed with an intravenous infusion titrated to normoglycemia for 3 days postoperatively had improved mortality, reduction in deep sternal wound infections and reduction in length of stay [16].

#### **Critical care setting**

The landmark study by Van den Berge *et al.* [17] showed that postoperative intensive insulin therapy (IIT) reduced mortality and morbidity in patients in the surgical intensive treatment unit (ITU). In a later study by the same group in medical ITU patients, IIT reduced morbidity but not mortality [18]. Randomized trials of IIT have shown inconsistent effects on mortality and increased rates of severe hypoglycemia. A recent meta-analysis of 26 trials involving 13 567 patients including the recent NICE-SUGAR trial, the pooled relative risk of death with IIT compared with conventional therapy was 0.93 (95% CI 0.83–1.04). Fourteen trials reported hypoglycemic events and showed a significant increase in severe hypoglycemia with a relative rate (RR) of 6.0 (95% CI 4.5–8.0). The different targets of IIT did not influence either mortality or risk of hypoglycemia [19].

---

### **Pathophysiology of hyperglycemia in acute illness**

A key goal of inpatient diabetes management is minimizing the metabolic decompensation from the stress of illness and surgery. Stress-induced hyperglycemia is caused by the combined effects of integrated endogenous hormonal, cytokines and counter-regulatory nervous system signals on glucose metabolic pathways [20]. Inflammatory and counter-regulatory responses to critical illness alter the effect of insulin on hepatic glucose production and skeletal muscle. Stress leads to the increased secretion of counter-regulatory hormones (glucagon, epinephrine, norepinephrine, cortisol and growth hormone), which stimulates hepatic glycogenolysis and gluconeogenesis. Peripheral uptake of glucose is inhibited. A major consequence of severe hyperglycemia is osmotic diuresis accompanied by dehydration and electrolyte disturbances (sodium, potassium, magnesium and phosphate). This increased osmotic state is procoagulant.

The stress hormones also accelerate fat and protein breakdown leading to a generalized catabolic state. In the surgical setting, starvation preoperatively and postoperatively can be a large contributor to this process. In people without diabetes, a compensatory increase in insulin secretion helps to mediate against these catabolic effects. Patients with an absolute insulin deficiency are prone to unopposed lipolysis and ketone body formation that can ultimately result in diabetic ketoacidosis.

Stress increases the release of inflammatory mediators, leading to insulin resistance and hyperglycemia [21]. Inflammatory cytokines interleukin-1, interleukin-6 and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) may directly or indirectly enhance both hepatic gluconeogenesis and glycogenolysis. TNF- $\alpha$  alters the signaling properties of insulin receptor substrate, leading to enhanced target organ insulin resistance.

Wound healing and the susceptibility to infection are also affected by hyperglycemia and insulin deficiency, as demonstrated by *in vitro* studies looking at white blood cell functioning [22]. Hyperglycemia-induced abnormalities in the phagocytic and bactericidal actions of neutrophils are reversed with improved glucose control.

There are other causes of hyperglycemia, which may be more specifically related to the hospital admission [23]. These include co-administered medications such as corticosteroids and immunosuppressants (e.g. cyclosporine, tacrolimus). Immobility secondary to surgery, trauma or acute illness can accelerate both hyperglycemic and procoagulant states.

### Effects of glucose lowering and intravenous insulin therapy

The mechanisms behind the improved outcomes from intravenous insulin are numerous. The vasodilatory, anti-inflammatory and anti-atherogenic effects of insulin have been studied. *In vitro*, insulin induces a dose-dependent increase in nitrous oxide synthase production in the endothelium. Ultimately, insulin treatment may improve endothelial function in patients with diabetes [24].

---

## Current recommended standards of care for hospital inpatients with diabetes

Several professional organizations from different countries have published suggested standards of care for hospital inpatients. The International Diabetes Federation (IDF) is an umbrella organization of over 200 national diabetes associations in over 160 countries which has also published a standards document about inpatient care in type 2 diabetes. The content of the major publications are reviewed below. There are a number of recurring themes which include equitable access to specialist services, empowerment of patients, delivery of care by agreed guidelines, setting of glycemic targets and embedding effective and audited hyperglycemic management protocols.

### International Diabetes Federation 2005

Within the guideline produced by the IDF on the care of patients with type 2 diabetes, a number of recommendations were made concerning inpatient care [25]. The standard recommendation of the IDF group fell broadly into four categories:

**1 Inpatient care organization.** This should be undertaken by a trained diabetes care health care professional with focus on

individual plans including discharge and follow-up, access to the multidisciplinary team and appropriate laboratory and investigative procedures, increasing staff awareness of the needs of people with diabetes and implementing strategies to prevent patient disempowerment by promotion of self-management of diabetes.

**2 General ward care.** Patients should be empowered to self-manage where appropriate with regard to glucose monitoring, food choices and insulin administration.

**3 Care of patients undergoing inpatient procedures.** There should be provision for assessment of glycemic control and of metabolic and vascular risk for those undergoing planned procedures and agreed protocols should be in place. Staff should be made aware of the special risks associated with diabetes such as development of new ulceration, cardiac risk and renal failure.

**4 Care of the critically ill.** Patients should be managed according to a strict glycemic protocol with glucose levels kept <110 mg/dL (6.1 mmol/L) and an active avoidance of hypoglycemia.

## American Diabetes Association and American Association of Clinical Endocrinologists 2006

The American Diabetes Association (ADA) *Technical Review on the Management of Diabetes and Hyperglycemia in Hospital* was published as an in-depth review of the literature on this topic and outlined practical management strategies [26]. The implementation of these policies and recommendations had remained an elusive goal in everyday clinical practice. Therefore, in 2006, the ADA and the American Association of Clinical Endocrinologists (AACE) produced a further consensus statement entitled *Inpatient Diabetes and Glycemic Control: A call to action* in an attempt to identify and overcome barriers to change in practice to facilitate improvement in inpatient diabetes care [27]. This was updated in 2009 with new glycemic targets based on recent publications that have demonstrated concern about the harmful effect of in-hospital hypoglycemia in some clinical settings [28].

### Canadian Diabetes Association

The Canadian guidelines include separate sections on peri-operative and peri-acute coronary syndrome glycemic control, recommending glucose levels of 6.1 mmol/L in post surgical ITU patients and 128–180 mg/dL (7.1–10 mmol/L) in peri-myocardial infarction patients [29].

### UK Diabetes Services

#### National Service Framework for Diabetes 2004

The Diabetes National Service Framework set out the first set of national standards for the treatment of diabetes [30]. Two standards were set for hospital care.

**1 Standard 7.** The NHS will develop, implement and monitor agreed protocols for rapid and effective treatment of diabetic emergencies by appropriately trained health care professionals. Protocols will include the management of acute complications and procedures to minimize the risk of recurrence.

**2 Standard 8.** All children, young people and adults with diabetes admitted to hospital, for whatever reason, will receive effective care of their diabetes. Wherever possible, they will continue to be involved in decisions concerning the management of their diabetes.

#### **National Diabetes Support Group (NHS Diabetes) 2008**

In 2008, the National Diabetes Support Group produced a document focusing on improvement of diabetes inpatient services and the commissioning of these services [31]. NHS Diabetes has now updated the commissioning toolkit to include the commissioning of emergency and inpatient care [31].

#### **Diabetes UK 2009**

Diabetes UK has produced a document for patients entitled “What care to expect in hospital”, available from Diabetes UK [32]. It is hoped that this empowerment of patients will help to drive up in-hospital standards of care. Diabetes UK in partnership with NHS Diabetes and a number of other professional bodies through the “Putting Feet First” campaign have recently promoted the dissemination of a national guideline for the management of patients with acute diabetic foot problems in hospital.

#### **National Health Institute of Innovation and Implementation 2009**

The National Health Institute of Innovation and Implementation recently launched a package of recommendations to improve standards of care in hospital inpatients. This was branded the “Think Glucose” campaign and has been cascaded to all UK hospitals. Each acute hospital in the UK has been provided with a set of recommendations and a toolkit to drive improvement in standards [33].

---

### **Aims of diabetes inpatient care**

Diabetes care in hospital inpatients poses a real challenge as most patients are admitted to a hospital bed with a condition unrelated to their diabetes, be that electively or as an emergency. Non-diabetes specialists are often in charge of their care, and they may often have little understanding of diabetes management and its importance on patient outcomes. As a result, there can be an increased risk of harm from issues such as lack of insulin dose adjustment or prescribing errors.

#### **Achieving a good outcome**

Patients should come to no harm because of their diabetes management. Hypoglycemia and excessive hyperglycemia are both associated with poorer clinical outcomes and should be managed according to local protocols. Clinical guidelines supported by the use of integrated care pathways should be in place to drive up standards of care. Management by a specialist team with agreed protocols against agreed standards improves care for those admitted to hospital [34].

#### **Supporting a rapid recovery**

Patients with diabetes are twice as likely to be admitted to hospital and stay twice as long in a hospital bed [35]. Minimizing excess length of stay should be one of the principal aims of good inpatient care. Prolonged length of stay occurs for a multiplicity of reasons but is often because of diabetes mismanagement secondary to poor staff knowledge and lack of education. There is evidence that involvement of the specialist diabetes team, and in particular diabetes inpatient specialist nurses (DISNs), significantly reduces length of stay and insulin errors and improves the patient experience [36–38]. This requires a culture that invests in excellent communication between the person with diabetes, diabetes specialists and non-specialist teams to activate timely intervention by avoiding glycemic deterioration during hospital stay.

#### **Facilitating a good patient experience and patients expressed concerns about inpatient care**

Patients are accustomed to managing their own diabetes. Traditionally, patients are disempowered in the management of their diabetes as soon as they are admitted to a hospital bed. For those people with diabetes accustomed to self-management by insulin adjustment this is a negative experience [35]. The ADA [28] and Diabetes UK [32], while acknowledging the importance of diabetes self-management, highlighted the need to educate people with diabetes to deliver safe self-care in the hospital setting. Individuals suitable for self-management in hospital must be competent adults with a stable level of consciousness who successfully manage their diabetes at home. In addition, while in hospital it is advised that these patients have the physical skills appropriate to self-administer insulin; be accustomed to performing self-monitoring of blood glucose; and have adequate oral intake. In the event that self-care is deemed unsafe or impossible (e.g. critically ill, post surgery or unwilling), then there must be a governance arrangement to assess patient competency and if necessary supersede patients’ right to self-care.

Encouraging and supporting patients to have as much responsibility for their diabetes management as they wish for, and their clinical status allows, is likely to enhance the patient experience during a hospital stay. The Diabetes UK position statement on what care adults with diabetes should expect in hospital clearly focuses on the importance of patient self-management, while reminding health care professionals of the importance of policies and strategies being in place to support this concept in the ward setting (Table 32.1).

---

### **Barriers to safe and effective diabetes care delivery in hospital**

#### **Systems failures**

It is essential that the patient with diabetes is identified and flagged at an early stage of the admission process. The ADA recommends that all patients admitted to hospital should be identified in the medical record as having diabetes. The UK NHS

**Table 32.1** Patients' experiences of in-hospital diabetes care [60].

1	Experiences of disempowerment and distress. Patients felt that they were not engaged as partners in their care during their admissions, and in some cases patronized by staff members
2	Food/food timings and their coordination with medication. This often reflected a lack of understanding amongst staff of the relationship between food and good diabetes management
3	Medicines mismanagement in hospital. People were given the wrong medication or dose
4	Lack of communication between different multidisciplinary team members and with the person with diabetes. This led to basic failures in communication such as notification of both changes in timings of procedures and dosages of medications to the patient
5	Lack of hospital staff knowledge of diabetes management both in terms of basic care and respecting patient autonomy
6	Importance of people with diabetes being allowed to self-manage and thereby respecting the role of the person with diabetes in usually self-managing their condition on a daily basis
7	Positive experiences of good diabetes management and proactively allowing patients to self-manage

Institute for Innovation and Improvement also recommends a diabetes identifier as a prerequisite for ensuring quality of care [33]. Yet this has not been achievable in the UK in secondary care because of systems failure as a result of poor coding and inadequate information systems technology. In addition, if we are to identify those patients with undiagnosed diabetes and stress hyperglycemia and make an impact on their poor outcomes there needs to be a policy of routine blood glucose screening for all hospital inpatients. This is not standard practice in the UK.

### Ward environment factors

Basic diabetes care is often not well delivered in hospital. An analysis of 44 US hospitals revealed persistent shortcomings in diabetes management, including persistent excessive hyperglycemia [39]. The hospital environment is one that is characterized by instability and unpredictability for the patient. It is a major contributor to the difficulty of managing inpatient diabetes well. Intercurrent illness, in-hospital changes to a patient's usual outpatient regimen, and the scheduling and unpredictability of tests and procedures contribute to glycemic instability [40]. A patient's dietary intake may also be erratic, because of poor appetite, palatability of food or timeliness of delivery.

### Staff training challenges

In the UK, qualified staff numbers have been reduced to a minimum and ward staff have little or no protected time for education and training other than mandatory training (fire, manual handling, back care, infection control) defined by the employing organization. Despite the large numbers of patients with diabetes in hospital, the only mandatory training in diabetes is in blood glucose monitoring. People with diabetes, who gener-

### Box 32.1 Defining adverse events and medical errors

Adverse events are described as: An unintentional injury caused by medical management rather than the underlying disease or condition of the patient. This can include physical or emotional harm [61]

Medical errors are described as: The failure to complete a planned action as intended or the use of a wrong plan to achieve an aim [61]

ally have a high level of knowledge about their condition, are therefore often being managed by nursing and medical staff with only a rudimentary training in diabetes care [41].

### Insulin prescribing and delivery errors

Insulin treatment in hospital can be life-saving. It also has the potential to be life-threatening given its narrow therapeutic index. The prescribing of insulin is a minefield of ignorance and error. Insulin has been identified as one of the top five high-risk medications in the inpatient environment [42,43]. There is a wealth of material, predominantly from the USA and the UK, describing both medical errors and adverse events in the general inpatient population (Box 32.1). Medical errors, including those related to insulin treatment, are described as common in hospitals worldwide [44,45]. Insulin medication errors can occur at any stage in the process of prescribing, preparing and delivering the medication to the patient [46]. The potential consequences of error can be catastrophic. One-third of all inpatient medical errors that cause death within 48 hours of the error involve insulin administration [47].

### Medical prescribing

A common recommendation emerging in both diabetes management and prescribing errors has been the need for appropriate medical staff education in diabetes and insulin treatment. Hellman [47] suggests that endocrinologists take on this role and maintain that junior doctors should be taught the principles of drug dosage and prescription writing before starting their ward placements. A report from the National Patient Safety Agency 2007 [49] devotes one entire page to insulin errors and advocates changes to pre-registration training to incorporate the principles and therapeutics of safe prescribing. The curriculum for junior doctors has been revised in recent years and new models of education have been implemented yet this has not reduced insulin prescribing errors in junior hospital doctors and therefore the process merits review.

### Non-medical prescribing

In the UK, legislation for nurse prescribing, now known as non-medical prescribing, was implemented in 2003. The editorial by Aronson *et al.* [50] compared medical student training (approximately 61 hours) to that of nurse prescribers (162 hours of theory

and 90 hours in practice). The authors called for the adoption of the British Pharmacological Society's prescribing and assessment processes to be applied for doctors in training in the teaching of diabetes and insulin treatment. Aronson also called for the formation of an independent systematic review of medical prescribing and teaching by a multi-organizational body in order to inform practice. This process has yet to be implemented but if introduced could form the basis for training in diabetes medicines management.

---

### **Delivering effective diabetes care: the role of diabetes inpatient team**

Diabetes inpatient teams are multidisciplinary; the health care professionals involved individually contribute specialist skills and together provide a holistic approach to patient care. As well as operating as a discreet unit, the team works closely with other medical specialities including the specialist diabetic foot team. The defined roles forming the diabetes specialist inpatient team include the following.

#### **The Patient**

Central to the diabetes team is the patient. The majority of people living with diabetes have developed highly competent and individualized management skills, therefore it is essential, where possible, that the patient is encouraged to participate in the formulation and conduct of their own care plan while in the ward setting.

#### **Consultant physician**

The primary role of the consultant physician is as leader of the multidisciplinary team. The consultant physician has ultimate responsibility for the clinical care of diabetes inpatients. They work closely to provide clinical support to diabetes specialist nurses (DSNs) and certified diabetes educators (CDEs), while being heavily involved in the training and education of other diabetes and non-diabetes health care professionals. With the need to maintain standards of care and update clinical guidelines, physicians are also frequently involved in audit and research work in order to ensure the highest quality of diabetes care for inpatients with diabetes.

#### **Certified Diabetes Educator**

In 2009, the Association of Diabetes Educators published a position statement, which emphasized the key role of CDEs in patient and staff education, the promotion and implementation of glycemic control strategies and appropriate nutritional therapies. In close partnership with social work, case managers and home care coordinators, they are able to facilitate a smooth patient pathway from hospital to home at discharge.

#### **Diabetes specialist nurse**

The work of DSNs is exclusively in diabetes care. In 2009, there were 1361 DSNs in the UK working in primary and/or secondary

care settings. DSNs deliver patient-centered care wherever required and influence care delivery at every stage of the patient journey, including inpatient care. The role of the DSN has evolved in recent times and specifically focuses on supporting inpatients and the ward staff caring for them. Aside from clinical care, DSNs are frequently involved in medical and nursing education and also in guideline production and update. Not only can DSNs significantly reduce inpatient length of stay [36,37], but if they also obtain non-medical prescribing skills, have also been seen to reduce insulin and diabetes management errors significantly [38].

#### **Diabetes specialist dietitian**

Diabetes specialist dietitians have a pivotal role in the care of diabetic inpatients with complex nutritional needs, in particular those patients who are unable to swallow or those required to adhere to a complex dietary regimen as in renal failure, cystic fibrosis and the elderly.

Other team members may include ward-based diabetes link nurses and diabetes specialist pharmacists.

#### **Which type of patient needs to be seen by the diabetes specialist team?**

The correct answer to this question is that all patients with diabetes should have access to specialist diabetes services; however, given that up to 20% of all inpatients now have diabetes then in real world it is going to be almost impossible for specialist team members to see every patient. Specialist teams therefore, driven by need, have drawn up a priority list for which patients should be referred for assessment. An example of one of these referral criteria documents from Leicester, UK, is seen in Table 32.2.

---

### **Management of in-hospital hyperglycemia**

All hospitals should have a policy for glycemic management and or blood glucose monitoring in place according to the ADA [28] or the National Institute for Health, Innovation and Improvement (NHSI) standards of care. The newly introduced UK "Think Glucose" campaign from the NHSI has as its mantra, "It is as unacceptable for hospitals not to have a glycemic management policy as it is for them not to have an infection control policy" [33].

Hyperglycemia in hospital is a common problem and occurs in around 25% of all hospital inpatients. The majority of patients with diabetes are not admitted to hospital to address and treat complications associated with the disease. Control of blood glucose often becomes secondary to the care of the primary diagnosis requiring admission. In patients without diabetes who develop hyperglycemia during an acute illness, high glucose levels are often ignored or treated inappropriately. Poor glycemic control is common among inpatients with diabetes, particularly

**Table 32.2** Indications for referral to diabetes inpatient specialist nurses (DISN). Adapted from University of Leicester Hospitals, UK.

Always refer	Hyperglycemic emergencies (e.g. DKA, HHS) Acute coronary syndromes Severe or repeated hypoglycemia New diagnosis of diabetes Problems with intravenous insulin infusion or duration >48 hours Active foot ulceration Reduced consciousness Enteral or parenteral nutrition Vomiting and sepsis Patient request Persistent hyperglycemia Pregnancy

DKA, diabetic ketoacidosis; HHS, hyperosmolar hyperglycemic syndrome; NBM, nil by mouth.

in those treated with insulin, for many reasons. Poorly defined management plans, poor coordination of care, overly high or absent glycemic targets, lack of therapeutic adjustment, over utilization of “sliding scales” which are often not adjusted to optimize control and under-utilization of insulin infusions represent some of the reasons for poor control of blood glucose. A further important contributing factor has been the fear of provoking hypoglycemia.

**Intravenous insulin to treat in-hospital hyperglycemia**

Insulin provides the greatest flexibility in the hospital setting to achieve optimal blood glucose control. As protocols for tight glucose control are introduced in a variety of hospital settings it will be essential to implement safeguards to minimize the risk of hypoglycemia and ensure patient safety. The systemic problems that create obstacles to appropriate and safe care of patients receiving insulin in hospital are well recognized [45]. Insulin administration errors could be minimized and clinical outcomes improved by thorough analysis of the setting, additional training for ward staff, setting of goals focused on patient safety, double checking of insulin prescription and administration and regular audit of adverse incidents.

**Indications for an intravenous insulin infusion**

Whether the patient has previously recognized diabetes or not, insulin provides the greatest flexibility to meet rapidly changing

**Box 32.2 Indications for an intravenous insulin infusion**

- To treat critical care illness
- Acute coronary syndromes
- Postoperative periods following heart surgery
- Patients on “nil by mouth” status
- Type 1 diabetes
- General preoperative, intra-operative and postoperative care
- Organ transplantation
- Stroke
- Hyperglycemia during high-dose corticosteroid therapy
- Labor and delivery
- Other acute illness for which prompt glycemic control is judged important to recovery such as prevention or treatment of infection
- Diabetes emergencies such as diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome

requirements in different hospital settings to achieve optimal blood glucose control. Intravenous infusion of insulin is the only insulin treatment strategy specifically developed for use in the hospital setting. The American College of Endocrinologists advised that intravenous insulin infusion should be used to control glycemia in certain indications (Box 32.2).

**Insulin infusion protocols**

The ideal insulin protocol should be safe, understandable, easily ordered and implemented. It should be effective in correcting hyperglycemia quickly and in maintaining glucose levels within a defined target range. The provision of an algorithm for making incremental changes to the infusion rate, which can be executed by nursing staff, is likely to improve the efficacy of the protocol. Hypoglycemia is a potential complication of intensified insulin therapy and is associated with poor outcomes. It is for this reason that intravenous insulin infusions should be supported by caloric input. In most patients this is in the form of a simultaneous infusion of dextrose but calories can be provided by other routes (e.g. enteral, parenteral or in a diasylate). If hypoglycemia develops despite adequate provision of calories then the patient should be treated promptly for hypoglycemia according to local protocol and the insulin infusion adjusted accordingly.

Successful implementation of an insulin infusion protocol is best achieved with the appointment of a champion to lead the multidisciplinary team. The protocol should be submitted to a medicines advisory or therapeutics committee and implemented with a widespread educational program to include medical, nursing and pharmacy staff. Adherence to a standard protocol is likely to reduce adverse events for patients and limit medical errors in insulin prescribing.

**Table 32.3** Insulin infusion table adapted from Oxford Radcliffe NHS Trust, UK.

Blood glucose (mmol/L)	Insulin infusion rate (unit/hour)				
	Rate A	Rate B	Rate C	Rate D	Tailored rate
0–4.0	0 and treat hypo	0 and treat hypo	0 and treat hypo	0 and treat hypo	0 and treat hypo
4.1–6.0	1	1	2	3	
6.1–8.0	2	3	4	5	
8.1–10.0	3	4	6	8	
>10.1	4	6	8	10	

>10 mmol/L

If blood glucose remains >10.1 for 4 hours move to the next infusion rate (e.g. A to B)  
Prescriptions should include the signature, bleep and date as well as the time and date infusion started

### Box 32.3 AACE/ADA recommendations for in-hospital glycemic control

- A target of 140–180 mg/dL (7.8–10.0 mmol/L) is preferable in most patients
- A target of 110–140 mg/dL (6.1–7.8 mmol/L) may be appropriate in selected patients
- A target of >180 mg/dL (10 mmol/L) or <110 mg/dL (6.1 mmol/L) is *not* recommended

### Preparation and delivery of an insulin infusion

The insulin infusion is prepared by adding 50 units of soluble insulin to 49.5 mL normal saline, which will provide 1 unit of insulin in 1 mL saline, which is delivered via an infusion pump. This insulin infusion can be piggy-backed into the infusion of dextrose using a three-way connector and a non-return valve. All patients should commence on algorithm A and uptitrate to achieve target glucose range (Table 32.3).

### Targets for glycemic control

The AACE/ADA has recently set new targets for the management of hyperglycemia in hospital (Box 32.3) [62]. The recommendation is that once intravenous insulin has been commenced the blood glucose level should be maintained at 140–180 mg/dL (7.8–10 mmol/L) with greater benefit possibly realized at the lower end of the target. There is recognition that lower targets may be beneficial in specified groups but there is insufficient evidence to make firm recommendations. It is recommended that target glucose should not fall below a level of 110 mg/dL (6.1 mmol/L). Where lower targets are being used, patients should be treated in sites with extensive experience and appropriate support such as areas caring for coronary artery bypass graft patients, sites with low rates of hypoglycemia, patients on total parenteral nutrition and those in ITUs.

### Transition from intravenous to subcutaneous insulin

Conversion to subcutaneous insulin should be delayed until patients are able to eat and drink normally without nausea or

### Box 32.4 Converting patients to subcutaneous insulin

- (a) *Estimation of insulin dose for a patient being converted from an intravenous insulin infusion*
  - Calculate average hourly insulin dose by totaling the last 6 hours' doses on the chart and dividing by 6 (e.g. 15 units divide by 6 = 2.5 units/hour. Multiply by factor of 20 to get the total daily dose (TDD) insulin (e.g. 50 units)
  - For a basal:bolus insulin regimen, divide 50:50 basal:bolus (e.g. 25 units as basal; 25 units as bolus. Give 25 units as a basal insulin (e.g. Lantus). Divide total bolus dose by three to get bolus for each meal (e.g. 8 units short-acting insulin, e.g. Novorapid)
  - For a twice daily fixed mixture regime divide 60:40 morning:evening (e.g. Humalog Mix 25, Novomix 30). Give 36 units am; 14 units pm
- (b) *Estimation of insulin dose when no insulin infusion has been used*

Calculate the total daily insulin dose according to diabetes type

  - Known type 2 diabetes 0.5–0.7 unit/kg
  - Known type 1 diabetes 0.3–0.5 unit/kg
  - Unsure 0.3–0.5 unit/kg
  - Divide insulin 50:50 for basal bolus regime (see above)
  - Divide 60:40 for twice daily mixed insulin (see above)

emesis. The most appropriate time to switch from IV to subcutaneous insulin is at the usual time of the patient's insulin administration, before a meal. Patients with known type 1 diabetes will become insulin deficient within minutes of the IV infusion being stopped because of the short half-life of IV insulin. It is therefore good practice to continue the infusion of insulin for 1 hour after the subcutaneous insulin has been administered to allow time for the insulin to be absorbed.

If the patient has been on an established insulin regimen, then this regimen should be restarted, but doses may have to be adjusted depending on the patient's clinical condition. If the patient is new to insulin therapy, then a rough estimation of the total daily dose (TDD) of insulin can be made from a simple calculation using the hourly rates delivered in the IV insulin infusion (Box 32.4a). Estimation of insulin doses can also be made

**Table 32.4** Causes of in-hospital hypoglycemia.

Cause of in-hospital hypoglycemia	Example
Primary reason for hospital stay	Medical causes: hepatic failure, cardiogenic shock, severe sepsis Surgical causes: nil by mouth for operation or procedure
Inappropriate food administration	Change of meal times, missed meals, poor access to snacks
Errors of insulin prescription or administration	Poorly written medication charts (e.g. writing of "U" instead of units) so that 4 U becomes 40 units, poor injection technique
Inappropriate use of "stat" insulin doses	Corrective dosing of insulin prescribed by untrained staff
Inappropriate use of sulfonylureas or interactions with other prescribed medication	Long-acting hypoglycemic agents should be avoided in hospital
Inappropriately timed diabetes medication for meal/enteral feed	Food and insulin or oral hypoglycemic agents mismatch
Use of unopposed intravenous insulin therapy	Dextrose infusion should be prescribed concurrently
Mobilization after acute illness	Insulin requirements may decrease with exercise

according to body weight, which is useful in calculating TDD in patients who are new to insulin but have not required an insulin infusion (Box 32.4b).

## Avoiding and treating in-hospital hypoglycemia

There is an increasing body of evidence supporting the widespread occurrence of hypoglycemia in hospitals and poor knowledge of how to detect and manage it. Acute hypoglycemia is associated with significant morbidity and more rarely mortality as it causes an intense hemodynamic response that can lead to potentially fatal cardiac arrhythmias, myocardial ischemia, cerebrovascular accidents, coma and death. In-hospital hypoglycemia is defined as a blood glucose level equal or below 72 mg/dL (4.0 mmol/L).

### Causes of in-hospital hypoglycemia

There are many reasons why hypoglycemia is more likely to be to occur during hospitalization but most of these relate to insulin administration and prescribing errors and inappropriate food administration (Table 32.4).

### Management of in-hospital hypoglycemia

In 2005, Tomky *et al.* [51] gave a clear overview of the topic in their article. 2006 saw the introduction of Hypoboxes™ for the management of hypoglycemia in the UK [52]. These boxes are often in a prominent place (e.g. on resuscitation trolleys) and are

brightly colored for instant recognition. They contain all the equipment required to treat hypoglycemia, from cartons of fruit juice to intravenous 20% glucose. There are general guidelines for the treatment of in-hospital hypoglycemia and these should be available in each ward and outpatient setting; however, each patient developing in-hospital hypoglycemia should be assessed as an individual and diabetes teams should agree local guidance for self-management. Certain conditions such as renal impairment or heart failure may require tailored treatment to avoid fluid overload. Many people with diabetes carry their own treatment supplies for hypoglycemic events and should be supported to self-manage when capable and appropriate. This information regarding capacity to self-manage should be recorded in the patient notes at the time of the admission assessment.

If the patient is not capable and/or uncooperative but is able to swallow, give either 1.5–2 tubes GlucoGel™ squeezed into the mouth between the teeth and gums or, if this is ineffective, give 1 mg glucagon intramuscularly (Figure 32.1). Monitor the blood glucose levels after 15 minutes. If the blood glucose levels are still less than 4 mmol/L, GlucoGel treatment can be repeated up to three times. If the hypoglycemia does not resolve at this stage, IV 10% glucose infusion at 100 mL/hour should be considered. Once the blood glucose is above 4 mmol/L and patient has recovered, a long-acting carbohydrate snack should be offered.

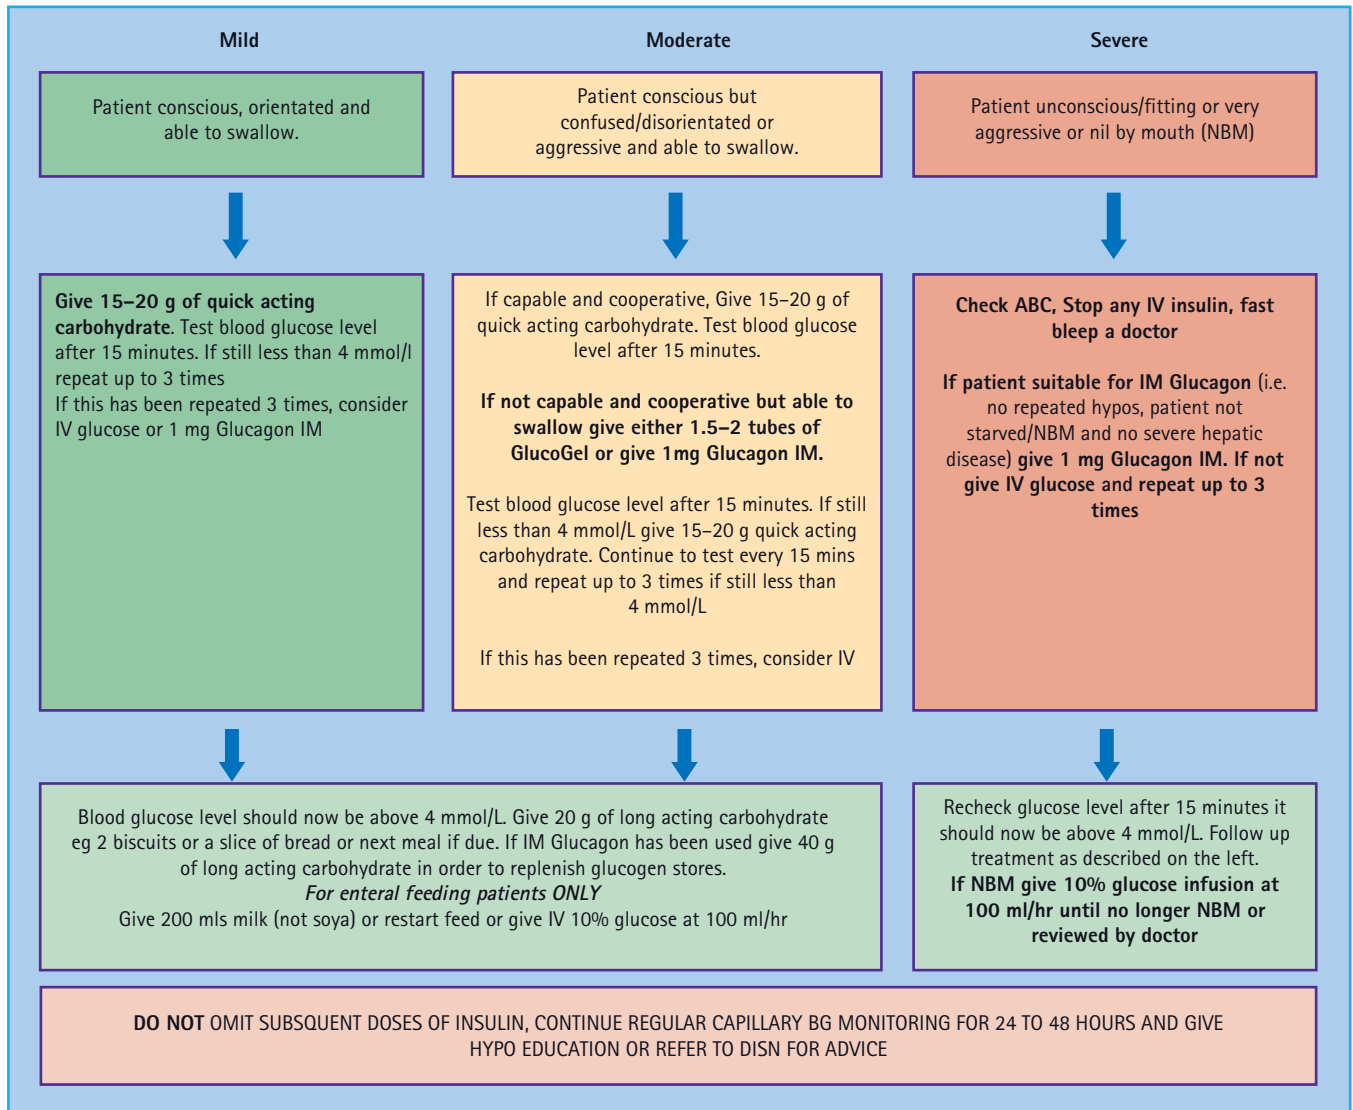

In adults who are unconscious with or without seizure activity and/or very aggressive, the patient's airway, breathing and circulation should be assessed, any insulin infusion *in situ* should be discontinued and a medical practitioner summoned. At this stage any of the following treatments can be considered for use.

Treatments such as 15–20 g quick-acting carbohydrate (e.g. 50–60 mL of Ensure Plus juice or Fortijuice 25 mL original or 3–4 heaped teaspoons sugar dissolved in water) can be administered via a feed tube. The capillary blood glucose measurement should be repeated 5–10 minutes later. If blood glucose is still less than 4 mmol/L, repeat this step up to three times. If the hypoglycemia is still not resolved after 15 minutes or three cycles, IV 10% glucose infusion at 100 mL/hour can be considered as a treatment option. Once the blood glucose is above 4 mmol/L and patient has recovered, a long-acting carbohydrate such as 200 mL milk (not soya) can be given and the feed. Insulin should not be omitted and regular continued capillary blood glucose level monitoring should be recorded for 24–48 hours.

### Prevention of recurrent in-hospital hypoglycemia

When hypoglycemia has been successfully treated it is important that the reason for hypoglycemia is ascertained and the treatment documented in the patient notes. If the hypoglycemic episode was severe or a recurrent event, or if patient has concerns regarding treatment of further recurrence of hypoglycemia and its treatment, then referral should be made to the CDE, DISN or specialist medical team. Measures such as medication adjustment or timing of meals should be introduced to prevent further episodes of hypoglycemia.

**Figure 32.1** Algorithm for the treatment and management of hypoglycemia in adults with diabetes mellitus in hospital. Hypoglycemia is defined as blood glucose of <4 mmol/L (if not <4 mmol/L but symptomatic, give a small carbohydrate snack for symptom relief). ABC, Airway, Breathing and Circulation; DISN, diabetes inpatient specialist nurse; IM, intramuscularly; IV, intravenously; NBM, nil by mouth.

## Surgery in patients with diabetes

Patients with diabetes have poorer health than those without diabetes so this means they are more likely to undergo surgery. It is estimated that 50% of those with diabetes will require surgery in their lifetime. Diabetes is associated with increased risk of perioperative infection and postoperative cardiovascular morbidity and mortality. The complex interplay of the operative procedure, anesthesia, fasting and additional postoperative factors such as artificial feeding and emesis all contribute to labile glycemic control in the perioperative period.

### Metabolic response to surgery

Surgery and anesthesia causes a state of relative insulin hyposecretion and insulin resistance. It induces a complex series of

hormonal and metabolic changes [53,54]. The secretion of the counter-regulatory or “stress” hormones, particularly cortisol and catecholamines, is greatly increased, and this can lead to an acute decrease in insulin sensitivity [54,55]. Enhanced sympathetic activity, together with raised circulating catecholamine concentrations, tends to inhibit insulin secretion. The net result of these changes is to push metabolism towards catabolism, leading to increased hepatic glucose production and hyperglycemia and enhanced breakdown of protein and fat. The magnitude of the counter-regulatory response varies in each individual and is greater with prolonged surgery and other factors such as postoperative sepsis.

### Preoperative evaluation

Nowadays, most patients are admitted on the same day as scheduled surgery. Pre-assessment planning in diabetes can prevent

**Table 32.5** Goldmann risk index [56].

Risk	Patient characteristics	Preoperative investigation
Low	<60 years old No history of cardiopulmonary disease Non-specific ECG changes	No further investigation necessary
Medium	All patients >60 years old Stable angina or previous MI Compensated heart failure	Determine functional capacity using ECG, exercise stress test (has a predictive value of 81% detection of multivessel disease)
High	Acute coronary syndromes Decompensated heart failure Supraventricular arrhythmias Known COPD	Consider preoperative coronary angiography

COPD, chronic obstructive pulmonary disease; ECG, electrocardiogram; MI, myocardial infarction.

unnecessary cancellation of surgery, give opportunities for joint care planning with the person with diabetes and enables optimization of glycemic control prior to surgery which can reduce length of stay, medication errors and improve the patient experience.

**Assessing cardiac risk**

Careful assessment of patients with diabetes is required because of their complexity and high risk of coronary heart disease, which is sometimes asymptomatic. It is therefore vital that all patients with diabetes attending for surgery have a robust risk assessment with particular focus on cardiopulmonary risk. In the assessment of risk for elective procedures one must consider the risk associated with the procedure itself in addition to the individual patient risk associated with pre-existing co-morbidities. Those at highest risk are those in whom there is significant cardiorespiratory pathology. There are several cardiac risk stratification indexes in the literature but essentially all use clinical variables that allow patients to be classified as low, intermediate or high risk of a major cardiac event during or after surgery. The Goldmann cardiac risk index [56] is widely used in clinical practice (Table 32.5).

**Assessing surgical risk**

The American College of Cardiology/American Heart Association guidelines introduce the concept of “surgery-specific risk.” Risk stratification is based on the degree of hemodynamic stress associated with specific procedures [57]. Table 32.6 summarizes the risk associated with various types of surgery.

**Physical assessment**

All patients require a careful history and physical examination. Key aspects of this should include assessment of glycemic control,

**Table 32.6** Surgery-specific risk.

	Procedure
Low	Peripheral and laparoscopic procedures
Medium	Orthopedic and prostatic operations
High	Major abdominal and thoracic operations, particularly major vascular surgery and ones where there are anticipated major fluid or blood loss

long-term complications, occurrence of hypoglycemia and its frequency, and the patient’s awareness and knowledge of all drug therapy. Patients should be given written information about changes in diabetes-specific and other medication in the days leading up to surgery.

**Laboratory assessment**

Basic investigations should include HbA<sub>1c</sub> as there is a suggestion that elevated levels over 7% (>53 mmol/mol) are associated with higher risks of postoperative infections [58].

There is good evidence that effective pre-assessment of people with diabetes will enable a safe and effective discharge from hospital. In Bolton, UK, a DSN has implemented a patient pathway from pre-assessment to discharge. This pathway includes assessment, optimization of glycemic control, the writing up of an insulin infusion scale preoperatively and the implementation of planning for routine diabetes care postoperatively. This work has resulted in significant improvement in reduced length of stay, medication errors and positive patient experience [59].

During the course of the pre-assessment visit each patient should undergo an explanation of the procedure and the planned anesthesia. The diabetes management plan should be discussed, thus enabling the patient to make an informed decision around the diabetes care to be offered. Further appointments should be offered if optimization of glycemic control is required. All information should be supported with appropriate literature. All recommendations for treatment should be written in the patient’s notes and in a handheld record kept by the patient.

**Same-day admissions and specific preparations**

High-risk patients are not suitable for same-day admission and should be admitted the day before surgery for assessment and optimization of glycemic control. There is evidence that elevated preoperative glucose levels >200 mg/dL (11 mmol/L) were associated with deep wound infections in a case-control study.

On the day of admission the patient’s notes including the diabetes management plan should be available to all staff caring for that individual. All guidelines pertaining to the plan of care should be in place and accessible for staff. If the blood glucose is unacceptably high on the day of admission, plans should be in place for rapid optimization of glycemic control including the use of an intravenous infusion of insulin.

**Table 32.7** Instructions for diabetes management on day of minor or intermediate surgery. Adapted from Nottingham University Trust, UK.

Morning list	Day before: normal food and medication. NBM from 02.00 Day of surgery: fast from 02.00 On tablets: omit diabetes tablets On insulin: omit any short-acting insulin, withhold insulin mixtures Give stat dose of isophane insulin, give 75% total daily dose if on once day insulin and 50% TDD if on twice daily insulin Continue long-acting analogs (Lantus, Levemir) at full dose Postoperative: lunch and normal insulin or tablets
Afternoon list	Day of surgery: light breakfast, fast from 08.00 On tablets: take diabetes tablets On insulin: take 50% normal insulin dose Continue long-acting analogs (Lantus, Levemir) at full dose Postoperative: late lunch and normal insulin or tablets

NBM, nil by mouth; TDD, total daily dose.

### Individual intra-operative diabetes care treatment plan

Management of the individual patient is determined by the following:

- Severity and nature of surgery (major or minor surgery)
- Duration of perioperative fast
- Timing of surgery
- Pre-existing diabetes treatment

#### Major surgery (prolonged fast >6 hours)

All patients with diabetes undergoing major surgery should have a dextrose and insulin infusion.

#### Minor surgery (short fast <6 hours)

Table 32.7 shows an example of the various treatment options for patients being admitted for minor surgery.

### Goals of glycaemic management

The goals of perioperative diabetes care are avoidance of marked hyperglycemia and of hypoglycemia. Patients with type 1 diabetes have no endogenous insulin and will therefore require exogenous insulin to prevent the development of severe hyperglycemia and subsequent life-threatening complications such as diabetic ketoacidosis. Such patients will also need a continuous supply of glucose of 5–10 g/hour to prevent hypoglycemia.

It is not clear how “tight” glucose control needs to be during surgery. There are a paucity of clinical trials to inform clinical practice in the surgical arena with the exception of cardiac surgery where there is evidence that good control, defined as BG 80–110 mg/dL (4.4–6.1 mmol/L), may reduce mortality.

The lack of clear evidence on glycaemic specific targets is reflected in the varying glucose targets recommended by national guidelines [24,27,28]. It would seem reasonable therefore to advise treatment regimens to aim for as near normal glycemia with avoidance of hypoglycemia (80 mg/dL, 4 mmol/L). This

range seems to be a safe and practicable target during the perioperative period.

### Intra-operative management of glycemia

Use of an IV insulin infusion to control glycemia has the advantage of easy titration to the glucose level because of the short half-life of IV insulin. Its safety has been demonstrated in many studies and is therefore the treatment of choice during surgery. The infusion requires close monitoring of blood glucose and potassium as well as appropriate interpretation by well-trained staff.

### Types of intravenous insulin infusion

No type of insulin infusion used during surgery has been shown to be superior in either safety or effectiveness in achieving glucose control. The fixed rate insulin infusion and the intermittent bolus regimens have failed to gain popularity and are little used in clinical practice and are therefore not discussed further.

#### Variable rate separate insulin and glucose intravenous infusions

In this commonly used regimen, intravenous dextrose is infused at a rate of 5–10 g/hour and a separate insulin infusion is given. The rate varies depending on the procedure and the level of insulin resistance. Following coronary artery bypass graft operations, insulin requirements may increase 10-fold [38]. Glucose should be measured hourly and electrolytes every 4 hours.

#### Glucose insulin potassium infusion

The glucose, insulin and potassium infusion is a single solution infusion comprising 500 mL 5% dextrose, 10 mmol/L potassium chloride and 15 units of soluble insulin. This is infused at a rate of 100 mL/hour. Glucose is usually measured 2-hourly and the insulin content of the infusion can be changed if necessary. This method has the disadvantage of inflexibility and wastefulness as the entire infusion has to be discarded and replaced if insulin requirements change.

### Postoperative care and discharge

For those undergoing minor surgery characterized by a short fast, generally the preoperative diabetes treatment can be reinstated at an early stage once the patient is eating well. For those undergoing major surgery, particularly abdominal surgery where there may be several days of fasting, then it is better to keep these patients on IV insulin infusion with appropriate fluid replacement. The IV fluid regimen should consist of replacement crystalloid, a minimum of 2L/day (normal saline, Hartmann solution, Ringer lactate) and a supply of substrate (e.g. 100 mL/hour 5% dextrose) to prevent onset of catabolism. Conversion to normal therapy, whether insulin or oral hypoglycemic therapy, should occur when the patient is eating and drinking and free from nausea and emesis.

For patients with prolonged periods of nil by mouth or who are severely unwell or malnourished, hyperalimentation may be introduced. In these circumstances, insulin requirements may increase considerably and so these patients are better managed on high dose IV insulin with the support of the specialist diabetes

team. Hospitals should have protocols in place to support this practice.

## Conclusions

Patients with diabetes are twice as likely to be admitted to hospital and stay twice as long as those without diabetes. They have worse outcomes and a poorer patient experience than those without diabetes. Diabetes inpatient care and training has become the Cinderella area of diabetes care delivery despite the setting of clinical standards by several professional bodies. Although there is now a wealth of evidence that specialist inpatient diabetes teams reduce length of stay, reduce errors in prescribing, improve the patient experience and clinical outcomes, many hospitals across the world still lack inpatient specialist teams.

Patients voices are being raised in anger against this imbalance in care delivery. Providers of care need to listen to patients and professionals and ensure the delivery of a high quality inpatient service to include appropriate medical and nursing staff training, an equitable access to specialist services across the board, and an active partnership with patients to deliver a comprehensive range of services. Systems need to be in place to enable patients to self-manage where it is clinically appropriate. If standards are to be improved there needs to be agreed national targets and key performance indicators for diabetes inpatient care for which health care providers should be held accountable.

## Acknowledgment

The authors thank Dr. Rif Malik for his contribution to this chapter.

# 33 Hypoglycemia in Diabetes

**Philip E. Cryer**

Division of Endocrinology, Metabolism and Lipid Research, Washington University School of Medicine, St. Louis, MO, USA

## Keypoints

- Iatrogenic hypoglycemia is the limiting factor in the glycemic management of diabetes. It occurs during treatment with an insulin secretagogue or with insulin.
- The key physiologic defenses against falling plasma glucose concentrations are decrements in insulin and increments in glucagon and epinephrine. The behavioral defense is carbohydrate ingestion prompted by symptoms that are largely the result of sympathetic neural activation.
- Hypoglycemia in diabetes is the result of therapeutic hyperinsulinemia. As glucose levels fall, decrements in insulin and increments in glucagon are lost, because of  $\beta$ -cell failure, in type 1 diabetes mellitus (T1DM) and advanced type 2 diabetes mellitus (T2DM). In that setting, attenuated increments in epinephrine cause the syndrome of defective glucose counter-regulation. Attenuated increments in sympathetic neural activity largely bring about the syndrome of hypoglycemia unawareness.
- The concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes posits that recent antecedent hypoglycemia, as well as prior exercise or sleep, causes both defective glucose counter-regulation and hypoglycemia unawareness by attenuating the sympathoadrenal response to subsequent hypoglycemia.
- Hypoglycemia unawareness and, in part, the reduced epinephrine component of defective glucose counter-regulation are reversible in 2–3 weeks with scrupulous avoidance of hypoglycemia in most affected patients.
- The risk factors for hypoglycemia, based on this pathophysiology, include relative as well as absolute therapeutic insulin excess, and factors indicative of HAAF which include absolute endogenous insulin deficiency, a history of severe hypoglycemia, hypoglycemia unawareness, or both as well as prior exercise or sleep, and aggressive glycemic therapy per se.
- This pathophysiology explains why the incidence of iatrogenic hypoglycemia increases over time in T2DM, approaching that in T1DM. Most episodes of hypoglycemia occur in people with T2DM.
- Minimizing the risk of iatrogenic hypoglycemia requires acknowledging the problem, applying the principles of aggressive glycemic therapy and considering the risk factors for relative as well as absolute therapeutic insulin excess and for HAAF.
- Maintenance of the greatest degree of glycemic control that can be accomplished safely in a given patient at a given stage of that individual's diabetes is in the patient's best interest. Concerns about hypoglycemia should not be an excuse for poor glycemic control.

## Overview of the clinical problem

Iatrogenic hypoglycemia is the most important limiting factor in the glycemic management of diabetes [1,2]. It causes recurrent morbidity in most people with type 1 diabetes mellitus (T1DM) and many with advanced type 2 diabetes mellitus (T2DM), and is sometimes fatal. It compromises physiologic and behavioral defenses against subsequent falling plasma glucose concentrations and thus causes a vicious cycle of recurrent hypoglycemia. It precludes maintenance of euglycemia over a lifetime of diabetes and thus full realization of the vascular benefits of glycemic control.

Hypoglycemia in diabetes is fundamentally iatrogenic, the result of pharmacokinetically imperfect treatments with an insulin secretagogue (e.g. a sulfonylurea or a glinide) or with exogenous insulin that results in episodes of hyperinsulinemia. Nonetheless, hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and comprised physiologic and behavioral defenses against falling plasma glucose concentrations [1,2].

The problem of hypoglycemia in diabetes has been summarized [1] and reviewed in detail [2]. My premise is that understanding of the pathophysiology of glucose counter-regulation, the mechanisms that normally prevent or rapidly correct hypoglycemia, leads to insight into the frequency of, risk factors for and prevention of iatrogenic hypoglycemia. Therefore, the physiology of glucose counter-regulation and its pathophysiology in diabetes are addressed first, followed by a summary of the magnitude of the clinical problem. With that background, a clinical approach to the prevention of iatrogenic hypoglycemia, and if necessary its treatment, is discussed.

## Physiology of glucose counter-regulation

### Hypoglycemia and the brain

Glucose is an obligate oxidative fuel for the brain under physiologic conditions [1–4]. The brain accounts for more than 50% of whole body glucose utilization. Because it cannot synthesize glucose, utilize physiologic concentrations of circulating non-glucose fuels effectively or store more than a few minutes supply as glycogen [1,2], the brain requires a virtually continuous supply of glucose from the circulation. Because facilitated blood–brain glucose transport is a direct function of the arterial plasma glucose concentration, that requires maintenance of the physiologic plasma glucose concentration. Hypoglycemia causes functional brain failure, which is typically reversed after the plasma glucose concentration is raised [4]. Rarely, profound prolonged hypoglycemic causes brain death [4].

### Responses to hypoglycemia

Falling plasma glucose concentrations cause a sequence of responses in individuals without diabetes (Table 33.1) [1,5–8]. The first physiologic response, which occurs as plasma glucose concentrations decline within the postabsorptive plasma glucose concentration range, is a decrease in insulin secretion. The secretion of glucose counter-regulatory (plasma glucose raising) hormones, including glucagon and epinephrine, increases as plasma glucose concentrations fall just below the physiologic range. Lower plasma glucose levels cause a more intense sympathoadrenal – sympathetic neural as well as adrenomedullary – response and symptoms. Even lower plasma glucose concentrations cause functional brain failure [4].

### Clinical manifestations of hypoglycemia

The symptoms and signs of hypoglycemia are not specific [8,9]. Thus, clinical hypoglycemia is most convincingly documented by Whipple's triad: symptoms, signs, or both, consistent with hypoglycemia; a low measured plasma glucose concentration; and resolution of those symptoms and signs after the plasma glucose concentration is raised.

Neuroglycopenic symptoms, which are the result of brain glucose deprivation per se, include cognitive impairments, behavioral changes and psychomotor abnormalities and, at lower plasma glucose concentrations, seizure and coma [1,2,4,8,9]. Neurogenic (or autonomic) symptoms, which are largely the result of the perception of physiologic changes caused by the sympathoadrenal – particularly the sympathetic neural [9] – discharge triggered by hypoglycemia, include both adrenergic (e.g. palpitations, tremulousness and anxiety/arousal) and cholinergic (e.g. sweating, hunger and paresthesias) symptoms [8]. Central mechanisms may also be involved in some of the latter symptoms such as hunger [10]. Awareness of hypoglycemia is largely the result of the perception of neurogenic symptoms [8].

Signs of hypoglycemia include pallor and diaphoresis, the result of adrenergic cutaneous vasoconstriction and cholinergic

**Table 33.1** Physiologic responses to decreasing plasma glucose concentrations.

Response	Glycemic threshold* (mg/dL [mmol/L])	Physiologic effects	Role in prevention or correction of hypoglycemia (glucose counter-regulation)
↓ Insulin	80–85 [4.4–4.7]	↑ $R_a$ (↓ $R_d$ )	Primary glucose regulatory factor, first defense against hypoglycemia
↑ Glucagon	65–70 [3.6–3.9]	↑ $R_a$	Primary glucose counter-regulatory factor, second defense against hypoglycemia
↑ Epinephrine	65–70 [3.6–3.9]	↑ $R_a$ , ↓ $R_d$	Involved, critical when glucagon is deficient, third defense against hypoglycemia
↑ Cortisol and growth hormone	65–70 [3.6–3.9]	↑ $R_a$ , ↓ $R_d$	Involved but not critical
Symptoms	50–55 [2.8–3.1]	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	<50 [<2.8]	–	Compromises behavioral defense

$R_a$ , rate of glucose appearance, glucose production by the liver and kidneys;  $R_d$ , rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle (no direct effect on central nervous system glucose utilization).

\* Arterialized venous, not venous, plasma glucose concentrations.

Reproduced from Cryer PE. Glucose homeostasis and hypoglycemia. In: Kronenberg HM, Melmed S, Polonsky KS, Larsen PR, eds. *Williams Textbook of Endocrinology*, 11th edn. Philadelphia: Saunders, 2008: 1503–1533, with permission.

activation of sweat glands, respectively [1,2]. Neuroglycopenic manifestations are often observable.

### Maintenance of systemic glucose balance

Because obligatory glucose utilization, largely by the brain, is fixed and exogenous glucose delivery from ingested carbohydrates is intermittent, systemic glucose balance is maintained, and hypoglycemia (as well as hyperglycemia) is prevented, by dynamic regulation of endogenous glucose production from the liver (and the kidneys) and of glucose utilization by non-neural tissues such as muscle [1,11]. Although an array of hormones, neurotransmitters and metabolic substrates are involved, endogenous glucose production and glucose utilization by non-neural tissues are regulated primarily by insulin (Figure 33.1; Table 33.1) [11].

The first physiologic defense against hypoglycemia is a decrease in pancreatic islet  $\beta$ -cell insulin secretion. That occurs as plasma glucose concentrations decline within the physiologic range (Table 33.1) and favors increased hepatic (and renal) glucose production with virtual cessation of glucose utilization by insu-

**Figure 33.1** Physiologic and behavioral defenses against hypoglycemia in humans. ACh, acetylcholine;  $\alpha$ -cell, pancreatic islet  $\alpha$ -cell;  $\beta$ -cell, pancreatic islet  $\beta$ -cell; NE, norepinephrine; PNS, parasympathetic nervous system; SNS, sympathetic nervous system; T1DM, type 1 diabetes mellitus. Reproduced from Cryer PE. Mechanisms of sympathoadrenal failure and hypoglycemia in diabetes. *J Clin Invest* 2006; **116**:1470–1473, with permission from the American Society for Clinical Investigation.

lin-sensitive tissues such as muscle (Figure 33.1). The second physiologic defense is an increase in pancreatic islet  $\alpha$ -cell glucagon secretion. That occurs as plasma glucose concentrations fall just below the physiologic range (Table 33.1) and stimulates hepatic glucose production (largely by stimulating glycogenolysis) (Figure 33.1). Increased glucagon secretion is signaled primarily by a decrease in intra-islet insulin, perhaps among other  $\beta$ -cell secretory products, in the setting of low glucose concentrations [1,2,12] and secondarily by increased autonomic nervous system – sympathetic, parasympathetic and adrenomedullary – inputs [1,2,13]. The third physiologic defense, which becomes critical when glucagon is deficient, is an increase in adrenomedullary epinephrine secretion [1,2,11]. That, too, occurs as plasma glucose concentrations fall just below the physiologic range

(Table 33.1). It raises plasma glucose concentrations largely by  $\beta_2$ -adrenergic stimulation of hepatic (and renal) glucose production (Figure 33.1), but the glucose-raising actions of epinephrine also involve limitation of glucose clearance by insulin sensitive tissues, mobilization of gluconeogenic substrates such as lactate and amino acids from muscle and glycerol from fat and  $\alpha_2$ -adrenergic limitation of insulin secretion [1,2,14]. Sympathoadrenal activity, including epinephrine secretion, is regulated in the brain [1,2,11]. Circulating epinephrine is almost exclusively derived from the adrenal medulla [9]; while circulating norepinephrine is largely derived from sympathetic nerves under resting and many stimulated (e.g. exercise) conditions, the plasma norepinephrine response to hypoglycemia is also largely adrenomedullary in origin [9].

**Table 33.2** Responses to falling plasma glucose concentrations in humans.

Plasma glucose	Individuals	Plasma		
		Insulin	Glucagon	Epinephrine
↓	Non-diabetic	↓	↑	↑
↓	T1DM*	No ↓	No ↑	Attenuated ↑
↓	Early T2DM	↓	↑	↑
↓	Late T2DM*	No ↓	No ↑	Attenuated ↑

\*These alterations account for the appearance of defective glucose counter-regulation and hypoglycemia unawareness in T1DM and late T2DM.

If these physiologic defenses fail to abort an episode of developing hypoglycemia, lower plasma glucose concentrations cause a more intense sympathoadrenal response that causes neurogenic symptoms (Figure 33.1) [1,2,11]. Those symptoms cause awareness of hypoglycemia that prompts the behavioral defense of ingestion of carbohydrates [1,2,11].

All of these defenses against hypoglycemia, not just insulin secretion, are typically compromised in people with T1DM and those with advanced (i.e. absolutely endogenous insulin deficient) T2DM (Figure 33.1) [1,2].

## Pathophysiology of glucose counter-regulation in diabetes

### Insulin excess

While substantial insulin excess alone can cause hypoglycemia, the integrity of the defenses against falling plasma glucose concentrations determines whether a typical episode of therapeutic hyperinsulinemia results in clinical hypoglycemia [1,2]. Thus, iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic hyperinsulinemia and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (Figure 33.1; Table 33.2) [1,2,15,16].

### Defective glucose counter-regulation and hypoglycemia unawareness

In fully developed (i.e. C peptide negative) T1DM circulating insulin concentrations cannot decrease as plasma glucose concentrations fall in response to therapeutic (exogenous) hyperinsulinemia (Table 33.2) [1,2,15]. That is the result of  $\beta$ -cell failure which also causes loss of the increase in circulating glucagon concentrations (Figure 33.2; Table 33.2) [1,2,12,15]. The latter conclusion is based on the finding that indirect reciprocal  $\beta$ -cell-mediated signaling normally predominates over direct  $\alpha$ -cell signaling in the regulation of glucagon secretion in humans [1,2,12]. Thus, the absence of a decrease in intra-islet insulin, perhaps among other  $\beta$ -cell secretory products, in concert with low glucose levels, plausibly explains loss of the glucagon response [1,2,12]. Therefore, both the first and second physiologic defenses

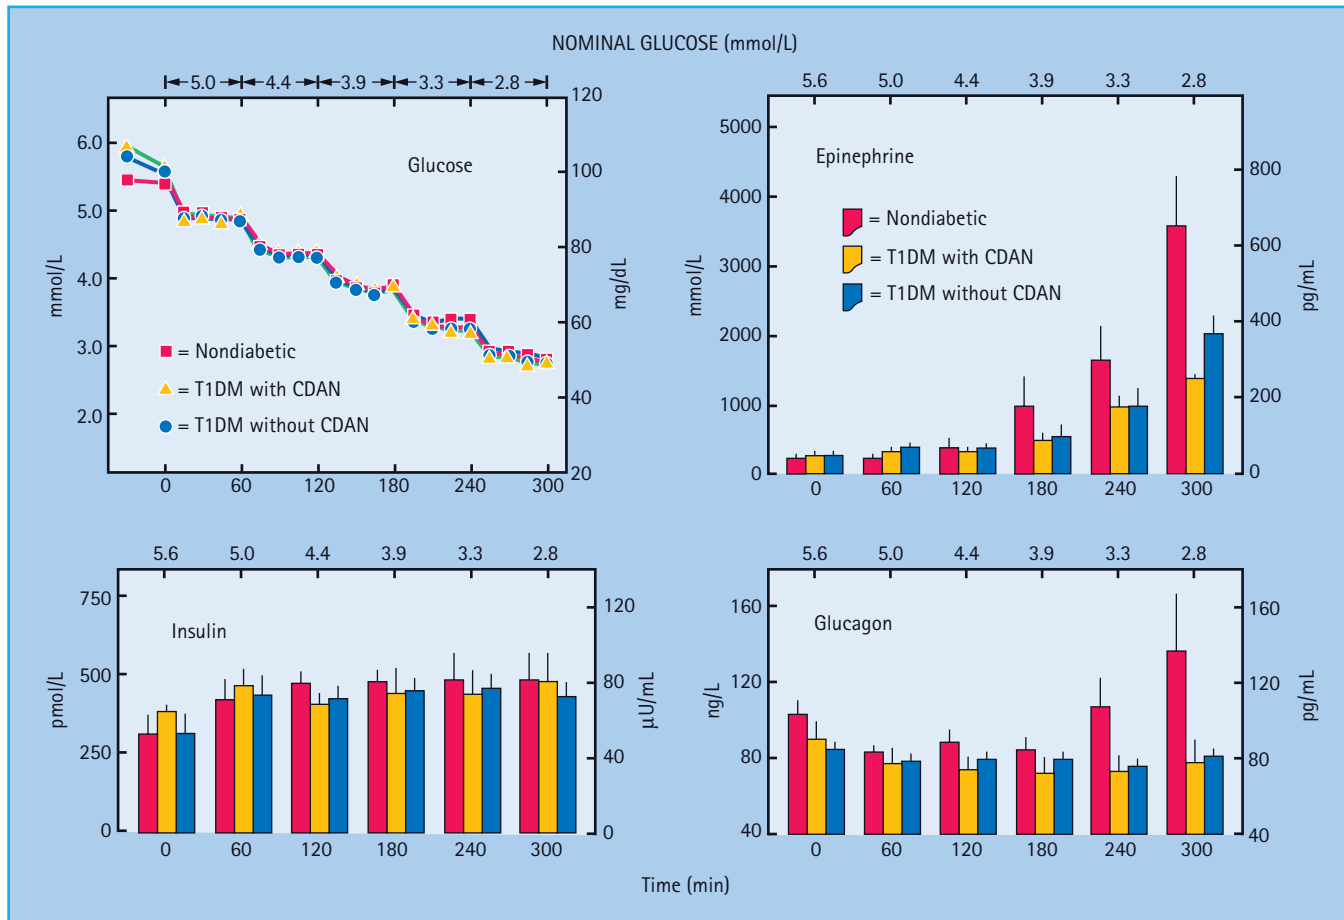

against hypoglycemia are lost. Furthermore, the increase in circulating epinephrine, the third physiologic defense, is typically attenuated (Figure 33.2; Table 33.2) [1,15]. In the setting of absent insulin and glucagon responses, the attenuated epinephrine response causes the clinical syndrome of defective glucose counter-regulation (Table 33.2) [1,2,15,17,18] which is associated with a 25-fold [17] or greater [18] increased risk of severe iatrogenic hypoglycemia in T1DM. In addition, the attenuated epinephrine response is a marker for an attenuated sympathoadrenal, including sympathetic neural, response (Table 33.2) which is largely responsible for reduced neurogenic symptom responses and therefore the clinical syndrome of hypoglycemia unawareness [1,2,9] which is associated with a sixfold increased risk of severe iatrogenic hypoglycemia in T1DM [19]. Attenuated sympathoadrenal responses to falling plasma glucose concentrations can be caused by recent antecedent hypoglycemia (Figures 33.3 and 33.4) [1,2,15,16,20], prior exercise [1,2,21–23] or sleep [1,2,24–26].

While hypoglycemia unawareness is largely the result of reduced release of the neurotransmitters norepinephrine and acetylcholine [1,9], there is evidence of decreased  $\beta$ -adrenergic sensitivity, specifically reduced cardiac chronotropic sensitivity to isoproterenol, in affected patients [27,28]. However, vascular sensitivity to  $\beta_2$ -adrenergic agonism was not found to be reduced in patients with unawareness [29], reduced sensitivity to  $\beta$ -adrenergic signaling of neurogenic symptoms remains to be demonstrated in patients with unawareness and it would be necessary to postulate decreased cholinergic sensitivity as well to explain reduced cholinergic symptoms such as sweating.

The pathophysiology of glucose counterregulation is the same in T1DM and advanced (i.e. absolutely endogenous insulin deficient) T2DM, albeit with different time courses (Table 33.2) [1,2,15,16]. The pathogenesis of an episode of iatrogenic hypoglycemia involves therapeutic hyperinsulinemia resulting in falling plasma glucose concentrations and loss of the appropriate decrements in insulin and increments in glucagon. The hypoglycemia, in turn, reduces the sympathoadrenal responses to subsequent hypoglycemia. Because  $\beta$ -cell failure, which causes loss of both the insulin and the glucagon responses [1,2,15,16], occurs rapidly in T1DM but slowly in T2DM, the syndromes of defective glucose counterregulation and hypoglycemia unawareness develop early in T1DM but later in T2DM. This temporal pattern of compromised glycemic defenses explains why iatrogenic hypoglycemia becomes progressively more frequent as patients approach the insulin deficient end of the spectrum of T2DM as discussed later in this chapter.

### Hypoglycemia-associated autonomic failure

The concept of hypoglycemia-associated autonomic failure (HAAF) in diabetes posits that recent antecedent hypoglycemia (Figures 33.3 and 33.4) [1,2,15,16,20] – as well as prior exercise [1,2,21–23] or sleep [1,2,24–26] – causes both defective glucose counter-regulation (by attenuating the epinephrine responses to subsequent hypoglycemia in the setting of absent decrements in

**Figure 33.2** Mean ( $\pm$  SE) plasma glucose, insulin, epinephrine and glucagon concentrations during hyperinsulinemic stepped hypoglycemic glucose clamps in individuals without diabetes (red squares and columns), people with type 1 diabetes (T1DM, insulin-dependent diabetes mellitus) with classic diabetic autonomic neuropathy (CDAN) (yellow triangles and columns) and people with type 1 diabetes without CDAN (blue circles and columns). Reproduced from Dagogo-Jack *et al.* [15] with permission from the American Society for Clinical Investigation.

insulin and absent increments in glucagon) and hypoglycemia unawareness (by attenuating the sympathoadrenal, including the sympathetic neural, and resulting neurogenic symptom responses to subsequent hypoglycemia). It therefore leads to a vicious cycle of recurrent iatrogenic hypoglycemia (Figure 33.5). Thus, HAAF is, at least in large part, a dynamic functional disorder that is distinct from classic diabetic autonomic neuropathy [1,2]. Nonetheless, the key feature of HAAF, an attenuated sympathoadrenal response to a given level of hypoglycemia, is more prominent in patients with diabetic autonomic neuropathy (Figure 33.2) [30,31].

The clinical impact of HAAF is well established in T1DM [1,2,15,32–37]. Recent antecedent hypoglycemia, even asymptomatic nocturnal hypoglycemia, reduces epinephrine, symptomatic and cognitive dysfunction responses to a given level of subsequent hypoglycemia [32], reduces detection of hypoglycemia in the clinical setting [33] and reduces defense against hyperinsulinemia [15] in T1DM. Perhaps the most compelling support for the concept of HAAF is the finding, initially by three independent research teams [34–37], that as little as 2–3 weeks of

scrupulous avoidance of hypoglycemia reverses hypoglycemia unawareness (Figure 33.6) and improves the attenuated epinephrine component of defective glucose counter-regulation in most affected patients.

People with advanced T2DM are also at risk for HAAF [1,2,16]. Glucagon responses to hypoglycemia are lost [16], as they are in T1DM. Furthermore, the glycemic thresholds for sympathoadrenal and symptomatic (among other) responses to hypoglycemia are shifted to lower plasma glucose concentrations by recent antecedent hypoglycemia [16], as they are in T1DM.

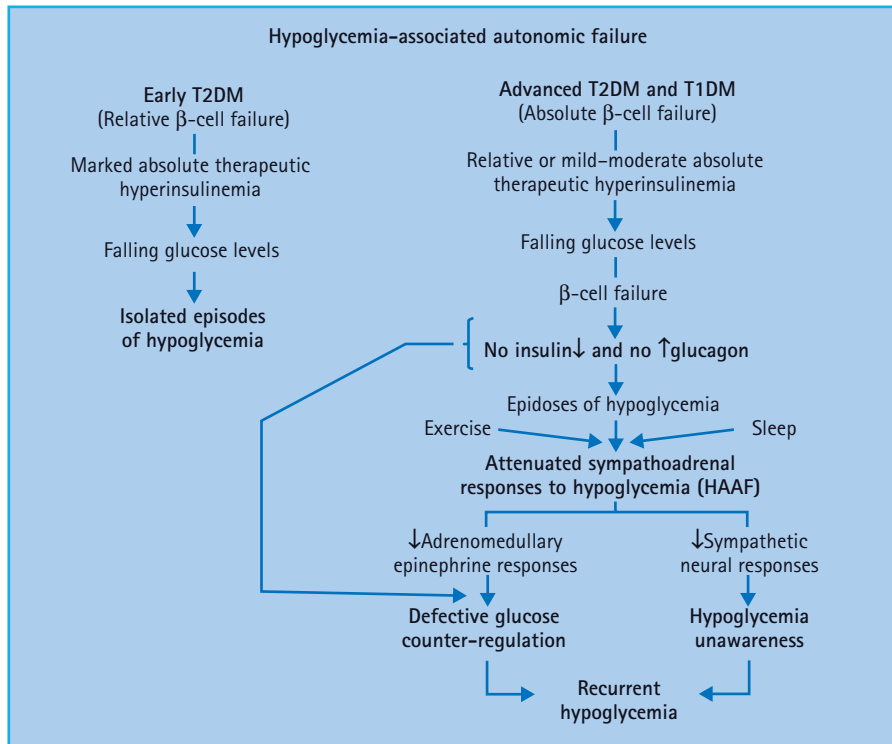

The three recognized causes of HAAF each cause attenuated sympathoadrenal and symptomatic (among other) responses to a given level of hypoglycemia [1,2]. Antecedent hypoglycemia-related HAAF [1,2,15,16,20] led to the concept. Exercise-related HAAF [1,2,21–23] is exemplified by late post-exercise hypoglycemia which typically occurs 6–15 hours after strenuous exercise and is often nocturnal [38,39]. Sleep-related HAAF [1,2,24–26] is the result of further attenuation of the sympathoadrenal response to hypoglycemia during sleep. Sleeping patients are

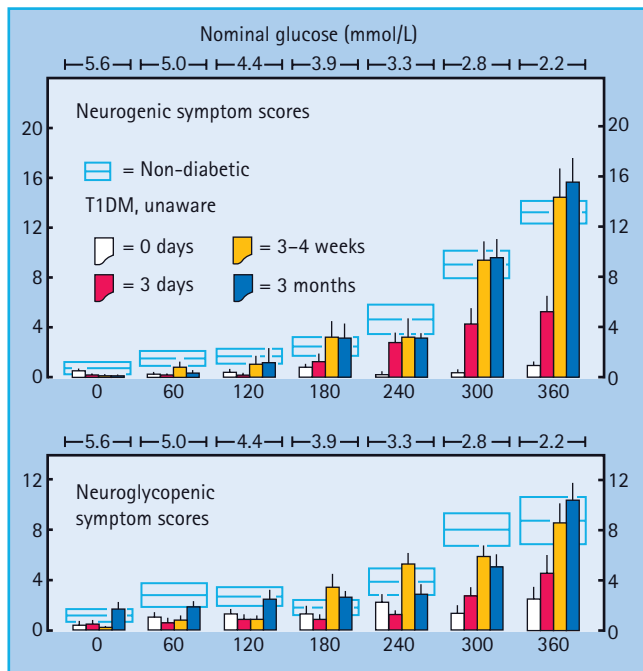

**Figure 33.3** Mean ( $\pm$  SE) plasma glucose, insulin, epinephrine and glucagon concentrations during hyperinsulinemic stepped hypoglycemic glucose clamps in patients with type 1 diabetes without classic diabetic autonomic neuropathy on mornings following afternoon hyperglycemia (red circles and columns) and on mornings following afternoon hypoglycemia (yellow circles and columns). therefore much less likely to be awakened by hypoglycemia than individuals without diabetes [25,26]. There may well be additional, as yet unrecognized, functional, and therefore potentially reversible, causes of HAAF [1,2]. In addition, there may be a structural component [1,2].

The mechanisms of HAAF are summarized in Figure 33.7 [1,2]. Loss of the insulin and glucagon responses to falling plasma glucose concentrations caused by therapeutic hyperinsulinemia is the result of  $\beta$ -cell failure in T1DM and advanced T2DM. Because normal insulin and glucagon responses to low glucose concentrations occur in patients with a transplanted (i.e. denervated) pancreas [40] and in dogs with a denervated pancreas [41] – as well as from the perfused pancreas and perfused pancreatic islets – innervation is not required.

In the setting of absent insulin and glucagon responses to falling plasma glucose concentrations, attenuated sympathoadrenal responses cause both defective glucose counter-regulation and hypoglycemia unawareness, the two components of HAAF [1,2]. The mechanism of the attenuated sympathoadrenal response is not known, but it must be at the level of the brain (or the afferent or efferent components of the sympathoadrenal system) (Figure 33.7). The proposed mechanisms include the systemic mediator, brain fuel transport and brain metabolism hypotheses, all of which have been reviewed [1,2,42,43].

Much of the research into the pathogenesis of HAAF has focused on the hypothalamus, the central integrator of the sympathoadrenal responses to hypoglycemia [43]. While the primary alteration could reside in the hypothalamus, the changes in hypothalamic function could be secondary to those in other brain regions. For example, measurements of regional cerebral blood

**Figure 33.7** Pancreatic islet, hypothalamic and cerebral network mechanisms of hypoglycemia-associated autonomic failure (HAAF) in diabetes. Reproduced from Cryer [1] with permission from the American Diabetes Association.

flow with [ $^{15}\text{O}$ ] water and positron emission tomography (PET) [44] indicate that hypoglycemia activates widespread but interconnected brain regions, including the medial prefrontal cortex, the lateral orbitofrontal cortex, the thalamus, the globus pallidus and the periaqueductal gray. These studies also show that recent antecedent hypoglycemia both reduces the sympathoadrenal and symptomatic responses (a model of HAAF) and causes a greater increase in synaptic activity in the dorsal midline thalamus during subsequent hypoglycemia [45]. Thus, it has been suggested that there may be a cerebral network that results in thalamic inhibition of hypothalamic activity in HAAF (Figure 33.7) [45]. That suggestion is generically consistent with the findings of various patterns of [ $^{18}\text{F}$ ] deoxyglucose uptake in T1DM patients with and without hypoglycemia unawareness [46].

## Risk factors for hypoglycemia in diabetes

The risk factors for hypoglycemia in diabetes follow directly from the pathophysiology of glucose counter-regulation and are based on the principle that iatrogenic hypoglycemia is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (i.e. HAAF) in T1DM and advanced T2DM [1,2,47].

### Absolute or relative insulin excess

The conventional risk factors for hypoglycemia in diabetes are based on the premise that absolute or relative therapeutic insulin excess is the sole determinant of risk (Table 33.3) [1,2,47]. Absolute therapeutic insulin excess occurs when insulin secretagogue or insulin doses are excessive, ill-timed or of the wrong

**Table 33.3** Risk factors for hypoglycemia in diabetes.

#### Relative or absolute insulin excess

- 1 Insulin or insulin secretagogue doses are excessive, ill-timed or of the wrong type
- 2 Exogenous glucose delivery is decreased (e.g. following missed meals and during the overnight fast)
- 3 Glucose utilization is increased (e.g. during and shortly after exercise)
- 4 Endogenous glucose production is decreased (e.g. following alcohol ingestion)
- 5 Sensitivity to insulin is increased (e.g. in the middle of the night and following weight loss or improved glycemic control)
- 6 Insulin clearance is decreased (e.g. with renal failure)

#### Hypoglycemia-associated autonomic failure

- 1 Absolute endogenous insulin deficiency
- 2 A history of severe hypoglycemia, hypoglycemia unawareness, or both as well as recent antecedent hypoglycemia, prior exercise and sleep
- 3 Aggressive glycemic therapy per se (lower HbA<sub>1c</sub> levels, lower glycemic goals)

type, or when insulin clearance is reduced as in renal failure. Relative therapeutic insulin excess occurs under a variety of conditions. It occurs when exogenous glucose delivery is decreased (as following missed or low carbohydrate meals and during the overnight fast), when glucose utilization is increased (as during and shortly after exercise), when endogenous glucose production is decreased (as following alcohol ingestion) and when sensitivity to insulin is increased (as following weight loss or improved glycemic control and in the middle of the night). People with diabetes and their caregivers must consider each of these risk factors when the problem of iatrogenic hypoglycemia is recog-

nized. Overall, however, they explain only a minority of episodes of hypoglycemia [48].

### Compromised defenses against hypoglycemia

The risk factors indicative of HAAF (Table 33.3) [1,2,47,49–55] include absolute endogenous insulin deficiency [1,2,47,49–53], a history of severe iatrogenic hypoglycemia, hypoglycemia unawareness, or both as well as recent antecedent hypoglycemia, prior exercise or sleep [1,2,47,50–52,54] and aggressive glycemic therapy per se (i.e. lower HbA<sub>1c</sub> levels, lower glycemic goals, or both) [1,2,47,50–55]. The degree of endogenous insulin deficiency (i.e.  $\beta$ -cell failure) determines the extent to which insulin levels will not decrease and glucagon levels will not increase as plasma glucose concentrations fall in response to therapeutic hyperinsulinemia. A history of severe hypoglycemia indicates, and that of hypoglycemia unawareness implies, recent antecedent hypoglycemia. The latter causes attenuated sympathoadrenal and symptomatic responses to subsequent hypoglycemia, the key feature of HAAF. In addition, prior exercise and sleep cause that feature of HAAF. Studies of intensive glycemic therapy with a control group treated to a higher HbA<sub>1c</sub> level consistently report higher rates of hypoglycemia in the group treated to lower HbA<sub>1c</sub> levels in T1DM [56–58] and T2DM [54,59,60]. That does not mean that one cannot both improve glycemic control and minimize the risk of hypoglycemia [1,2,47] as discussed below.

### Magnitude of the clinical problem of hypoglycemia in diabetes

Diabetes is an increasingly common disease. It has been estimated that its prevalence will rise from 285 million people in the year 2009 to 435 million people by the year 2030 [61]. Iatrogenic hypoglycemia affects most of the minority with T1DM and many of the majority with T2DM [1,2]. Indeed, because it precludes maintenance of euglycemia over a lifetime of diabetes, the barrier of hypoglycemia ultimately affects all people with diabetes [1,2].

### Frequency of hypoglycemia

Hypoglycemia is a fact of life for people with T1DM (Table 33.4) [1,2,55,62,63]. The average patient has untold numbers of episodes of asymptomatic hypoglycemia and experiences two episodes of symptomatic hypoglycemia per week – thousands of such episodes over a lifetime of diabetes – and one or more episodes of severe, temporarily disabling hypoglycemia, often with seizure or coma, per year. There is no evidence that this problem has abated since it was highlighted by the report of the Diabetes Control and Complications Trial (DCCT) in 1993 [56]. For example, in 2007 the UK Hypoglycemia Study Group [63] reported an incidence of severe hypoglycemia that was twice that in the DCCT in patients with T1DM for <5 years and an incidence fivefold higher than that in the DCCT in those with T1DM for >15 years (Table 33.4). An incidence comparable to the latter was also found in a large observational study [55].

Overall, hypoglycemia is less frequent in T2DM (Table 33.4) [1,2,55,63–80], but for the pathophysiologic reasons discussed, hypoglycemia becomes progressively more frequent as patients approach the insulin deficient end of the spectrum of T2DM [1,2,63,78]. Indeed, its frequency has been reported to be similar in those with T2DM and T1DM matched for duration of insulin therapy [78]. When the UK Hypoglycemia Study Group [63] contrasted patients with T2DM treated with insulin for <2 years

with those treated with insulin for >5 years they found severe hypoglycemia prevalences of 7% and 25% and incidences of 10 and 70 episodes per 100 patient-years, respectively. The pattern for self-treated hypoglycemia was similar [63]. Thus, while the incidence of iatrogenic hypoglycemia is relatively low (with current less than euglycemic goals) in the first few years of insulin treatment of T2DM, the risk increases substantially, approaching that in T1DM, in advanced of T2DM.

Because asymptomatic episodes will almost invariably be missed, symptomatic episodes may not be recognized as the result of hypoglycemia [81] and, even if they are, they are not long remembered [82,83], estimates of the frequency of iatrogenic hypoglycemia are underestimates. Although they represent only a small fraction of the total hypoglycemic experience, because they are dramatic events that are more likely to be reported (by the patient or an associate) [82,83], estimates of the frequency of severe hypoglycemia, requiring the assistance of another person, are more reliable, particularly if they are determined in population-based prospective studies that include a focus on hypoglycemia [1,2].

The prospective population-based data of Donnelly *et al.* [65] indicate that the overall incidence of hypoglycemia in insulin treated T2DM is approximately one-third of that in T1DM (Table 33.4). The incidence of any and of severe hypoglycemia was approximately 4300 and 115 episodes per 100 patient-years, respectively, in T1DM and approximately 1600 and 35 episodes per 100 patient-years, respectively, in insulin-treated T2DM. In addition, in population-based studies the incidence of severe hypoglycemia requiring emergency treatment in insulin-treated T2DM was approximately 40% [79] and approximately 100% [80] of that in T1DM. Because the prevalence of T2DM is approximately 20-fold greater than that of T1DM, and most people with T2DM ultimately require treatment with insulin, these data suggest that most episodes of iatrogenic hypoglycemia, including severe hypoglycemia, occur in people with T2DM.

### Impact of hypoglycemia

Iatrogenic hypoglycemia causes recurrent physical and psychologic morbidity, and some mortality, impairs defenses against subsequent hypoglycemia and precludes maintenance of euglycemia over a lifetime of diabetes [1,2]. In the short-term it causes brain fuel deprivation that, if unchecked, results in functional brain failure that is typically corrected after the plasma glucose concentration is raised [4]. Rarely, it causes sudden, presumably cardiac arrhythmic [84,85], death or, if it is profound and prolonged, brain death [4].

The physical morbidity of an episode of hypoglycemia ranges from unpleasant symptoms to seizure and coma [1,2,4]. It can impair judgment, behavior and performance of physical tasks. Permanent neurologic damage is rare. While there is concern that recurrent hypoglycemia might cause chronic cognitive impairment, long-term follow-up of the DCCT patients is reassuring in that regard [86]. Nonetheless, the possibility that it does so in young children remains [87,88], and there are no corresponding

data in the elderly [86]. The psychologic morbidity includes fear of hypoglycemia [89], which can be a barrier to glycemic control.

Three early reports indicated that 2–4% of people with diabetes die from hypoglycemia [90–92]. More recent reports indicated that 6% [86], 7% [93] and 10% [94] of deaths of people with T1DM were the result of hypoglycemia. Similar data are not available for T2DM but mortality rates of up to 10% during episodes of severe sulfonylurea induced hypoglycemia have been reported [95,96].

The cause of excess mortality during intensive glyceemic therapy of patients with T2DM in the large Action to Control Cardiovascular Risk in Diabetes (ACCORD) study [60] is not known, and likely will not be known with certainty [1,2]. It could have been chance; excessive mortality during intensive glyceemic therapy was not observed in the ADVANCE trial [59] although there was less glyceemic separation between the groups. It could have been the result of a non-glyceemic effect of the intensive therapy regimen (e.g. an adverse effect of a drug, weight gain or something else). Nonetheless, the most plausible cause of excess mortality during intensive glyceemic therapy in ACCORD is hypoglycemia [1,2]:

- 1 Median glyceemia (HbA<sub>1c</sub>) was lower in the intensive glyceemic therapy group.
- 2 Lower median glyceemia is associated with a higher frequency of hypoglycemia in T2DM [59,60,68].
- 3 Hypoglycemia can be fatal in T2DM [4,84,85,95,96].
- 4 More patients died in the intensive glyceemic therapy group.

### Clinical definition and classification of hypoglycemia

The American Diabetes Association (ADA) Workgroup on Hypoglycemia [97] defined hypoglycemia in diabetes as “all episodes of abnormally low plasma glucose concentration that expose the individual to potential harm.” It is not possible to state a specific plasma glucose concentration that defines clinical hypoglycemia. Although symptoms typically develop at a plasma glucose concentration of approximately 50–55 mg/dL (2.8–3.1 mmol/L) (Table 33.1) [11] in individuals without diabetes, the glyceemic threshold for symptoms (as well as those for glucose counter-regulatory and cognitive dysfunction responses) shift to lower plasma glucose concentrations in people with tightly controlled diabetes and recurrent hypoglycemia [98,99] and to higher plasma glucose concentrations in those with poorly controlled diabetes [98,100].

The ADA Workgroup recommended that people with drug-treated diabetes (implicitly those treated with an insulin secretagogue or insulin) become concerned about the possibility of developing hypoglycemia at a plasma glucose concentration of  $\leq 70$  mg/dL (3.9 mmol/L) [97]. Within the error of self-monitoring of blood glucose (or continuous glucose sensing), that conservative alert value approximates the lower limit of the non-diabetic post-absorptive plasma glucose concentration range [11] and the normal glyceemic thresholds for activation of physiologic glucose counter-regulatory systems [11], and is low enough to reduce glyceemic defenses against subsequent hypoglycemia

**Table 33.5** American Diabetes Association Workgroup on Hypoglycemia classification of hypoglycemia in people with diabetes [97].

**Severe hypoglycemia**

An event requiring assistance of another person to administer actively carbohydrate, glucagon or other resuscitative actions. Plasma glucose measurements may not be available during such an event, but neurologic recovery attributable to the restoration of plasma glucose to normal is considered sufficient evidence that the event was induced by a low plasma glucose concentration

**Documented symptomatic hypoglycemia**

An event during which typical symptoms of hypoglycemia are accompanied by a measured plasma glucose concentrations  $\leq 70$  mg/dL (3.9 mmol/L)

**Asymptomatic hypoglycemia**

An event not accompanied by typical symptoms of hypoglycemia but with a measured plasma glucose concentration  $\leq 70$  mg/dL (3.9 mmol/L)

**Probable symptomatic hypoglycemia**

An event during which symptoms typical of hypoglycemia are not accompanied by a plasma glucose determination but that was presumably caused by a plasma glucose concentration  $\leq 70$  mg/dL (3.9 mmol/L)

**Relative hypoglycemia**

An event during which the person with diabetes reports any of the typical symptoms of hypoglycemia, and interprets those as indicative of hypoglycemia, with a measured plasma glucose concentration  $> 70$  mg/dL (3.9 mmol/L) but approaching that level

[101], in individuals without diabetes. It also generally provides some margin for the relative inaccuracy of glucose monitors at low plasma glucose concentrations [102]. The use of this plasma glucose cutoff value, compared with lower values, will result in higher frequencies of hypoglycemia, and a greater proportion of episodes that are asymptomatic.

The recommended generic alert value does not mean that people with diabetes should always treat for hypoglycemia at an estimated plasma glucose concentration of  $\leq 70$  mg/dL (3.9 mmol/L). Rather, it indicates that they should consider actions ranging from repeating the measurement in the near-term through behavioral changes such as avoiding exercise or driving without treatment to carbohydrate ingestion and subsequent regimen adjustments.

The ADA Workgroup also recommended a clinical classification of hypoglycemia (Table 33.5) [97].

**Prevention and treatment of hypoglycemia in diabetes**

**Prevention of hypoglycemia: hypoglycemia risk factor reduction**

Iatrogenic hypoglycemia is a barrier to glycemic control in people with diabetes [1,2], but that barrier can be lowered in individual patients with diabetes by the practice of hypoglycemia risk factor reduction (Table 33.6) [1,2,47]. That involves four steps:

**Table 33.6** Hypoglycemic risk factor reduction.

- 1 Acknowledge the problem
- 2 Apply the principles of aggressive glycemic therapy
  - Diabetes self-management (patient education and empowerment)
  - Frequent self-monitoring of blood glucose (and in some instances continuous glucose sensing)
  - Flexible and appropriate insulin (and other drug) regimens
  - Individualized glycemic goals
  - Ongoing professional guidance and support
- 3 Consider the conventional risk factors for hypoglycemia (Table 33.3)
- 4 Consider the risk factors indicative of hypoglycemia-associated autonomic failure (Table 33.3)

- 1 Acknowledge the problem;
- 2 Apply the principles of aggressive glycemic therapy [1,2,47,103–107];
- 3 Consider the conventional risk factors for hypoglycemia (Table 33.3); and
- 4 Consider the risk factors for hypoglycemia-associated autonomic failure (HAAF) in diabetes (Table 33.3).

The issue of hypoglycemia should be addressed in every contact with people with diabetes, at least those treated with an insulin secretagogue or with insulin [1,2,47]. Acknowledging the problem allows the caregiver either to move on if hypoglycemia is not an issue or to address it, and keep it in perspective, if hypoglycemia is an issue. Patient concerns about the reality, or even the possibility, of hypoglycemia can be a barrier to glycemic control [108,109]. It is often also helpful to question close associates of the patient because they may have observed clues to episodes of hypoglycemia not recognized by the patient. Even if no concerns are expressed, examination of the self-monitoring of blood glucose records (or continuous glucose sensing data) will often disclose that hypoglycemia is a problem.

If hypoglycemia is an issue, the principles of aggressive glycemic therapy in diabetes [1,2,47,103–107] should be reviewed and applied. Those include diabetes self-management based on patient education and empowerment, frequent self-monitoring of blood glucose (and in some instances continuous glucose sensing), flexible and appropriate insulin (and other drug) regimens, individualized glycemic goals, and ongoing professional guidance and support (Table 33.6).

Patient education and empowerment are fundamentally important. As the therapeutic regimen becomes progressively more complex – early in T1DM and later in T2DM – the success of glycemic management becomes progressively more dependent on the many management decisions and skills of the well-informed person with diabetes. In addition to basic training about diabetes, people with insulin secretagogue or insulin-treated diabetes need to be taught about hypoglycemia [110]. They need to know the common symptoms of hypoglycemia, and their individual most meaningful symptoms, and how to treat (and not overtreat) an episode. Close associates also need to be

taught the symptoms and signs of hypoglycemia, and when and how to administer glucagon. Patients need to understand the relevant conventional risk factors for hypoglycemia (Table 33.3) including the effects of the dose and timing of their individual secretagogue or insulin preparation(s) as well as the effects of missed meals and the overnight fast, exercise and alcohol ingestion. They also need to know that episodes of hypoglycemia signal an increased likelihood of future, often more severe, hypoglycemia [50–52,54,110–113]. Finally, patients using an online glucose sensor need to apply those data critically to their attempts to minimize hypoglycemia as well as hyperglycemia.

In patients treated with an insulin secretagogue, and particularly those treated with insulin, frequent self-monitoring of blood glucose becomes progressively more key to diabetes self-management as the therapeutic regimen becomes more complex, early in T1DM and later in T2DM. Ideally, patients should estimate their glucose levels whenever they suspect hypoglycemia. That would not only confirm or deny an episode of hypoglycemia, it would also help the individual learn the key symptoms of their hypoglycemic episodes and might lead to regimen adjustments. It is particularly important for people with hypoglycemia unawareness to monitor their glucose level before performing a critical task such as driving. Self-monitoring of blood glucose provides a glucose estimate only at one point in time; it does not indicate whether glucose levels are falling, stable or rising. That limitation is addressed by evolving technologies for continuous glucose sensing [114–118]. While the utility of such data seems self-evident, critical clinical data on that point are needed.

Flexible and appropriate drug regimens are key components of hypoglycemia risk factor reduction [1,2,47]. Hypoglycemia is typically the result of relative or absolute therapeutic (endogenous or exogenous) insulin excess and compromised defenses against falling plasma glucose concentrations. The relevant treatments include insulin or an insulin secretagogue such as a sulfonylurea (e.g. glibenclamide [glyburide], glipizide, glimepiride and gliclazide) or a glinide (e.g. repaglinide or nateglinide). Early in the course of T2DM, patients may respond to drugs that do not raise insulin levels at low or normal plasma glucose concentrations and therefore should not, and probably do not, cause hypoglycemia [119]. Those include the biguanide metformin, which nonetheless has been reported to cause self-reported hypoglycemia [68,120], thiazolidinediones (e.g. pioglitazone, rosiglitazone),  $\alpha$ -glucosidase inhibitors (e.g. acarbose, miglitol), glucagon-like peptide 1 (GLP-1) receptor agonists (e.g. exenatide, liraglutide) and dipeptidyl peptidase 4 (DPP-4) inhibitors (e.g. sitagliptin, vildagliptin). All of these drugs require endogenous insulin secretion to lower plasma glucose concentrations, and insulin secretion declines appropriately as glucose levels fall into the normal range. That is true even for the GLP-1 receptor agonists and the DPP-4 inhibitors which enhance glucose stimulated insulin secretion (among other actions). They do not stimulate insulin secretion at normal or low plasma glucose concentrations (i.e. they increase insulin secretion in a glucose-dependent fashion); however, the latter feature may be lost, and hypogly-

cemia can occur, when they are used with an insulin secretagogue [121]. Indeed, all five categories of drugs increase the risk of hypoglycemia if used with an insulin secretagogue or insulin.

Among the commonly used sulfonylureas, the longer acting glibenclamide (glyburide) is more often associated with hypoglycemia than the shorter acting glimepiride [122,123]. The use of long-acting insulin analogs (e.g. glargine or detemir), rather than neutral protamine Hagedorn (NPH) insulin, as the basal insulin in a multiple daily injection (MDI) insulin regimen reduces at least the incidence of nocturnal hypoglycemia, and perhaps that of total, symptomatic and nocturnal hypoglycemia as well, in T1DM and T2DM [124–126]. The use of a rapid-acting analog (e.g. lispro, aspart or glulisine) as the prandial insulin in a MDI regimen reduces the incidence of nocturnal hypoglycemia, at least in T1DM [124,126]. Albeit conceptually attractive, the superiority of continuous subcutaneous insulin infusion (CSII) over MDI with insulin analogs with respect to the frequency and severity of hypoglycemia at comparable levels of glycemic control remains to be established convincingly [127,128]. In addition to the use of insulin analogs [124–126], approaches to the prevention of nocturnal hypoglycemia include attempts to produce sustained delivery of exogenous carbohydrate or sustained endogenous glucose production throughout the night [129].

Partial glycemic control reduces, but does not eliminate, the development of microvascular complications of diabetes, namely retinopathy, nephropathy and neuropathy, in T1DM [56,57] and in T2DM [67,130]. Extrapolation of the DCCT retinopathy data suggests that long-term maintenance of euglycemia might eliminate those complications [131]. Follow-up of the DCCT patients seemingly indicates that a period of earlier partial glycemic control also reduces macrovascular complications in T1DM [132]. Aside from the metformin subset of the UK Prospective Diabetes Study (UKPDS) [130], randomized controlled trials have not documented a cardiovascular mortality benefit of partial glycemic control in T2DM [59,60,67]; however, those trials do not exclude a macrovascular benefit of glycemic control, or even partial glycemic control, if that could be maintained over a longer period of time. Indeed, follow-up of the UKPDS patients also seemingly indicates a macrovascular benefit of a period of earlier partial glycemic control [133]. In any event, given its documented microvascular benefit, maintenance of euglycemia over a lifetime of diabetes would be in the best interests of people with diabetes if that could be accomplished safely [1,2]. Unfortunately, it cannot be accomplished safely in the vast majority of patients with currently available treatment methods because of the barrier of hypoglycemia [1,2]. Thus, the generic glycemic goal is a HbA<sub>1c</sub> level as close to the non-diabetic range as can be accomplished safely in a given patient [134,135] at a given point in the evolution of his or her diabetes. Nonetheless, there is substantial long-term benefit from reducing HbA<sub>1c</sub> levels from higher to lower, although still above recommended levels [56,57,67,130,136]. Clearly, glycemic goals should be individualized and may need to be reconsidered over time because of progression of endogenous insulin deficiency, the development of co-morbid illness and

functional impairment that negates the benefit of glycemic control, or both [137].

Because the glycemic management of diabetes is empirical, caregivers should work with each individual patient over time to find the most effective and safest method of glycemic control at a given point in the course of that patient's diabetes. Care is best accomplished by a team that includes, in addition to a physician, professionals trained in, and dedicated to, translating the standards of care into the care of individual patients and making full use of modern communication and computing technologies.

Having recognized the problem and reviewed and applied the principles of aggressive glycemic therapy, the next step is to consider the conventional risk factors for hypoglycemia, those that result in relative as well as absolute therapeutic insulin excess. In addition to insulin secretagogue or insulin doses, timing and type, those include conditions in which exogenous glucose delivery or endogenous glucose production is decreased, glucose utilization or sensitivity to insulin is increased, or insulin clearance is reduced (Table 33.3).

Finally, the risk factors for HAAF need to be considered. Those include the degree of endogenous insulin deficiency, a history of severe hypoglycemia, hypoglycemia unawareness, or both, as well as any relationship between hypoglycemic episodes and recent antecedent hypoglycemia, prior exercise or sleep, and lower HbA<sub>1c</sub> levels (Table 33.3). Unless the cause is easily remediable, a history of severe hypoglycemia should prompt consideration of a fundamental regimen adjustment. Without that, the risk of a subsequent episode of severe hypoglycemia is high [50–52,54,110–113]. Given a history of hypoglycemia unawareness, a 2–3 week period of scrupulous avoidance of hypoglycemia, which may require acceptance of somewhat higher glycemic goals in the short term, is advisable because that can be expected to restore awareness [34–37]. A history of late post-exercise hypoglycemia, nocturnal hypoglycemia, or both, should prompt appropriately timed regimen adjustments (generically, less insulin action, more carbohydrate ingestion, or both).

When prevention fails, treatment of hypoglycemia becomes necessary. Most episodes of asymptomatic hypoglycemia (detected by self-monitoring of blood glucose or continuous glucose sensing) and of mild–moderate symptomatic hypoglycemia are effectively self-treated by ingestion of glucose tablets or carbohydrate containing juice, soft drinks, candy, other snacks or a meal [138,139]. A reasonable dose is 20 g glucose [139]. Clinical improvement should occur in 15–20 minutes, however, in the setting of ongoing hyperinsulinemia, the glycemic response to oral glucose is transient, typically less than 2 hours [139]. Thus, ingestion of a more substantial snack or meal shortly after the plasma glucose concentration is raised is generally advisable.

Parenteral treatment is required when a hypoglycemic patient is unwilling (because of neuroglycopenia) or unable to take carbohydrate orally. Glucagon, injected subcutaneously or intramuscularly (in a usual dose of 1.0 mg in adults) by an associate of the patient, is often used. That can be life-saving, but it often

causes substantial, albeit transient, hyperglycemia and it can cause nausea or even vomiting. Smaller doses of glucagon (e.g. 150 µg), repeated if necessary, have been found to be effective without side effects [140]. Because it acts by stimulating hepatic glycogenolysis, glucagon is ineffective in glycogen depleted individuals (e.g. following a binge of alcohol ingestion).

Although glucagon can be administered intravenously by medical personnel, intravenous glucose is the standard parenteral therapy. A common initial dose is 25 g [138]. The glycemic response to intravenous glucose is, of course, transient in the setting of ongoing hyperinsulinemia.

The duration of an episode of iatrogenic hypoglycemia is a function of its cause. An episode caused by a rapid-acting insulin secretagogue or insulin analog will be relatively brief, that caused by a long-acting sulfonylurea or insulin analog substantially longer. The latter can result in prolonged hypoglycemia requiring hospitalization.

---

## Perspective on hypoglycemia in diabetes

Glycemic control, a focus of this chapter, is but one aspect of the management of diabetes. It is now possible to drive plasma low density lipoprotein (LDL) cholesterol concentrations to subphysiologic levels and to normalize blood pressure pharmacologically, usually without major side effects, in most people with diabetes. Weight loss and smoking cessation are more challenging. While it is not possible to maintain euglycemia over a lifetime of diabetes, because of the barrier of hypoglycemia, maintenance of the lowest mean glycemia that can be accomplished safely is in the best interest of people with diabetes.

Despite the difficulty, people with diabetes and their caregivers should keep the problem of iatrogenic hypoglycemia in perspective. Early in the course of T2DM, by far the most common type of diabetes, hyperglycemia may respond to lifestyle changes, specifically weight loss, or to glucose lowering drugs that do not raise insulin levels and therefore do not cause hypoglycemia. In theory, when such drugs are effective in the absence of side effects there is no reason not to accelerate their dosing until euglycemia is achieved. Over time, however, as people with T2DM become progressively more insulin deficient, those drugs, even in combination, fail to maintain glycemic control. Insulin secretagogues are also effective early in the course of T2DM, but they cause hyperinsulinemia and therefore introduce the risk of hypoglycemia. Euglycemia is not an appropriate goal during therapy with an insulin secretagogue or with insulin. Nonetheless, as discussed earlier, the frequency of hypoglycemia is relatively low (with current less than euglycemic goals) during treatment with an insulin secretagogue or even with insulin early in the course of T2DM when glycemic defenses against falling plasma glucose concentrations are still intact. Thus, over much of the course of the most common type of diabetes it is possible to maintain a meaningful degree of glycemic control with no risk or relatively low risk of hypoglycemia.

The challenge is greater in people with advanced T2DM and T1DM caused by compromised defenses against falling plasma glucose concentrations and the resulting higher barrier of iatrogenic hypoglycemia. In such patients therapy with insulin is demonstrably effective, but it is not demonstrably safe. Nonetheless, concerns about hypoglycemia should not be used as an excuse for poor glycemic control. It should be recalled that the DCCT data [56,136] document that the relationship between microvascular complications and mean glycemia is curvilinear; some degree of glycemic control puts the patient at substantially lower risk than little or no glycemic control.

Diabetes will someday be cured and prevented. Pending that, elimination of hypoglycemia from the lives of people with diabetes will likely be accomplished by new treatment methods that provide plasma glucose regulated insulin replacement or secretion. In the meantime, innovative research is needed if we are to improve the lives of all people affected by diabetes by lowering the barrier of iatrogenic hypoglycemia.

---

## Acknowledgments

The author's original work cited has been supported, in part, by US Public Health Service, National Institutes of Health grants R37 DK27085, MO1 RR00036 (now UL1 RR24992), P60 DK20579 and T32 DK07120 and by a fellowship award from the American Diabetes Association. The author is grateful for the contributions of the postdoctoral fellows who did the bulk of the work and made the work better by their conceptual input, and the skilled nursing, technical, dietary and data management/statistical assistance of the staff of the Washington University General Clinical Research Center. Ms. Janet Dedeker prepared this manuscript.

This chapter was written shortly after completion of the author's Perspective in Diabetes [1] and his book *Hypoglycemia in Diabetes: Pathophysiology, Prevalence and Prevention* [2]. Therefore, much of the factual and interpretive content here is the same, as is no small part of the phraseology.

## Acute Metabolic Complications of Diabetes: Diabetic Ketoacidosis and Hyperosmolar Hyperglycemia

**Troels Krarup Hansen & Niels Møller**

Medical Department M (Endocrinology and Diabetes), Aarhus University Hospital, Aarhus, Denmark

### Keypoints

#### Diabetic ketoacidosis

- Lack of insulin is the culprit in diabetic ketoacidosis.
- The most common precipitating cause is infection.
- The classic signs include polyuria and polydipsia, rapid weight loss, weakness, Kussmaul respiration, drowsiness and, rarely, coma.
- The cornerstones of treatment are rehydration, IV insulin and potassium supplementation.
- Intravenous insulin administration should continue until the acidosis is normalized (i.e. not merely until euglycemia is achieved).

#### Hyperosmolar non-ketotic hyperglycemia

- This is characterized by hyperosmolality with progressive hyperglycemia of  $>35$ – $40$  mmol/L and an effective serum osmolality of  $>320$  mOsm/kg.
- It typically affects elderly patients with type 2 diabetes.
- The most common precipitating causes are infection and cardiovascular disease.
- Treatment involves aggressive rehydration and IV insulin.

### Introduction

Both diabetic ketoacidosis (DKA) and hyperosmolar non-ketotic hyperglycemia (HH) are caused by a lack of insulin leading to unrestricted flux of stored lipid, carbohydrate and amino acid nutrients into the blood. These conditions are both acute and life-threatening, and represent the ultimate metabolic consequences of deranged type 1 (T1DM) and type 2 diabetes mellitus (T2DM), respectively [1–3]. The hallmark of DKA is a high-anion-gap metabolic acidosis caused by a rapidly progressive excess of ketoacids (3-hydroxybutyrate and acetoacetate – “ketone bodies”) while severe hyperosmolality caused by hyperglycemia is the most notable feature of HH. The distinction is not always obvious on clinical grounds; patients with DKA may be very hyperosmolar and ketone body levels are in general somewhat elevated in HH. Although the clinical picture may vary considerably depending on co-morbidities, differential diagnosis seldom poses any major problem and in the rare cases in which distinction remains difficult, treatment generally follows the same prin-

ciples, regardless of whether ketosis or hyperglycemia is the most urgent clinical challenge.

Mortality rates have been steadily declining over the past few years [4], but remain close to 5% for DKA and 10–15% for HH [2,5]. The decline in mortality may be a consequence of lower incidence of DKA and HH, earlier diagnosis, improved treatment or, more plausibly, all of these effects combined. Improved education schedules and self-monitoring (e.g. blood ketone testing), organization of specialized diabetes clinics and the use of standardized low-dose insulin regimens have also contributed to this favorable trend [2,6].

### Diabetic ketoacidosis

#### Definitions

Diabetic ketoacidosis is the most common, serious and demanding medical emergency within the fields of diabetology and endocrinology. There is no generally accepted definition of DKA and, in particular, very mild cases may be difficult to diagnose. At a minimum, it is reasonable to require that pH is below the normal range and that the levels of ketoacids (ketone bodies) in the blood or urine are markedly elevated. As outlined in Table 34.1, there is a continuous deterioration from clinically insignificant “stress” ketosis to full-blown severe ketoacidosis. In the US population,

**Table 34.1** Classification of clinical pictures and diagnostic criteria. Adapted from Standards of Medical Care in Diabetes – 2004/2006 position statement. *Diabetes Care* 2004; **27**:S94–S101, with permission from the American Diabetes Association.

	Stress ketosis	Compensated DKA	Diabetic ketoacidosis			Hyperosmolar hyperglycemia
			Mild	Moderate	Severe	
Plasma glucose	Variable	Generally increased	Generally increased	Generally increased	Generally increased	>35–40 mmol/L
Arterial pH	Normal	Normal	Decreased >7.25	7.0–7.25	<7.0	Generally normal
Serum bicarbonate	Normal	Marginally decreased	15–18 mmol/L	10–15 mmol/L	<10 mmol/L	>15 mmol/L
Urine ketones	Increased	Increased	Increased	Increased	Increased	Normal/marginally increased
Blood ketones	Increased	Increased	Increased	Increased	Increased	Normal/marginally increased
Anion gap*	Normal/marginally increased	Marginally increased	>10	>12	>12	Variable
Mental status	Normal	Normal	Normal	Normal/drowsy	Drowsy–coma	Drowsy–coma

DKA, diabetic ketoacidosis.

\* Anion gap can be calculated as:  $[Na^+] - ([Cl^-] + [HCO_3^-])$ .

it has been estimated that 2–8% of hospital admissions in children with diabetes are a result of DKA and that the annual incidence rate of DKA in children is around 5 per 1000 patients [1].

### Pathogenesis and pathophysiology

#### Insulin deficiency

DKA is caused by insulin deficiency. Insulin deficiency may be relative (e.g. in the setting of severe infection) where normal amounts of insulin are insufficient, or absolute when insulin therapy is neglected. Lack of insulin leads to uncontrolled lipolysis and ketogenesis and increases plasma glucose. Although often disregarded it should also be borne in mind that insulin deficiency, most particularly when longstanding, causes increased breakdown of body protein, as evidenced by the extreme sarcopenia and cachexia of patients with T1DM prior to the insulin era. Excessive protein breakdown and ensuing release of ketogenic and gluconeogenic amino acids may contribute to ketosis and hyperglycemia.

#### Stress hormones and cytokines

At some stage insulin deficiency becomes coupled with excess of “counter-regulatory” or “stress” hormones and cytokines [7,8]. Release of stress hormones may in part be triggered by cytokines and in part by general stress, such as dehydration, hypotension and hypoperfusion. It has been shown that both endotoxin and tumor necrosis factor (TNF) mimics all metabolic responses to infection including hyperthermia and stress hormone release [9,10]. The traditional stress hormones include glucagon, epinephrine, growth hormone (GH) and cortisol, all of which have well-described metabolic actions. Glucagon and epinephrine have a rapid onset of action, whereas GH and cortisol act with a latency of hours.

Cytokine levels are elevated in DKA, even in the absence of infection. The metabolic actions of cytokines are in general not so well understood and it is possible that many of these actions

are mediated by hypothalamo-pituitary activation and subsequent stress hormone release. Certain cytokines, such as TNF- $\alpha$ , may impair insulin sensitivity in peripheral tissues [11,12] and a vicious circle may thus be initiated with self-perpetual increments in blood glucose and cytokine levels. Insulin has anti-inflammatory properties in critically ill patients [13], and administration of exogenous insulin may in itself increase insulin sensitivity [14], conceivably to some extent by breaking this vicious circle but also because glucotoxicity and lipotoxicity wane.

#### Lipid metabolism

Contrary to popular belief, deranged lipid – not carbohydrate – metabolism is the main cause of DKA. In essence, DKA is brought about by uncontrolled lipolysis in adipose tissue and uncontrolled ketogenesis in liver.

Adipose tissue is present in regional depots such as subcutaneous upper and lower body and visceral fat [15]. Apart from these classic depots, fat is present in most other tissues (e.g. connective tissue, bone marrow, liver and muscle). The picture is further complicated by the fact that within each tissue fat is distributed in compartments. In muscle, for instance, fat is present intramyocellularly, intermyocellularly and intermuscularly. Under physiologic conditions, lipolysis is tightly controlled by lipases. Hormone-sensitive lipase and probably also adipose triglyceride lipase stimulate release of free fatty acids and glycerol into the circulation. This process is inhibited by insulin and low insulin levels increase lipolysis swiftly. The stress hormones, such as epinephrine, growth hormone and cortisol, stimulate lipolysis. It is plausible that dehydration per se also participates in the stimulation of lipolysis [16]. These events take place in the course of hours and may rapidly triple or quadruple blood concentrations of free fatty acids.

Ketogenesis occurs in the liver by oxidation of free fatty acids to ketoacids or ketone bodies (Figure 34.1). Ketone bodies, in

**Figure 34.1** Mechanisms of ketogenesis. NEFA, non-esterified fatty acids.

particular 3-OH-butyrate, are phylogenetically ancient fuel compounds, which are present and prominent in very primitive species [17], suggesting that they have had an important role throughout evolution for the past 2–3 billion years. Physiologically, ketone bodies provide important fuel energy for the brain and other tissues under fasting, prolonged exercise and other conditions of fuel shortage. In DKA, ketogenesis becomes uncontrolled and circulating levels of ketone bodies rise rapidly and excessively. This occurs because of both increased supply of fatty acids to the liver and because low levels of insulin and high levels of glucagon in the liver promotes ketogenesis [18]. In normal individuals this unrestrained process is prevented by compensatory

risers in insulin secretion, but this does not occur in those with T1DM.

### Glucose metabolism

Hyperglycemia is usually present in DKA, but it is important to stress that DKA not infrequently presents with normal or modestly elevated glucose concentrations [19]. This may particularly be the case during caloric deprivation caused by gastrointestinal disease, for example. Hyperglycemia is caused by a combination of lack of insulin and an excess of stress hormones, leading to insulin resistance. In the liver this increases gluconeogenesis and hepatic glucose production. The kidney is unlikely to have any

significant role in the initial stages of DKA [20]. The ensuing high glucose levels generate a high flux state with increased peripheral glucose disposal, but the increased mass action of glucose is generally insufficient to compensate fully. Muscle glucose metabolism is characterized by insulin resistance because of high levels of stress hormones, high levels of free fatty acids and varying degrees of dehydration.

### Precipitating factors

In patients with known diabetes, DKA is usually precipitated by a coexisting illness or by omission of insulin therapy. The most common factor is infection, ranging from trivial viral infections to full-blown septicemia. Other precipitating factors include cardiovascular events (myocardial infarction, stroke), gastrointestinal disease, inflammatory diseases, pancreatitis, trauma and major surgery, alcohol abuse and drugs, especially glucocorticoids. All of these factors induce insulin resistance because of the stress hormone responses. Furthermore, poor appetite and food deprivation will often lead the patient to take less insulin. In this context, gastrointestinal disease with nausea and vomiting pose a specific problem and it may be necessary to admit such patients to the hospital for intravenous glucose and insulin therapy. Diabetes ketoacidosis may be a presenting feature of new onset T1DM (see Chapter 19).

Psychologic factors also play an important part. Poor compliance is commonly seen in younger patients, patients with psychiatric illnesses and in minority groups who unfortunately may have a poor understanding of diabetes care principles for linguistic or cultural reasons.

### Diagnosis and clinical presentation

DKA usually develops over a short period of time, generally in less than 24 hours. There may have been some antecedent days with general malaise and poor metabolic control. Depending on the degree of hyperglycemia, the history will include symptoms of polydipsia and polyuria (Table 34.2). Specific symptoms depend on the precipitating factors and other co-morbidities that might be present. Physical examination may reveal poor skin turgor, hyperventilation (Kussmaul respirations), hypotension, tachycardia and impairment of mental state. Many patients have infections but with normothermia or even hypothermia, caused by peripheral vasodilatation brought about by the acidemia.

**Table 34.2** Common clinical features of diabetic ketoacidosis.

Polyuria, polydipsia
Rapid weight loss
Muscular weakness
Visual disturbance
Air hunger with Kussmaul respiration, dry lips
Abdominal pain, leg cramps
Nausea, vomiting
Confusion, drowsiness, coma

Prompt diagnosis and initial treatment rests on:

- 1 Careful clinical examination;
- 2 Determination of plasma glucose;
- 3 Measurement of ketones in blood or urine;
- 4 Measurement of plasma potassium and other electrolytes; and
- 5 Assessment of acidemia.

If glucose is high and blood or urine ketones are markedly elevated, DKA is likely and fluid and insulin therapy can usually be initiated, unless the patient is severely hypokalemic ( $<3.5$  mmol/L). If potassium is very low, supplementation must be given prior to insulin therapy; however, rehydration should not be delayed while waiting for a potassium measurement.

The next diagnostic steps usually include arterial blood gas analysis, blood electrolytes (including anion gap), serum lactate (if there is doubt about the cause of the acidemia), complete blood cell count, biochemical assessment of liver and renal function, blood and urine cultures, myocardial biomarkers (if there is suspicion of a myocardial infarction), electrocardiogram (ECG) and chest X-ray. In this context it is advantageous that most modern gas analyzers also readily provide potassium concentrations. Another recent advantage is the advent of bedside ketone body monitors. Thus, it is now possible to have a quick and reliable measure of 3-hydroxybutyrate concentrations in blood, as opposed to unreliable measurements of acetoacetate in urine or the time-consuming conventional laboratory methods used in the past. The diagnostic criteria are shown in Table 34.1.

Despite potassium depletion, serum potassium is typically either normal or elevated because of water deficiency and an intracellular to extracellular shift caused by insulin deficiency and acidemia. Patients with potassium in the low range have a severe total body potassium deficiency and should receive vigorous replacement therapy guided by cardiac monitoring. Sodium concentrations can be normal or low, as a result of osmotic shifts. It can be calculated that for every 3 mmol/L rise in plasma glucose the plasma sodium falls by 1 mmol/L. Thus, there is often a real hypernatremia with sodium levels rising as the glucose is brought under control. A majority of patients will have a leukocytosis, which correlates with ketone body levels rather than with the presence of infection. There is also a water deficit of around 10% of body weight. Non-specific elevations of amylase and liver enzymes are also common.

Differential diagnoses include all other causes of acidosis. Note that many acute medical conditions induce a stress ketosis and may be associated with acidosis. DKA is a metabolic acidosis characterized by a high anion gap and varying degrees of respiratory compensation. Thus, it is crucial to obtain measures of ketone body concentrations and perform an arterial gas analysis. If there is a major discrepancy between the extent of the ketonemia and the acidemia then lactate measurements are warranted. Starvation ketosis and alcoholic ketoacidosis can usually be identified by clinical history. Other conditions causing metabolic acidosis include lactic acidosis and intoxication with salicylate, methanol, ethylene glycol (antifreeze) and paraldehyde. The clinical picture may be blurred whenever the acidosis is aggra-

vated by renal failure or respiratory failure. In addition, DKA may imitate other diseases. High levels of potassium may also cause ECG changes suggestive of myocardial infarction and elevation of myocardial enzymes and biomarkers may occur in the absence of a clinical myocardial infarction [21]. DKA may also mimic an acute abdomen, particularly in younger patients.

## Management

Management and treatment of DKA rests on four pillars:

- 1 Fluid and electrolyte therapy;
- 2 IV insulin therapy;
- 3 Treatment of co-morbidities; and
- 4 Careful monitoring of the clinical course.

It is particularly important that treatment is initiated without delay and that the patient is monitored frequently and carefully, preferably in a highly specialized unit. Severe cases should be treated and monitored in an intensive care unit where possible. Useful algorithms for treatment are available from many sources including the American Diabetes Association. In general, the overall goal is a controlled, gradual correction of metabolic abnormalities and fluid and electrolyte deficiencies in the course of around 24 hours.

Treatment of DKA in children and young adolescents follows slightly different guidelines than those presented below (see Chapter 51) [22]. It is recommended that in children insulin is given continuously intravenously (0.1 IU/kg body weight/hour) after initiation of fluid and electrolyte therapy in order to minimize the risk of cerebral edema. Otherwise children are in general treated with weight reduced doses as indicated below.

### Fluid/saline therapy

The first priority is to start to replace fluids. Water and sodium deficits typically are around 10% of body weight and 10 mmol/kg and isotonic saline (0.154 mmol/L; 0.9% NaCl) is given at a rate of approximately 15–20 mL/kg/hour or 1 L/hour initially, followed by 250 mL/hour after the first 2–3 hours depending on the state of dehydration. Depending on prevailing sodium concentrations and hydration, hypotonic saline may also be used, but this is rarely necessary. Urine production as well as cardiovascular, renal and mental performance should be monitored frequently.

### Insulin

Lack of insulin is the culprit in DKA and insulin treatment is mandatory. Insulin therapy in adults is given by infusion of 0.1 IU/kg body weight/hour or more simply as 6 units/hour. An IV bolus of 0.15 IU/kg body weight (or 10 IU) of regular insulin can be given initially but is not really required, as most of the initial improvement in metabolic status is brought about by rehydration. Alternatively, a bolus of 0.15 IU/kg body weight (or 10 IU) may be given every hour or a 20 unit bolus IM followed by 6 units every hour. If the patient is very insulin resistant as assessed by daily insulin requirements, dosage can be increased and vice versa if the patient is insulin sensitive. Considering the

short half-life of IV administered insulin, it is imperative that insulin is given at least every hour, regardless of the prevailing blood glucose.

Insulin therapy is adjusted based on hourly measurements of blood glucose and – if possible – blood ketones, with the overall aim being a gradual decline in both. The initial decline is to a large extent caused by rehydration and expansion of the extracellular volume. Repeated analysis of arterial blood gases may be indicated but only in those patients with very low pH values and/or poor clinical condition. Measurements of ketone levels in urine is in general unreliable in this phase; these methods measure acetoacetate, which is quantitatively of minor importance compared to 3-OH-butyrate and acetoacetate in urine may exhibit an paradoxical initial increase because of increasing blood concentrations (and low urine production), despite successful treatment. In particular, acetone is also measured by standard urine dipstick methods and may continue to be excreted for up to 48 hours after the onset of treatment as it is fat soluble and leaches out slowly during treatment.

When glucose concentrations are 10–15 mmol/L, glucose is given IV and/or orally to avoid hypoglycemia. It is usually possible to taper IV insulin treatment when 3-hydroxybutyrate concentrations are well below 3 mmol/L. Ten percent glucose should be used for IV replacement as this provides some extra anabolic substrate. If the patient is still dehydrated then the saline infusion should be continued.

### Potassium, bicarbonate and phosphate

#### Potassium

Even though the body is potassium depleted, with a typical deficit of around 5 mmol/kg, initial potassium values are usually normal or elevated. Insulin therapy, rehydration and correction of acidosis all cause a decrease in serum potassium and 20–30 mmol potassium/hour may be administered once potassium levels are below 5.0 mmol/L, provided renal function is intact. Subsequent potassium administration is guided by frequent concentration measurements; adjuvant oral administration may be used in very mild cases of DKA. It is a frequent practical problem that there may be some delay before values are available from the laboratory; gas analyzers that provide instant bedside potassium concentrations greatly facilitate this process.

#### Bicarbonate

Bicarbonate use in DKA is a matter of controversy [23], but it is empirically recommended that 25–50 mmol sodium bicarbonate is given hourly for 1–2 hours if the pH is below 7.0.

#### Phosphate

Phosphate deficiency of around 1 mmol/kg is typically present in DKA, but there is no evidence that phosphate supplementation should be given routinely. In patients with severe hypophosphatemia and/or cardiac and skeletal or respiratory muscle weakness, 20–30 mmol potassium phosphate can be given hourly for 1–2 hours.

**Co-morbidity**

Coexisting diseases precipitate DKA and DKA precipitates coexisting disease. Most often, patients with DKA have infectious disease and signs of infection should be vigorously sought for and treatment should be instituted as appropriate. Other prominent co-morbidities include cardiovascular events (myocardial infarction, stroke, thrombophlebitis, pulmonary embolism), acute gastrointestinal disorders and a variety of intoxications.

**Complications**

Iatrogenic hypoglycemia and hypokalemia are common and preventable, provided there is access to rapid analysis of glucose and potassium and – not less important – a competent and experienced medical team. Another frequent complication is recurrence of DKA or unnecessary protraction of the course, typically caused by insufficient insulin therapy. Thrombotic events are also not uncommon although more often in HH than DKA.

Cerebral edema is a rare, but often fatal, complication preponderant in children and adolescents. The pathophysiology is poorly understood, but may relate to overly aggressive therapy, the use of hypotonic replacement fluids, local cerebral overhydration and abnormalities of vasogenic function [22]. Symptoms frequently develop 4–12 hours after initiation of therapy and include headache, altered mental status, specific neurologic deficits and signs of increased intracranial pressure. Treatment with mannitol or hypertonic saline may be beneficial in this condition.

In some patients, the high anion-gap ketoacidosis may be further complicated by the appearance of a non-anion-gap hyperchloremic acidosis during treatment with insulin and saline infusions [24]. This is because of loss of alkali in the form of ketoanions with sodium or potassium in the urine. This component often results in protracted acidosis, which can confuse clinical assessment. Some of these patients may benefit from bicarbonate therapy.

**Prevention**

Implementation of self-care and shared-care principles is crucial. Patients should learn about symptoms of DKA and be able to measure ketones in blood or urine when they feel ill or if their blood glucose is high. A common lapse is the omission or reduction of insulin during episodes with impaired well-being and poor appetite. Persistent ketosis should be treated with extra insulin, fluid and carbohydrate, when necessary. Furthermore, it is very important that the individual patient has ready, 24 hours/day access to diabetologic expertise, preferably in a specialized diabetes center.

**Hyperosmolar hyperglycemia**

Hyperosmolar hyperglycemia (HH) is generally the fulminant result of poorly treated T2DM or delayed diagnosis of previously unknown T2DM. HH is less frequent than DKA, but mortality is higher and remains close to 15% in many centers [2,25]. As

implied, hyperosmolality is the primary clinical problem accompanied by hyperglycemia of >35–40 mmol/L and an effective serum osmolality of >320 mOsm/kg (Table 34.1). HH most often occurs in frail patients in combination with other potentially fatal conditions. Strict differentiation between DKA and HH can be difficult, because some degree of ketosis may be present in HH and because lactic acidosis, respiratory and renal failure may also be present. In practice this dilemma is mainly ornamental, because diagnostic and therapeutic efforts follow the same principles.

In line with DKA, HH is most often precipitated by infectious diseases or cardiovascular events and symptoms of hyperglycemia usually have been present for some days. Hyperglycemia is caused by a vicious cycle, in which relative insulin deficiency and high levels of stress hormones lead to increased endogenous glucose production and decreased peripheral glucose utilization; hyperglycemia in turn induces hyperosmolality and dehydration, which amplifies the stress hormone response and further impairs insulin secretion and vice versa.

At presentation, the patient's clinical condition is poor, with severe dehydration, poor skin turgor and often an altered level of consciousness (ranging from drowsiness to coma) and signs of hypovolemic shock. In general, the diagnostic procedures are similar to DKA. Typically, there will be a water deficit of 10–20% of body weight together with sodium, chloride and potassium deficits of 5–10 mmol/kg body weight.

Treatment of HH in general follows the same guidelines as for DKA, the main aim being a controlled correction of hyperglycemia, hyperosmolality and water and electrolyte deficits over 24 hours. Patients are generally more sensitive to insulin and an infusion of 0.1 IU/kg body weight/hour is more than adequate in most cases. Repeated hourly boluses of 0.15 IU/kg body weight (or 10 IU) may also be used. As with DKA, the dosage should be adjusted according to normal daily insulin needs and depending on the therapeutic response. Usually 1 L isotonic saline is infused in the first hour but after that slower rehydration is advisable. Hemodynamic performance should be monitored carefully and it should be borne in mind that many of the patients have pre- or coexisting cardiac disease. The use of a central venous pressure line is helpful. It should be noted that a significant proportion of HH patients are hypernatremic. In this case hypotonic saline can be used but more slowly. Potassium is administered along the same lines as with DKA and it is often prudent to monitor the patient in the intensive care unit.

# 7 Microvascular Complications in Diabetes

# 35

## Pathogenesis of Microvascular Complications

**Ferdinando Giacco & Michael Brownlee**

Diabetes Research Center, Departments of Medicine and Endocrinology, Albert Einstein College of Medicine, NY, USA

### Keypoints

- Microvascular complications are caused by prolonged exposure to hyperglycemia.
- Hyperglycemia damages cell types that cannot downregulate glucose uptake, causing intracellular hyperglycemia.
- Intracellular hyperglycemia damages tissues by five major mechanisms: increased flux of glucose and other sugars through the polyol pathway; increased intracellular formation of advanced glycation end-products (AGEs); increased expression of the receptor for AGEs and its activating ligands; activation of protein kinase C isoforms; and overactivity of the hexosamine pathway.
- A single process – increased mitochondrial production of oxygen free radicals – activates each of these mechanisms.
- Persistent consequences of hyperglycemia-induced mitochondrial superoxide production may also explain the continuing progression of tissue damage after improvement of glycemic levels (“hyperglycemic memory”).
- Different individual susceptibility to microvascular complications have been linked to polymorphisms in the superoxide dismutase 1 gene.
- Hyperglycemia-induced mitochondrial reactive oxygen species production impairs the neovascular response to ischemia by blunting hypoxia-inducible factor 1 transactivation.
- Hypertension accelerates microvascular damage by increasing intracellular hyperglycemia through upregulation of the glucose transporter 1.
- Potential mechanism-based therapeutic agents for diabetic microvascular complications include transketolase activators, poly(ADP-ribose) polymerase inhibitors and catalytic antioxidants.

### Overview of diabetic complications

All forms of diabetes are characterized by hyperglycemia, a relative or absolute lack of insulin action, and the development of diabetes-specific pathology in the retina, renal glomerulus and peripheral nerve. Diabetes is also associated with accelerated atherosclerotic disease affecting arteries that supply the heart, brain and lower extremities. As a consequence of its disease-specific pathology, diabetes mellitus is now the leading cause of new blindness in people 20–74 years of age and the leading cause of end-stage renal disease (ESRD) in the developed world. Survival of patients with diabetic ESRD on dialysis is half that of those without diabetes. More than 60% of patients with diabetes are affected by neuropathy, which includes distal symmetrical polyneuropathy, mononeuropathies and a variety of autonomic neuropathies causing erectile dysfunction, urinary incontinence, gastroparesis and nocturnal diarrhoea. Diabetic accelerated lower extremity arterial disease in conjunction with neuropathy

accounts for 50% of all non-traumatic amputations in the USA. Diabetes and impaired glucose tolerance increase cardiovascular disease (CVD) risk three- to eightfold. Thus, over 40% of patients hospitalized with acute myocardial infarction (MI) have diabetes and 35% have impaired glucose tolerance. Finally, new blood vessel growth in response to ischemia is impaired in diabetes, resulting in decreased collateral vessel formation in ischemic hearts, and in non-healing foot ulcers. The focus of this chapter is on the microvascular complications comprising retinopathy, nephropathy and peripheral neuropathy.

Much of the impact of chronic diabetes falls on the microcirculation [1,2]. With long-standing disease, there is progressive narrowing and eventual occlusion of vascular lumina, resulting in impaired perfusion, ischemia and dysfunction of the affected tissues. Several processes contribute to microvascular occlusion. One of the earliest is increased vascular permeability, allowing extravasation of plasma proteins that accumulate as periodic acid–Schiff-positive deposits in the vessel walls. In addition, the extracellular matrix elaborated by perivascular cells such as pericytes (retina) and mesangial cells (glomerulus) is increased, brought about by changes in synthesis and turnover of its component proteins and glycosaminoglycans. As a result, the basement membrane is thickened in many tissues, including retinal capillaries and the vasa nervorum, while mesangial matrix is

expanded in the renal glomerulus. Hypertrophy and hyperplasia of endothelial, mesangial and arteriolar smooth muscle cells also contribute to vessel wall thickening. Finally, increased coagulability of the blood and adhesion of platelets and leukocytes to the endothelial surface lead to microthrombus formation and luminal occlusion.

The progressive narrowing and blockage of diabetic microvascular lumina are accompanied by loss of microvascular cells. In the retina, diabetes induces apoptosis of Müller cells and ganglion cells [3], pericytes and endothelial cells [4]. In the glomerulus, widespread capillary occlusion and declining renal function are associated with podocyte loss. In the vasa nervorum of diabetic nerves, endothelial cell and pericyte degeneration occur [5] and appear to precede functional abnormalities of peripheral nerves [6]. Increased apoptosis of cells in the retina, renal glomerulus and peripheral neurons is a prominent feature of diabetic microvascular tissue damage [7–11] and may also cause damage to adjacent cells.

### Role of hyperglycemia in microvascular complications

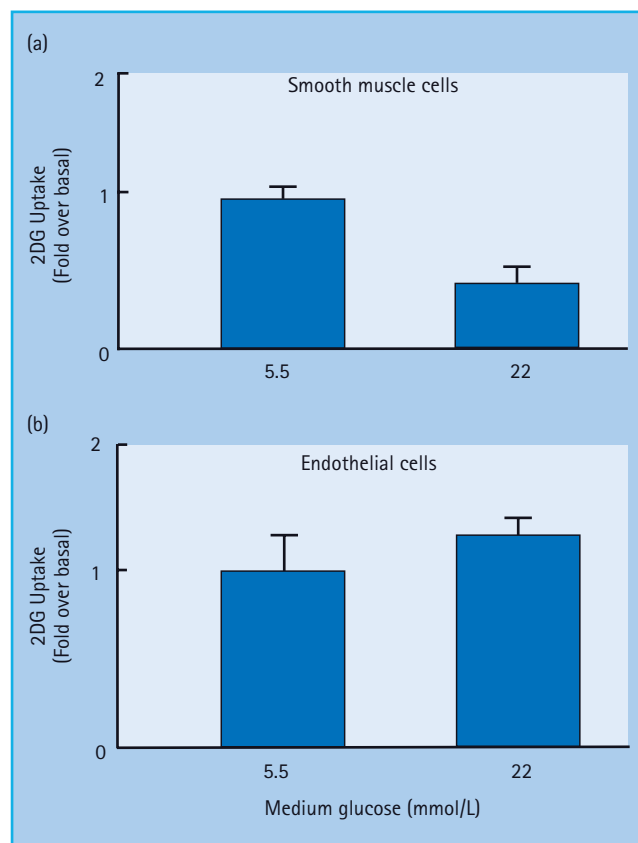

Overall, diabetic microvascular complications are caused by prolonged exposure to high glucose levels. This has been established by large-scale prospective studies for both type 1 diabetes (T1DM) by the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications Study [DCCT/EDIC] [12] and for type 2 diabetes (T2DM) by the UK Prospective Diabetes Study [UKPDS] [13]). Similar data have been reported by the Steno-2 study [14].

Because every cell in the body of people with diabetes is exposed to abnormally high glucose concentrations, why does hyperglycemia selectively damage some cell types and not others? The targeting of specific cell types by generalized hyperglycemia reflects the failure of those cells to downregulate their uptake of glucose when extracellular glucose concentrations are elevated. Cells that are not directly susceptible to direct hyperglycemic damage such as vascular smooth muscle show an inverse relationship between extracellular glucose concentrations and glucose transport. In contrast, vascular endothelial cells, a major target of hyperglycemic damage, show no significant change in glucose transport rate when glucose concentration is elevated, resulting in intracellular hyperglycemia (Figure 35.1). These differences are caused in part by tissue-specific differences in expression and function of different glucose transporter (GLUT) proteins [15].

### Mechanisms of hyperglycemia-induced damage

There are nearly 2000 publications supporting five major mechanisms by which hyperglycemia causes diabetic complications:

1 Increased flux of glucose and other sugars through the polyol pathway;

**Figure 35.1** Lack of downregulation of glucose transport by hyperglycemia in cells affected by diabetic complications. (a) 2-Deoxyglucose uptake in vascular smooth muscle cells pre-exposed to 5.5 or 22 mmol/L glucose. (b) 2-Deoxyglucose uptake in aortic endothelial cells pre-exposed to 5.5 or 22 mmol/L glucose. Data from Kaiser N, Sasson S, Feener EP, Boukobza-Vardi N, Higashi S, Moller DE, *et al*. Differential regulation of glucose transport and transporters by glucose in vascular endothelial and smooth muscle cells. *Diabetes* 1993; **42**:80–89.

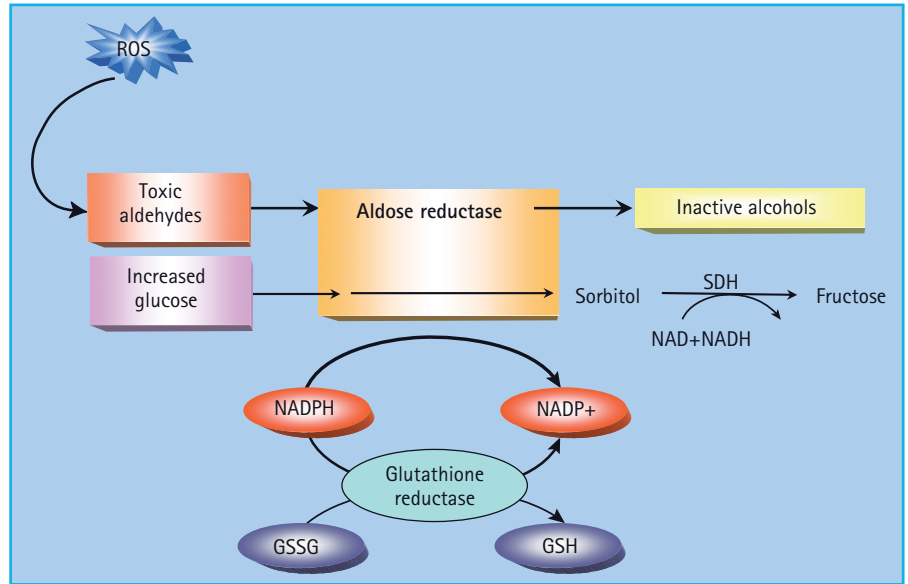

- 2 Increased intracellular formation of advanced glycation end-products (AGEs);
- 3 Increased expression of the receptor for AGEs (RAGE) and its activating ligands;
- 4 Activation of protein kinase C (PKC) isoforms; and
- 5 Overactivity of the hexosamine pathway.

Despite this, the results of clinical studies in which one of these pathways is blocked have been disappointing. This led to the hypothesis in 2000 that all five mechanisms are activated by a single upstream event: mitochondrial overproduction of the reactive oxygen species (ROS) superoxide as a result of intracellular hyperglycemia. This provides a unifying hypothesis for the pathogenesis of diabetic complications.

### Increased polyol pathway flux

The polyol pathway is based on a family of aldoketo reductase enzymes which can utilize as substrates a wide variety of sugar-derived carbonyl compounds and reduce these by nicotinic acid

**Figure 35.2** The polyol pathway. When glucose concentration is normal, aldose reductase reduces toxic aldehydes generated by reactive oxygen species (ROS) to inactive alcohols. With intracellular hyperglycemia, it can also reduce glucose to sorbitol. Both reactions use nicotinic acid adenine dinucleotide phosphate (NADPH) as a co-factor. When aldose reductase activity is sufficient to deplete reduced glutathione (GSH), oxidative stress is augmented. Sorbitol-dehydrogenase (SDH) oxidizes sorbitol to fructose using  $\text{NAD}^+$  as a co-factor. GSSG, glutathione disulfide (oxidized glutathione).

adenine dinucleotide phosphate (NADPH) to their respective sugar alcohols (polyols). The classic representation holds that glucose is converted to sorbitol, and galactose to galactitol. Sorbitol is then oxidized to fructose by the enzyme sorbitol dehydrogenase (SDH), with  $\text{NAD}^+$  being reduced to NADH (Figure 35.2).

The first and rate-limiting step of the polyol pathway is governed by aldose reductase, which is found in tissues such as nerve, retina, lens, glomerulus and blood vessel wall. In these tissues, glucose uptake is mediated by GLUT proteins other than GLUT-4 and so does not require insulin; intracellular glucose concentrations therefore rise in parallel with hyperglycemia.

Several mechanisms have been proposed to explain how hyperglycemia-induced increases in polyol pathway flux could damage the tissues involved. These include sorbitol-induced osmotic stress, decreased cytosolic  $\text{Na}/\text{K}^+$ -ATPase activity, increased cytosolic  $\text{NADH}/\text{NAD}^+$ , and decreased cytosolic NADPH. It was originally suggested that intracellular accumulation of sorbitol, which does not diffuse easily across cell membranes, could result in osmotic damage, but it is now clear that sorbitol levels in diabetic vessels and nerves are far too low to do this. Another early suggestion was that increased flux through the polyol pathway led to decreased phosphatidylinositol synthesis, and that this inhibited  $\text{Na}/\text{K}^+$ -ATPase activity. The latter abnormality does occur in diabetes, but has recently been shown to result from hyperglycemia-induced activation of PKC which increases the production of two inhibitors of  $\text{Na}/\text{K}^+$ -ATPase, arachidonate and prostaglandin  $\text{E}_2$  [16].

It has also been suggested that the reduction of glucose to sorbitol by NADPH (Figure 35.2) consumes the latter. NADPH is a co-factor required to regenerate reduced glutathione (GSH); as GSH is an important scavenger of ROS, this could induce or exacerbate intracellular oxidative stress. Indeed, overexpression

of human aldose reductase increased atherosclerosis in diabetic mice and reduced the expression of genes that regulate regeneration of GSH [17]. Reduced GSH is depleted in the lens of transgenic mice that overexpress aldose reductase and in diabetic rat lens compared with non-diabetic lens [18,19]. It has also been recently demonstrated that decreased glutathiolation of cellular proteins is related to decreased nitric oxide (NO) availability in diabetic rats which would decrease S-nitrosoglutathione (GSNO). Restoring the NO levels in diabetic animals increases glutathiolation of cellular proteins, inhibits aldose reductase activity and prevents sorbitol accumulation.

Moreover, hyperglycemia can also inhibit glucose-6-phosphate dehydrogenase, the major source of NADPH regeneration, which may further reduce NADPH concentration in some vascular cells and neurons [20].

In diabetic vascular cells, however, glucose does not appear to be the substrate for aldose reductase, because the Michaelis constant ( $K_m$ ) of aldose reductase for glucose is 100 mmol/L, while the intracellular concentration of glucose in diabetic retina is 0.15 mmol/L [21,22]. Glycolytic metabolites of glucose such as glyceraldehyde-3-phosphate, for which aldose reductase has much higher affinity, may be the physiologically relevant substrate.

### Increased intracellular AGE formation

AGEs are formed by the reaction of glucose and other glycation compounds (e.g. dicarbonyls such as 3-deoxyglucosone, methylglyoxal and glyoxal) with proteins and, to a lesser extent, nucleic acids. The reactions proceed through a series of stages that are initially reversible and yield early glycation products, but eventually undergo irreversible changes that markedly impair the structural, enzymatic or signaling functions of the glycated proteins (Figure 35.3). A familiar example of this process yields glycated hemoglobin ( $\text{HbA}_{1c}$ ). AGEs are found in increased amounts in

**Figure 35.3** Increased production of intracellular advanced glycation end-products (AGE) precursors damages cells by three mechanisms: modification of intracellular proteins; modification of the extracellular matrix (upper panel); and interactions with AGE receptors such as RAGE in endothelial cells and macrophages. NFκB, nuclear factor κB; ROS, reactive oxygen species.

extracellular structures of diabetic retinal vessels [23–25] and renal glomeruli [26–28], where they can cause damage through the mechanisms described below.

These AGEs were originally thought to arise from non-enzymatic reactions between extracellular proteins and glucose; however, the rate of AGE formation from glucose is orders of magnitude slower than that induced by glucose-derived dicarbonyl precursors generated intracellularly, and it now seems likely that raised intracellular glucose is the primary initiating event in the formation of both intracellular and extracellular AGEs [29]. AGEs can arise intracellularly from the autooxidation of glucose

to glyoxal [30], the decomposition of an Amadori product to the 3-deoxyglucosone, or the fragmentation of glyceraldehyde-3-phosphate to yield methylglyoxal [31]. All these reactive intracellular dicarbonyls react readily with uncharged amino groups of intracellular and extracellular proteins to form AGEs. Methylglyoxal is the major intracellular AGE precursor [32,33].

### Intracellular effects of AGEs

Intracellular production of AGE precursors can damage cells by three general mechanisms. First, intracellular proteins modified by AGEs have altered function. Secondly, extracellular matrix components modified by AGE precursors interact abnormally with other matrix components and with matrix receptors (integrins) which are expressed on the surface of cells. Finally, plasma proteins modified by AGE precursors bind to AGE receptors on cells such as macrophages; binding induces the production of ROS, which in turn activates the pleiotropic transcription factor, nuclear factor κB (NFκB), causing multiple pathologic changes in gene expression [34].

It has been recently demonstrated that AGE modification of intracellular protein can be involved in diabetic retinopathy. In diabetes, retinal capillary formation is regulated by complex context-dependent interactions among pro- and anti-angiogenic factors [35,36], including angiopoietin-2 (Ang-2). When vascular endothelial growth factor (VEGF) levels are insufficient, Ang-2 causes endothelial cell death and vessel regression. Diabetes induces a significant increase in retinal expression of Ang-2 in rat [37], and diabetic Ang-2 +/- mice have both decreased pericyte loss and reduced acellular capillary formation [38].

Moreover, in mouse kidney endothelial cells, high glucose causes increased methylglyoxal modification of the corepressor mSin3A. Methylglyoxal modification of mSin3A results in increased recruitment of O-GlcNAc-transferase, with consequent increased modification of Sp3 by O-linked N-acetylglucosamine. This modification of Sp3 causes decreased binding to a glucose-responsive GC-box in the Ang-2 promoter, resulting in increased Ang-2 expression. Increased Ang-2 expression induced by high glucose in renal endothelial cells increased expression of intracellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) in cells and in kidneys from diabetic mice and sensitized microvascular endothelial cells to the pro-inflammatory effects of tumor necrosis factor α (TNF-α) [39].

### Effects of AGEs on extracellular matrix

AGE formation alters the functional properties of several important matrix molecules. Collagen was the first matrix protein in which glucose-derived AGEs were shown to form covalent intermolecular bonds. This process is partly mediated by H<sub>2</sub>O<sub>2</sub> production [40,41]. With type I collagen, this cross-linking causes expansion of molecular packing [42], while AGE formation on type IV collagen from basement membrane inhibits the normal lateral association of these molecules into a network-like structure by interfering with binding of the non-collagenous NC1 domain to the helix-rich domain [43]. AGE formation on laminin

prevents the molecules from self-assembling into a polymer and also decreases binding with type IV collagen and heparan sulfate proteoglycan [44].

These AGE-induced cross-links alter tissue function, notably in blood vessels. AGEs decrease elasticity in arteries from diabetic rats, even after vascular tone is abolished, and increase fluid filtration across the carotid artery [45]. *In vitro*, AGE formation on intact glomerular basement membrane increases its permeability to albumin in a manner that resembles the abnormal permeability of diabetic nephropathy [46,47].

AGE formation on extracellular matrix also interferes with the ways in which cells interact with the matrix. For example, methylglyoxal modification of type IV collagen's cell-binding domains decreases endothelial cell adhesion and inhibits angiogenesis [48].

AGE formation on a 6-amino acid, growth-promoting sequence in the A chain of the laminin molecule markedly reduces neurite outgrowth [49], while AGE modification of vitronectin reduces its ability to promote cell attachment [50]. In addition, matrix glycation impairs agonist-induced  $Ca^{2+}$  increases which might adversely affect the regulatory functions of endothelium [51].

### Receptor-mediated biologic effects of AGEs

AGE-modified proteins in the circulation can affect a range of cells and tissues. Specific receptors for AGEs were first identified on monocytes and macrophages. Two AGE-binding proteins isolated from rat liver, identified as OTS-48 (60kDa) and 80K-H (90kDa) [52], are both present on monocytes and macrophages; antisera against either protein block AGE binding [53]. AGE protein binding to this receptor stimulates macrophages to produce cytokines, including interleukin-1, TNF- $\alpha$ , transforming growth factor  $\beta$  (TGF- $\beta$ ), macrophage colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, as well as insulin-like growth factor I (IGF-I). These factors appear to be produced at concentrations that can increase glomerular synthesis of type IV collagen and induce chemotaxis and proliferation of both arterial smooth muscle cells and macrophages [54–62]. The macrophage scavenger receptor type II (class A), galectin-3 and CD36 (a member of the class B macrophage scavenger receptor family) have also been shown to recognize AGEs [63–67].

AGE receptors have also been identified on glomerular mesangial cells. *In vitro*, AGE protein binding to its receptor on mesangial cells stimulates secretion of platelet-derived growth factor which in turn mediates mesangial cells to produce type IV collagen, laminin and heparan sulfate proteoglycan [68,69].

Vascular endothelial cells and other cell types also express specific AGE receptors (RAGEs), notably 35-kDa and 46-kDa AGE-binding proteins that have been purified to homogeneity [70–72]. The N-terminal sequence of the 35-kDa protein is identical to lactoferrin, whereas the 46-kDa AGE-binding protein is a novel member of the immunoglobulin superfamily, containing three disulfide-bonded immunoglobulin homology units. RAGE

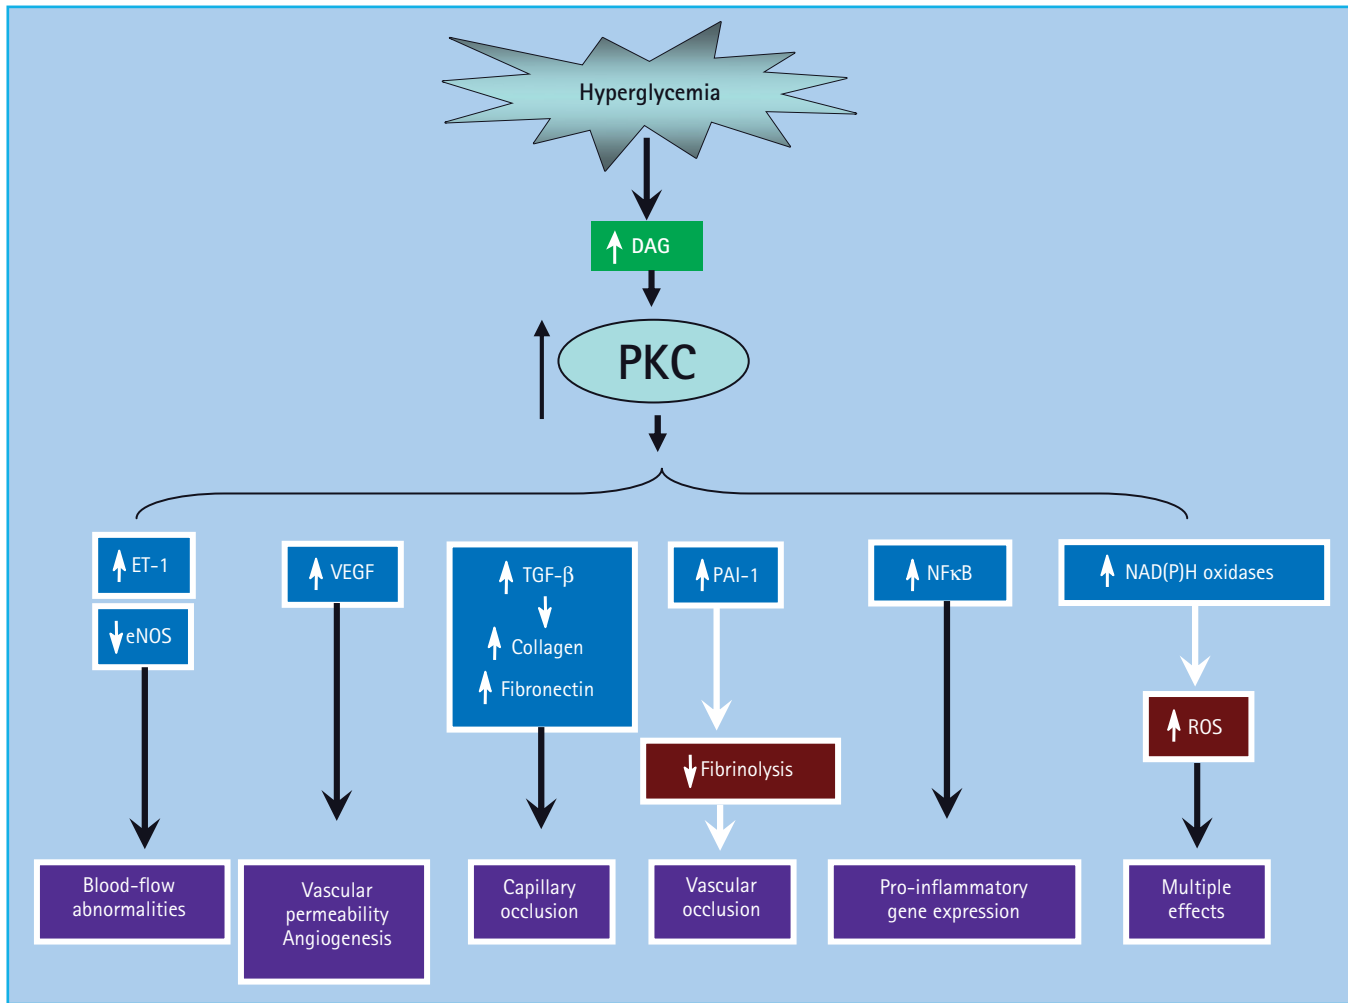

have been shown to mediate signal transduction via generation of ROS, activation of NF $\kappa$ B, and p21 *ras* [73–75]. AGE signaling can be blocked in cells by expression of RAGE antisense cDNA [76] or anti-RAGE ribozyme [77]. It has been also recently demonstrated that a RAGE–NF $\kappa$ B axis operates in diabetic neuropathy by mediating functional sensory deficits [78].

In endothelial cells, AGE binding to its receptor alters the expression of several genes, including thrombomodulin, tissue factor and VCAM-1 [79–81]. These effects induce procoagulatory changes on the endothelial cell surface and increase the adhesion of inflammatory cells to the endothelium. In addition, endothelial AGE receptor binding appears to mediate in part the increased vascular permeability induced by diabetes, probably through the induction of VEGF [82–85]. RAGE deficiency attenuates the development of atherosclerosis in the diabetic apoE(–/–) model of accelerated atherosclerosis. Diabetic RAGE(–/–)/apoE(–/–) mice had significantly reduced atherosclerotic plaque area. These beneficial effects on the vasculature were associated with attenuation of leukocyte recruitment, decreased expression of pro-inflammatory mediators, including the NF $\kappa$ B subunit p65, VCAM-1, and monocyte chemoattractant protein 1 (MCP-1) and reduced oxidative stress [86].

It is important to note that more recent studies indicate that AGEs at the concentrations found in diabetic sera are not the major ligand for RAGE. Rather, several pro-inflammatory protein ligands have been identified, which activate RAGE at low concentrations. These include several members of the S100 calgranulin family and high mobility group box 1 (HMGB1), all of which are increased by diabetic hyperglycemia. Binding of these ligands with RAGE causes cooperative interaction with the innate immune system signaling molecule toll-like receptor 4 (TLR-4) [87,88].

### Increased protein kinase C activation

The group of PKCs consist of at least 11 isoforms that are widely distributed in mammalian tissues. The activity of the classic isoforms is dependent on both  $Ca^{2+}$  ions and phosphatidylserine and is greatly enhanced by diacylglycerol (DAG). Persistent and excessive activation of several PKC isoforms might also operate as a third common pathway mediating tissue injury induced by hyperglycemia and associated biochemical and metabolic abnormalities. This results primarily from enhanced *de novo* synthesis of DAG from glucose via triose phosphates, whose availability is increased because raised intracellular glucose levels enhance glucose flux through the glycolytic pathway [89–92]. Finally, recent evidence suggests that the enhanced activity of PKC isoforms could also result from the interaction between AGEs and their cell-surface receptors [93]. Hyperglycemia primarily activates the  $\beta$  and  $\delta$  isoforms of PKC, both in cultured vascular cells [94–96] and in the retina and glomeruli of diabetic animals [91,92,93], but increases in other isoforms have also been found, such as PKC- $\alpha$  and PKC- $\epsilon$  isoforms in the retina [89] and PKC- $\alpha$  and PKC- $\delta$  in the glomerulus of diabetic rats [97,98] (Figure 35.4).

**Figure 35.4** Activation of protein kinase C (PKC) by *de novo* synthesis of diacylglycerol (DAG) and some of its pathologic consequences. eNOS, endothelial NO synthase; ET-1, endothelin-1; NADPH, nicotinic acid adenine dinucleotide phosphate; NFκB, nuclear factor κB; PAI-1, plasminogen activator inhibitor 1; ROS, reactive oxygen species; TGF-β, transforming growth factor β; VEGF, vascular endothelial growth factor.

In early experimental diabetes, activation of PKC-β isoforms has been shown to mediate the diabetes-related decreases in retinal and renal blood flow [99], perhaps by depressing the production of the vasodilator NO and/or increasing endothelin-1, a potent vasoconstrictor. Overactivity of PKC has been implicated in the decreased NO production by the glomerulus in experimental diabetes [100] and by smooth muscle cells in the presence of high glucose levels [101], and has been shown to inhibit insulin-stimulated expression of endothelial NO synthase (eNOS) in cultured endothelial cells [102]. Hyperglycemia increases the ability of endothelin-1 to stimulate mitogen activated protein kinase (MAPK) activity in glomerular mesangial cells, and this occurs by activating PKC isoforms [103]. The increased endothelial cell permeability induced by high glucose in cultured cells is mediated by activation of PKC-α [104]; activation of PKC by high glucose also induces expression of the permeability-enhancing factor VEGF in smooth muscle cells [105].

In addition to mediating hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC may contribute to the accumulation of microvascular matrix protein by inducing expression of TGF-β1, fibronectin and type IV collagen in both cultured mesangial cells [106,107] and in glomeruli of diabetic rats [97]. This effect also appears to be mediated through the inhibition of NO production by PKC [108]. Hyperglycemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor, plasminogen activator inhibitor 1 (PAI-1) [109], and in the activation of NFκB in cultured endothelial cells and vascular smooth muscle cells [110,111].

#### Increased hexosamine pathway flux

Several data suggest that hyperglycemia could cause diabetic complications by shunting glucose into the hexosamine pathway [112–115]. Here, fructose-6-phosphate is diverted from glycolysis to provide substrates for reactions that utilize UDP-N-

**Figure 35.5** The glucosamine pathway. Glucosamine-6-phosphate is generated from fructose-6-phosphate and glutamine, by glutamine:fructose-6-phosphate amidotransferase (GFAT), the rate-limiting enzyme of this pathway. Glucosamine-6-phosphate is converted to UDP-*N*-acetylglucosamine (UDP-GlcNac), which can glycosylate transcription factors and thus enhance transcription of genes including plasminogen activator inhibitor 1 (PAI-1) and transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1). OGT, O-linked *N*-acetylglucosamine (GlcNac) transferase.

acetylglucosamine, particularly the formation of *O*-linked *N*-acetylglucosamine. This pathway has been shown to have an important role in hyperglycemia-induced and fat-induced insulin resistance [116–118]. The rate-limiting step in the conversion of glucose to glucosamine is regulated by glutamine:fructose-6-phosphate amidotransferase (GFAT), and inhibition of this enzyme blocks hyperglycemia-induced increases in the transcription of both TGF- $\alpha$  [112] and TGF- $\beta$ 1 [113].

It is not entirely clear how increased glucose flux through the hexosamine pathway mediates hyperglycemia-induced increases in the gene transcription of key genes such as TGF- $\alpha$ , TGF- $\beta$ 1 and PAI-1, however, it has been shown that the transcription factor Sp1 regulates hyperglycemia-induced activation of the PAI-1 promoter in vascular smooth muscle cells [119], raising the possibility that covalent glycation of Sp1 by *N*-acetylglucosamine to form its *O*-GlcNacylated derivative could explain how hexosamine pathway activation might operate. Virtually every RNA polymerase II transcription factor examined is *O*-GlcNacylated [120], and this glycosylated form of Sp1 appears to be more transcriptionally active than its non-glycosylated counterpart [121]. A fourfold increase in Sp1 *O*-GlcNacylation (caused by inhibition of the enzyme *O*-GlcNac- $\beta$ -*N*-acetylglucosaminidase) resulted in a reciprocal

30% decrease in the level of serine/threonine phosphorylation of Sp1; thus, *O*-GlcNacylation and phosphorylation may compete to modify the same sites on Sp1 (Figure 35.5) [122].

GlcNac modification of Sp1 may regulate other glucose-responsive genes in addition to TGF- $\beta$ 1 and PAI-1. Glucose-responsive transcription of the acetylcoenzyme A carboxylase gene (the rate-limiting enzyme for fatty acid synthesis) is regulated by Sp1 sites, and post-transcriptional modification of Sp1 may similarly be responsible [123,124]. Because so many RNA polymerase II transcription factors are *O*-GlcNacylated [120], others in addition to Sp1 may be regulated by reciprocal modification (glycosylation vs phosphorylation) at key serine and threonine residues and so cause gene transcription to be glucose-responsive. In addition to transcription factors, many other nuclear and cytoplasmic proteins can be modified by *O*-GlcNac moieties perturbing their normal function and regulation. One example relevant to diabetes is the inhibition of eNOS activity by *O*-GlcNacylation at the Akt site of eNOS protein [125–127]. Hyperglycemia also increases GFAT activity in aortic smooth muscle cells which increases *O*-GlcNac modification of several proteins in these cells [128]. Overall, activation of the hexosamine pathway by hyperglycemia may result in many changes in both gene expression and in protein function that

together contribute to the pathogenesis of diabetic complications. Recently, increased modification of key signaling molecules by O-GlcNAc was shown to cause reduced insulin signal transduction [129]. Pathway selective insulin resistance in vascular cells and resultant overactivation of the MAPK pathway by hyperinsulinemia could contribute further to diabetic microvascular damage [130].

**A single process underlying different hyperglycemia-induced pathogenic mechanisms: mitochondrial superoxide production**

Specific inhibitors of aldose-reductase activity, AGE formation, RAGE ligand binding, PKC activation and hexosamine pathway flux each ameliorate various diabetes-induced abnormalities in cell culture or animal models, but it has not been clear whether these processes are interconnected or might have a common cause [99,131–134]. Moreover, all the above abnormalities are rapidly corrected when euglycemia is restored, which makes the phenomenon of hyperglycemic memory conceptually difficult to explain.

It has now been established that all of the different pathogenic mechanisms described above stem from a single hyperglycemia-induced process, overproduction of superoxide by the mitochondrial electron-transport chain [135,136]. Superoxide is the initial oxygen free radical formed by the mitochondria which is then converted to other, more reactive species that can damage cells in numerous ways. [137]. To understand how this occurs, mitochondrial glucose metabolism is briefly reviewed (Figure 35.6).

Intracellular glucose oxidation begins with glycolysis in the cytoplasm, which generates NADH and pyruvate. Cytoplasmic NADH can donate reducing equivalents to the mitochondrial electron-transport chain via two shuttle systems, or it can reduce pyruvate to lactate, which leaves the cell to act as a substrate for hepatic gluconeogenesis. Pyruvate can also be transported into the mitochondria where it is oxidized by the tricarboxylic acid (TCA) cycle to produce CO<sub>2</sub>, H<sub>2</sub>O, four molecules of NADH and one molecule of reduced flavine adenine dinucleotide (FADH<sub>2</sub>). Mitochondrial NADH and FADH<sub>2</sub> provide energy for ATP production via oxidative phosphorylation by the electron transport chain. Electron flow through the mitochondrial electron transport chain is effected by four enzyme complexes, plus cytochrome *c* and the mobile carrier ubiquinone, all of which lie in the inner mitochondrial membrane [137]. NADH derived from both cytosolic glucose oxidation and mitochondrial TCA cycle activity donates electrons to NADH:ubiquinone oxidoreductase (Complex I) which ultimately transfers its electrons to ubiquinone. Ubiquinone can also be reduced by electrons donated from several FADH<sub>2</sub>-containing dehydrogenases, including succinate:ubiquinone oxidoreductase (Complex II) and glycerol-3-phosphate dehydrogenase. Electrons from reduced ubiquinone are then transferred to ubiquinol:cytochrome *c* oxidoreductase (Complex III) by the Q cycle which generates ubisemiquinone radicals [138]. Electron transport then proceeds through cytochrome *c*, cytochrome *c* oxidase (Complex IV) and, finally, molecular oxygen.

Electron transfer through Complexes I, III and IV extrudes protons outwards into the intermembrane space, generating a proton gradient that drives ATP synthase (Complex V) as protons

**Figure 35.6** Mitochondrial metabolism. Flow of electrons (e<sup>-</sup>) through the electron transport chain in the inner mitochondrial membrane pumps H<sup>+</sup> ions into the intermembrane space; superoxide is generated as a consequence of one electron leak. H<sup>+</sup> ions can pass back across the inner membrane along their concentration gradient, either via ATP synthase (to produce ATP) or via uncoupling proteins (UCP). When intracellular hyperglycemia increases electron flux by generating more NADH and FADH<sub>2</sub>, more superoxide is produced. Cyt c, cytochrome c; Q, ubiquinone.

pass back through the inner membrane into the matrix. That is what happens in normal cells. In contrast, in diabetic cells with high glucose inside, there is more glucose being oxidized in the TCA cycle which in effect pushes more electron donors (NADH and FADH<sub>2</sub>) into the electron transport chain. As a result of this, the voltage gradient across the mitochondrial membrane increases until a critical threshold is reached. At this point, electron transfer inside Complex III is blocked [139], causing the electrons to back up to co-enzyme Q which donates the electrons one at a time to molecular oxygen and thereby generating superoxide. The mitochondrial isoform of the enzyme superoxide dismutase degrades this oxygen free radical to hydrogen peroxide which is then converted to H<sub>2</sub>O and O<sub>2</sub> by other enzymes. Intracellular hyperglycemia did, indeed, increase the voltage across the mitochondrial membrane above the critical threshold necessary to increase superoxide formation [140] and, subsequently, increase in production of ROS.

It has been also recently demonstrated that dynamic changes in mitochondrial morphology are associated with high glucose-induced overproduction of ROS and inhibition of mitochondrial fission prevented periodic fluctuation of ROS production during high glucose exposure [141]. Hyperglycemia does not increase ROS and does not activate any of the pathways when either the voltage gradient across the mitochondrial membrane is collapsed by uncoupling protein 1 (UCP-1), or when the superoxide produced is degraded by manganese superoxide dismutase (MnSOD) [142]. Overexpression of either MnSOD and UCP-1 also prevents inhibition of eNOS activity by hyperglycemia [125]. Importantly, inhibition of hyperglycemia-induced superoxide overproduction using a transgenic approach (superoxide dismutase [SOD]) also prevents long-term experimental diabetic nephropathy and retinopathy [143]. In humans, skin fibroblast gene expression profiles from two groups of patients with T1DM – 20 with very fast (fast track) versus 20 with very slow (slow track) rate of development of diabetic nephropathy lesions – showed that the fast-track group has increased expression of oxidative phosphorylation genes, electron transport system Complex II and TCA cycle genes compared to that of the slow track group. This association is consistent with a central role for mitochondrial ROS production in the pathogenesis of diabetic complications [144].

### Hyperglycemia-induced mitochondrial superoxide production activates the five damaging pathways by inhibiting GAPDH

Diabetes in animals and humans and hyperglycemia in cells decrease the activity of the key glycolytic enzyme glyceraldehyde-3 phosphate dehydrogenase (GAPDH) in cell types that develop intracellular hyperglycemia. Inhibition of GAPDH activity by hyperglycemia does not occur when mitochondrial overproduction of superoxide is prevented by either UCP-1 or MnSOD [145]. When GAPDH activity is inhibited, the level of all the glycolytic intermediates that are upstream of GAPDH increase. An increased level of the upstream glycolytic metabolite glyceraldehyde-3-phosphate activates two major pathways. It

activates the AGE pathway because the major intracellular AGE precursor methylglyoxal is formed non-enzymatically from glyceraldehyde-3 phosphate. Hyperglycemia-induced methylglyoxal formation has recently been shown to cause both increased expression of RAGE and its activating ligands S100 calgranulins and HMGB1 (M. Brownlee, unpublished).

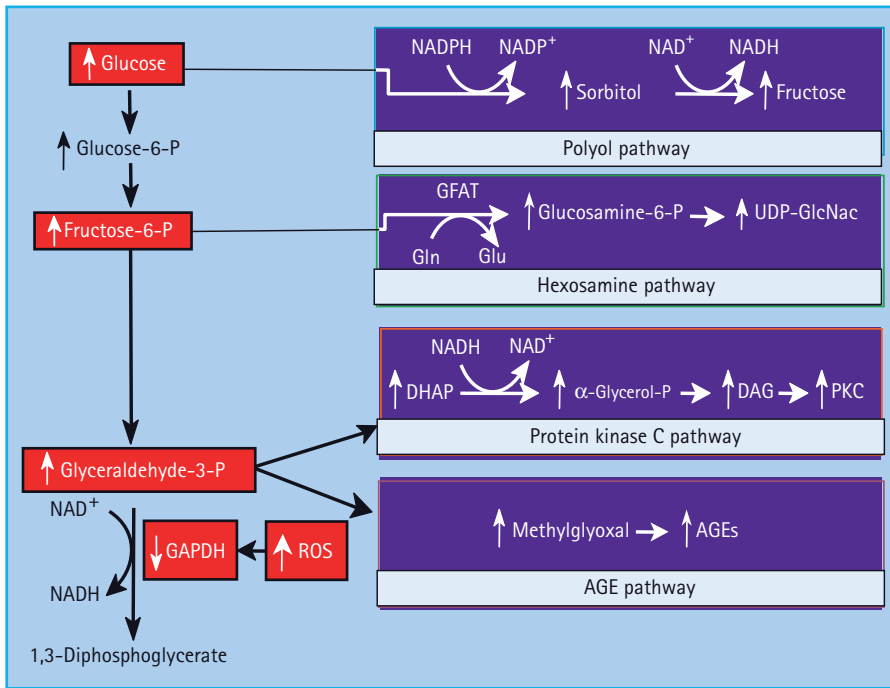

Increased glyceraldehyde-3-phosphate also activates the classic PKC pathway, because the activator of PKC, DAG, is also formed from glyceraldehyde-3 phosphate. Further upstream, levels of the glycolytic metabolite fructose-6 phosphate increase, which increases flux through the hexosamine pathway, where fructose-6 phosphate is converted by the enzyme GFAT to UDP-N-acetylglucosamine (UDP-GlcNAc). Finally, inhibition of GAPDH increases intracellular levels of the first glycolytic metabolite, glucose. This increases flux through the polyol pathway where the enzyme aldose reductase reduces it (or glyceraldehyde-3-phosphate), consuming NADPH in the process (Figure 35.7). Inhibition of GAPDH in 5 mmol/L activity using antisense DNA elevates the activity of each of the major pathways of hyperglycemic damage to the same extent as that induced by hyperglycemia [146].

### Hyperglycemia-induced mitochondrial superoxide production inhibits GAPDH by activating poly(ADP-ribose) polymerase

Hyperglycemia-induced superoxide inhibits GAPDH activity *in vivo* by modifying the enzyme with polymers of ADP-ribose [146]. By inhibiting mitochondrial superoxide production with either UCP-1 or MnSOD, both modification of GAPDH by ADP-ribose and reduction of its activity by hyperglycemia are prevented. Most importantly, both modification of GAPDH by ADP-ribose and reduction of its activity by hyperglycemia are also prevented by a specific inhibitor of poly(ADP-ribose) polymerase (PARP), the enzyme that makes these polymers of ADP ribose. Normally, PARP resides in the nucleus in an inactive form, waiting for DNA damage to activate it. When increased intracellular glucose generates increased ROS in the mitochondria, free radicals induce DNA strand breaks, thereby activating PARP. Both hyperglycemia-induced processes are prevented by either UCP-1 or MnSOD [146]. Once activated, PARP splits the NAD<sup>+</sup> molecule into its two component parts: nicotinic acid and ADP ribose. PARP then proceeds to make polymers of ADP ribose, which accumulate on GAPDH and other nuclear proteins. GAPDH is commonly thought to reside exclusively in the cytosol. In fact, it normally shuttles in and out of the nucleus, where it has a critical role in DNA repair (a summary of the integrated mechanism is shown in Figure 35.8) [147,148].

### Glycemic memory

In 1993, the results of the landmark DCCT study showed that, in people with short-duration T1DM, intensive glycemic

**Figure 35.7** Mitochondrial overproduction of superoxide activates the major pathways of hyperglycemic damage by inhibiting glyceraldehyde-3 phosphate dehydrogenase (GAPDH).

**Figure 35.8** The unifying mechanism of hyperglycemia-induced cellular damage.

control dramatically reduced the occurrence and severity of diabetic microvascular complications. After the announcement of the DCCT results, many patients who had been in the standard therapy group adopted more intensive therapeutic regimens, and their level of glycemic control improved, as measured by HbA<sub>1c</sub>.

At the same time, the mean level of HbA<sub>1c</sub> worsened for patients who had been in the intensive therapy group. The post-DCCT HbA<sub>1c</sub> values for both groups became statistically identical during the approximate 14 years of follow-up in the ongoing EDIC Study.

**Figure 35.9** “Hyperglycemic memory”: previous higher blood glucose levels make people with diabetes more susceptible to damage from subsequent lower blood glucose exposure. After the end of the Diabetes Control and Complications Trial (DCCT) study, the group that had been poorly controlled on conventional insulin therapy continued to have a higher incidence of diabetic retinopathy than the tightly controlled group given intensive therapy, even though post-trial HbA<sub>1c</sub> levels were comparable in the two groups. EDIC, Epidemiology of Diabetes Interventions and Complications Study.

Surprisingly and provocatively, however, the effects of a 6.5-year difference in HbA<sub>1c</sub> during the DCCT on the incidence of retinopathy and nephropathy have persisted and have even become greater over the subsequent 14 years of follow-up. People in the standard therapy group continue to have a higher incidence of complications, even with an improvement in glycemic control during the 14 years of EDIC, while people in the intensive therapy group continue to have a lower incidence of complications, even with a deterioration in glycemic control during the EDIC years. This phenomenon has been given the name “glycemic memory” (Figure 35.9). More recent data indicate that glycemic memory also occurs in patients with T2DM. Indeed, the tight glucose control group from the UKPDS demonstrated a continued reduction in microvascular risk and emergent risk reductions for myocardial infarction and death from any cause, despite an early loss of glycemic differences (also termed “the legacy effect”). A continued benefit was evident during the 10-year post-trial follow-up

among overweight patients [149–151]. Glycemic memory has several important clinical implications:

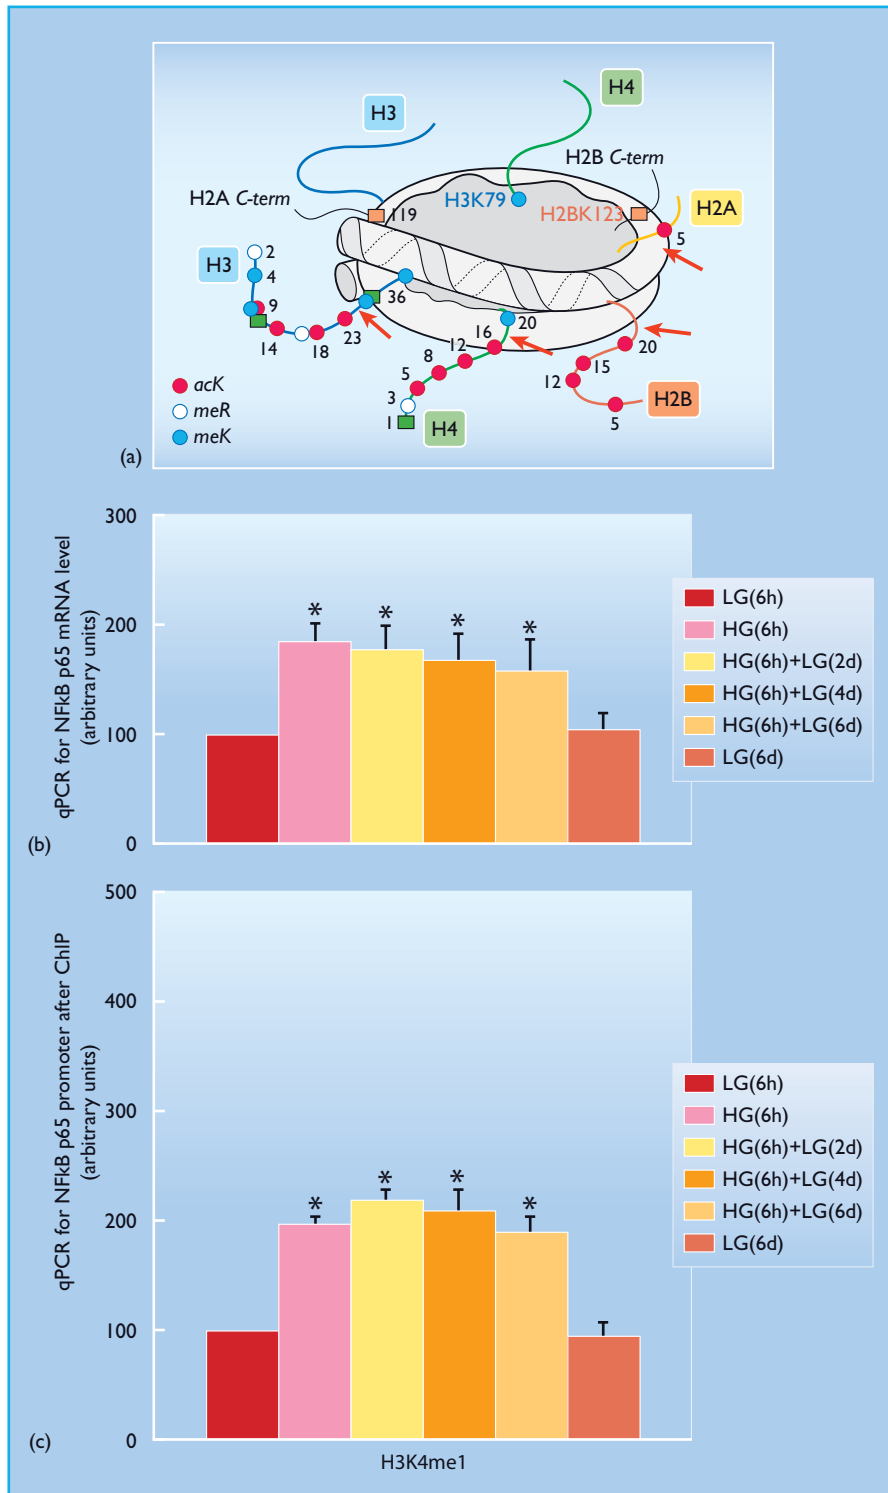

- 1 Early tight control is very important;
- 2 Cure of diabetes may not prevent subsequent development of complications; and
- 3 Novel therapies that reverse hyperglycemic memory may be needed.

Hyperglycemia-induced mitochondrial superoxide production may provide an explanation for the continuing progression of tissue damage after the correction of hyperglycemia (“hyperglycemic memory”). Post-translational modifications of histones cause chromatin remodeling and changes in levels of gene expression [152–154]. Because these modifications do not involve differences in DNA sequence, they are called “epigenetic” (Figure 35.10a). Transient hyperglycemia was recently shown to induce long-lasting activating epigenetic changes in the promoter of the NFκB-subunit p65 in human aortic endothelial cells (16 hours exposure) and in aortic cells *in vivo* in non-diabetic mice (6 hours exposure) which cause sustained increases in p65 gene expression (Figure 35.10b) and in the expression of p65-dependent pro-inflammatory genes. Both the epigenetic changes and the gene expression changes persist for at least 6 days of subsequent normal glycemia. Hyperglycemia-induced epigenetic changes and increased p65 expression are prevented by normalizing mitochondrial superoxide production or superoxide-induced methylglyoxal (Figure 35.10b,c) [155]. These results highlight the dramatic and long-lasting effects that short-term hyperglycemic spikes can have on vascular cells and suggest that transient spikes of hyperglycemia may be an HbA<sub>1c</sub>-independent risk factor for diabetic complications.

Demethylation of another histone lysine residue, H3K9, is also induced by hyperglycemia-induced overproduction of ROS. This reduces inhibition of p65 gene expression, and thus acts synergistically with the activating methylation of histone 3 lysine 4 [156]. Consistent with these observations, others have shown similar epigenetic changes in lymphocytes from patients with T1DM [157] and in vascular smooth muscle cells derived from *db/db* mice [158,159].

### Determinants of individual susceptibility to hyperglycemia-induced damage

As with all complex diseases, the occurrence and progression of diabetic complications vary markedly among patients. Some patients have T1DM for over 50 years with minimal complications, while others manifest severe disease or death within 15 years after diagnosis. The control of blood glucose, as well as blood pressure and blood lipid profiles, are important factors in predicting the risk of complications, but they only partially explain the risk of complications for an individual patient. Therefore, genetic factors have been investigated for their influence on the risk of developing complications. An understanding of the genes involved in the susceptibility to or protection from

**Figure 35.10** Transient hyperglycemia causes persistent epigenetic changes and altered gene expression during subsequent normoglycemia. (a) Schematic representation of several histone modifications (acK: acetylated lysine; meK, methylated lysine; meR: methylated arginine). (b and c) Transient hyperglycemia induces persistent increased expression of the NFκB-p65 subunit, caused by persistent epigenetic changes, including histone 3 lysine 4 monomethylationn (H3K4me1) in the proximal promoter of the NFκB-subunit p65. HG, high glucose; LG, low glucose. Data from El-Osta A, Brasacchio D, Yao D, Pocai A, Jones PL, Roeder RG, *et al.* Transient high glucose causes persistent epigenetic changes and altered gene expression during subsequent normoglycemia. *J Exp Med* 2008; **205**:2409–2417.

diabetic complications can lead to both a better understanding of the pathophysiologic mechanisms, as well as new biomarkers and molecular targets for drug development. Familial clustering studies strongly support a role for genetic determinants of susceptibility to hyperglycemic damage.

In two studies of families that have two or more siblings with T1DM, if one sibling had advanced diabetic nephropathy, the other sibling with diabetes had a nephropathy risk of 83% and 72%, respectively. By contrast, the risk was only 17% or 22% if the index patient did not have diabetic nephropathy [160,161] or

retinopathy. Numerous associations have been made between various genetic polymorphisms and the risk of various diabetic complications. Those include the HLA-DQB10201/0302 alleles [162], polymorphisms of the aldose reductase gene [163], of the sorbitol dehydrogenase gene [164] and of the promoter of erythropoietin gene [165]. Study in European descent families of patients with T1DM showed a positive linkage and association with diabetic nephropathy of simple tandem repeat polymorphisms and single nucleotide polymorphisms in 20 genes. Five genes code for transcription factors and signaling molecules (*HNF1B1/TCF2*, *NRP1*, *PRKCB1*, *SMAD3* and *USF1*). Three genes code for components of the extracellular matrix (*COL4A1*, *LAMA4* and *LAMC1*), and two are involved in its degradation (*MMP9* and *TIMP3*). Three genes code for growth factors or growth factors receptors (*IGF-IR*, *TGFBR-2* and *TGFBR-3*). The others are genes likely to be important in kidney function (*AGRT1*, *AQP1*, *BCL2*, *CAT*, *GPX1*, *LPL* and *p22phox*) [166].

The DCCT/EDIC trial also reported familial clustering and association with gene polymorphisms. The odds ratio for risk of severe retinopathy in diabetic relatives of positive versus negative subjects from the conventional treatment group is 5.4; coronary artery calcification also showed familial clustering [167]. In the same cohort, an association of multiple superoxide dismutase 1 variants is associated with the development and progression of diabetic nephropathy [168].

In the future, the challenge will be to identify specific genes involved in the varying clinical severity of diabetic complications. Recent emphasis in human disease genetics has been on so-called modifying genes, i.e. genetic variants that are distinct from disease susceptibility genes and that modify the phenotypic and clinical expression of the disease genes. Studies show that genetic modifiers can be “tipping point” genes. This means that one gene changes the whole phenotype in an all-or-nothing fashion, in contrast with the incremental effects seen with changes in a large number of non-modifier genes. Many examples of modifier genes are known in model organisms, and several have been identified in humans [169,170].

### Impaired neovascular response to ischemia

Tissue ischemia promotes vasculogenesis through chemokine-induced recruitment of bone marrow-derived endothelial progenitor cells (EPCs). Diabetes significantly impairs this process in tissues whose cells develop intracellular hyperglycemia. Many of the defects responsible for impaired vasculogenesis involve hypoxia-inducible factor 1 (HIF-1) regulated genes. Recently, HIF-1 function was shown to be impaired in diabetes because of ROS-induced modification of HIF-1 $\alpha$  and its coactivator p300 by the glyoxalase 1 (GLO1) substrate methylglyoxal (Brownlee, unpublished data) [171]. Decreasing superoxide in diabetic mice by either transgenic expression of MnSOD or by administration of a small molecular weight SOD mimetic corrected post-ischemic defects in neovascularization, oxygen delivery and chemokine

expression, and normalized tissue survival. In hypoxic fibroblasts cultured in high glucose, overexpression of GLO1 prevented reduced expression of both the EPC mobilizing chemokine stromal cell-derived factor 1 (SDF-1) and of VEGF which modulates growth and differentiation of recruited EPCs. In hypoxic EPCs cultured in high glucose, overexpression of GLO1 prevented reduced expression of both the SDF-1 receptor CXCR4, and endothelial nitric-oxide synthase, an enzyme essential for EPC mobilization. HIF-1 $\alpha$  modification by methylglyoxal reduced heterodimer formation, and HIF-1 $\alpha$  binding to all relevant promoters [171]. These results provide a basis for the rational design of new therapeutics to normalize impaired ischemia-induced vasculogenesis in patients with diabetes such as occurs in non-healing foot ulcers.

---

### Hemodynamic factors

Hypertension is one of the most significant secondary risk factors for the development of microvascular diabetic complications. In both retina and glomerulus, reduction of vascular surface area appears to occur first in microvessels with high perfusion pressure, and in patients with unilateral ophthalmic or renal artery stenosis there is a pronounced decrease in the severity of retinopathy or nephropathy on the affected side.

Tight control of blood pressure delays the progression of retinopathy and nephropathy, while elevated blood pressure accelerates the onset of nephropathy and its progression [172–174]. In the kidney, glomerular hypertension occurs with diabetes as a result of altered afferent and efferent arteriolar tone, increasing renal damage. This is one of the major targets of blockers of the angiotensin system (ARBs). How might hypertension connect to intracellular ROS generation, and activation of the five mechanisms of hyperglycemic damage? In hypertensive rats with glomerular hypertension, there is an 80% increase in glomerular GLUT-1 expression, associated with glomerulosclerosis and proteinuria. When mesangial cells, an important target for mechanically induced glomerular injury, were subjected to mechanical stretch, GLUT-1 protein expression was also upregulated, causing an increase in basal glucose transport. It has also been demonstrated that overexpression of GLUT-1 in mesangial cells grown in normal glucose concentration induces a diabetic cellular phenotype, with diabetic changes in gene expression [175,176]. Together, these data suggest that hypertension contributes to diabetic microvascular complications by further increasing intracellular hyperglycemia.

---

### Potential mechanism-based therapeutic agents for diabetic complications

#### Transketolase activators

The first new class of potential therapeutic agents is transketolase activators. This concept originated from a feature of the unifying

mechanism. When increased superoxide inhibits GAPDH activity, the glycolytic intermediates above the enzyme accumulate and are then shunted into the four pathways of hyperglycemic damage. Two of these glycolytic intermediates, fructose-6-phosphate and glyceraldehyde-3-phosphate, are also the final products of the transketolase reaction, which is the rate-limiting enzyme in another metabolic pathway, the pentose phosphate pathway [177]. Because in diabetes the concentration of these two glycolytic intermediates is high, activating transketolase could reduce their concentration by converting them to pentose phosphates. This would divert their flux away from three of the damaging pathways normally activated by hyperglycemia. This enzyme requires the vitamin thiamine as a co-factor. Although thiamine itself only activated transketolase by 25% in arterial endothelial cells, the thiamine derivative benfotiamine activated transketolase 250% in arterial endothelial cells.

Based on those findings, several groups have demonstrated the effectiveness of benfotiamine to counteract glucose-mediated toxicity in cultured endothelial cells, endothelial progenitor and endothelial cells and mouse models of diabetes [177–179]. Most importantly, it has been recently demonstrated that beneficial effects of benfotiamine on complication-causing pathways in rodent models of diabetic complications and in humans with T1DM [180]. Benfotiamine treatment prevented experimental diabetic retinopathy and nephropathy in mice, and treatment with high-dose thiamine reduced albuminuria in patients with T2DM. Diabetes has recently been implicated as a cause of intracellular thiamine depletion, which would impair normal transketolase conversion of hyperglycemia-induced elevation of glycolytic intermediates, further exacerbating activation of the five damaging pathways [181–183].

### PARP inhibitors

The second new class of potential therapeutic agents based on the unified mechanism is PARP inhibitors. In cultured endothelial cells, a specific PARP inhibitor prevents hyperglycemia-induced activation of PKC, NFκB, intracellular AGE formation, and the hexosamine pathway [146]. In animal models of diabetes, PARP inhibition prevents podocyte apoptosis, ameliorates nephropathy and alleviates sensory neuropathy [184,185].

### Catalytic antioxidants

Although increased superoxide activates the five damaging pathways implicated in the pathogenesis of microvascular complications, it is important to recognize that excess superoxide itself can also directly inhibit critical endothelial enzymes without any involvement of these four mechanisms. Two of these enzymes that are particularly important for vascular biology are eNOS and prostacyclin synthase. Both are dramatically inhibited in diabetic patients with diabetes and diabetic animals. To prevent direct oxidative inactivation of these key enzymes, it is necessary to directly reduce the amount of superoxide directly; however, conventional antioxidants are unlikely to do this effectively because conventional antioxidants neutralize reactive oxygen molecules on a one-for-one basis, while hyperglycemia-induced over-

production of superoxide is a continuous process. What is needed then is a new type of antioxidant, a catalytic antioxidant, such as an SOD/catalase mimetic [186], that works continuously. Hyperglycemia-induced reactive oxygen overproduction directly reduces eNOS activity in diabetic aortas by 65%; however, when these diabetic animals are treated with an SOD/catalase mimetic, there is no reduction in activity of this anti-atherogenic enzyme. Similarly, but more dramatically, hyperglycemia-induced reactive oxygen overproduction directly reduces prostacyclin synthase activity in diabetic aortas by 95%. Treatment of these diabetic animals with an SOD/catalase mimetic completely prevents diabetes-induced oxidative inactivation of aortic prostacyclin synthase, and also normalizes all five of the pathways implicated in hyperglycemic damage. Inhibition of hyperglycemia-induced ROS production in diabetic mice using either transgenic antioxidant enzyme expression or combinations of antioxidant compounds prevents the development of experimental diabetic retinopathy, nephropathy, neuropathy and cardiomyopathy [143,187–192]. Together, these data strongly suggest that therapeutic correction of diabetes-induced superoxide overproduction may be a powerful approach for preventing diabetic microvascular complications.

## Diabetic Retinopathy

**Peter H. Scanlon**

Gloucestershire and Oxford Eye Units, University of Oxford, Oxford, UK

### Keypoints

- In the Wisconsin study [1], proliferative diabetic retinopathy (PDR) occurred in 67% of persons with type 1 diabetes mellitus (T1DM) for 35 or more years. One would therefore expect that two-thirds of people with T1DM would need laser treatment for PDR during their lifetime.
- In the same study, the 4-year incidence of panretinal photocoagulation was 2.5 times higher than the rate of macular laser.
- In patients with type 2 diabetes mellitus (T2DM), the rate of PDR is not as high but it is estimated that 1 in 3 patients with T2DM will develop sight-threatening diabetic retinopathy requiring laser during their lifetime.
- The prevalence of blindness is influenced by duration of diabetes, blood glucose and blood pressure control, and by the presence or absence of screening and preventive laser treatment.
- Achieving a high compliance as achieved in Iceland [2] can lower the risk of blindness to very low levels.

### Introduction – a historical perspective

In 1877, Mackenzie and Nettleship [3], in one of the first pathologic reports on diabetic retinopathy (DR), observed capillary aneurysms. In 1900, the average life expectancy for men was 48.5 years and for women was 52.4 years and this rose over the next century to 76.0 years for men and 80.6 years for women. In 1921, Banting and Best discovered insulin in the laboratory of Dr. J. MacLeod. In 1923, Banting and MacLeod were awarded the Nobel Prize for Medicine. In 1943, Ballantyne and Loewenstein [4] examining flat unstained retinas, noted many capillary aneurysms and they first coined the phrase “diabetic retinopathy.” In 1953, Ashton [5] described changes in the arterioles in DR, studied in retinas removed postmortem. Examples of the Indian ink preparations published in his article [5] written in 1953 are shown in Figure 36.1.

### The normal eye

The eye is an approximate globe with the innermost surface of the eye, the retina, containing specialized photoreceptor cells (Figure 36.2).

The central foveal region is thinner and is devoid of retinal blood supply; essential supply is provided through diffusion from

the capillaries of the innermost vascular layer of underlying choroid through contact with the retinal pigment epithelium. The majority of the retina is provided with oxygen by means of the retinal vascular circulation (Figure 36.3).

The blood vessels in the retina exhibit tight junctions between adjacent cells maintaining the blood–retinal barrier. The normal structure of retinal vessels is shown in Figure 36.4.

The cells of the choroidal circulation have small gaps (fenestrations) between the cells in the walls of smaller choroidal vessels allowing transport of essential nutrients and other small molecules and hence support the nutrition and oxygenation of the foveal region through the retinal pigment epithelium.

### Risk factors for diabetic retinopathy

Major international epidemiologic trials have established that the development of DR is related to the following modifiable and non-modifiable risk factors.

#### Modifiable risk factors

##### Blood glucose

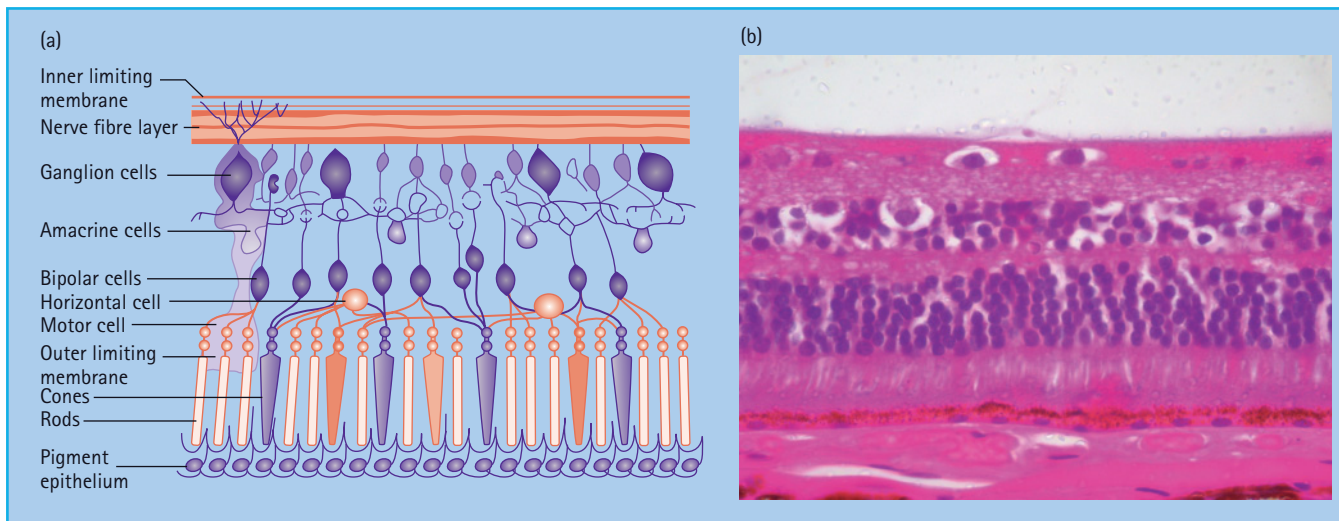

Evidence for the link between poor glucose control and greater progression of DR was provided by numerous early studies.

The study that confirmed that intensive blood glucose control reduces the risk of new onset DR and slows the progression of existing DR for patients with type 1 diabetes mellitus (T1DM) was the Diabetes Control and Complications Trial (DCCT) [6]. In the DCCT [7], early worsening of DR was reported at the 6- and/or 12-month visit in 13.1% of patients assigned to intensive

**Figure 36.1** Diabetic retinopathy showing an artery on the left and vein on the right. Hemorrhages and microaneurysms are present; in the center of the picture they are seen on an arteriole. The arteriolar side of the circulation is extensively atrophied. Injected Indian ink. Periodic acid–Schiff stain  $\times 44$ . Reproduced from Ashton N. Arteriolar involvement in diabetic retinopathy. *Br J Ophthalmol* 1953; **37**:282–292.

treatment; however, the long-term benefits of intensive insulin treatment greatly outweighed the risks of early worsening.

Similarly, for type 2 diabetes (T2DM) the UK Prospective Diabetes Study (UKPDS) [8] demonstrated that intensive blood glucose control reduces the risk of new onset DR and slows the progression of existing DR for patients with T2DM.

### Blood pressure

Control of systemic hypertension has been shown to reduce the risk of new onset DR and slow the progression of existing DR [9,10].

### Lipid levels

There is evidence that elevated serum lipids are associated with macular exudates and moderate visual loss; partial regression of hard exudates may be possible by reducing elevated lipid levels [11,12].

### Smoking

There is some evidence that smoking may be a risk factor in the progression of DR in T1DM as described by Muhlhauser *et al.* [13] and Karamanos *et al.* [14]; however, in T2DM the evidence is controversial.

### Non-modifiable risk factors

#### Duration

The major non-modifiable determinant of progression of DR is duration of diabetes [15,16].

#### Age

There is a rather complex link with age, with the Wisconsin Epidemiological Study [1,17,18] demonstrating that in those whose age of diagnosis was less than 30 years and who had diabetes of 10 years' duration or less, the severity of retinopathy was related to older age at examination, whereas when the age at diagnosis was 30 years or more, the severity of retinopathy was related to younger age at diagnosis. In the UKPDS [19], in those who already had retinopathy, progression was associated with older age.

#### Genetic predisposition

Early studies of identical twins with diabetes suggest familial clustering of DR. An association between severity of DR and human leukocyte antigens has been suggested in a number of studies [20,21], although this has not been uniformly accepted [22]. The majority of candidate genes studied exhibit weak or no association with retinopathy status, and where associations have been detected these results have not been replicated in multiple populations.

#### Ethnicity

Emanuele *et al.* [23] reported a higher prevalence of DR scores >40 in Latin Americans (36%) and African-Americans (29%) than for whites of Northern European ancestry (22%). Simmons

*et al.* [24] compared ethnic differences in the prevalence of DR in European, Maori and Pacific peoples with diabetes in Auckland, New Zealand. They demonstrated that moderate or more severe DR is more common in Polynesians than Europeans. In neither of these two studies could the differences be accounted for by an imbalance in traditional risk factors such as age, duration of diagnosed diabetes, HbA<sub>1c</sub> and blood pressure.

## Pathophysiologic events in diabetic retinopathy

### Basement membrane thickening

An early histopathologic sign of DR is thickening of the basement membrane (Figure 36.5) [25].

### Pericyte loss

Fallout of pericytes, which are sensitive to high glucose concentrations and undergo apoptosis [26], is an early and crucial event

**Figure 36.5** (a) Basement membrane thickening (arrow) in a retinal arteriole. Periodic acid-Schiff stain, original magnification  $\times 250$ . (b) Pericyte loss, in a flat-mounted tryptic digest of retina. Pericytes (small, dark nuclei) normally occur in a 1:1 ratio with the endothelial cells (pale, elongated nuclei). Original magnification  $\times 400$ .

**Figure 36.6** Tryptic digest of diabetic retina, showing two large microaneurysms in an area of acellular capillaries. One aneurysm (left) appears to be filled with clotted blood, while the second is hypercellular. Hematoxylin and eosin stain, original magnification  $\times 400$ .

in DR (Figure 36.5b). Loss of retinal capillary endothelial cells follows soon after pericyte loss with the formation of acellular capillaries.

### Increased capillary permeability

Endothelial cells form a continuous sheet with each cell being fused to neighbors by tight junctions that maintain the inner blood–retinal barrier, which may break down in DR leading to leakage of plasma proteins. Focal leakage is also observed around microaneurysms but this is likely to be caused by local endothelial cell damage caused by inflammatory mediators released from adherent leukocytes [27].

### Microaneurysms

The microaneurysm is the hallmark of retinal microvascular disease in patients with diabetes (Figure 36.6). It has been suggested that microaneurysms may be asymmetric dilatations of the capillary wall where it is weakened or damaged, following the loss of the supporting pericytes (Figure 36.5b) and localized increases in hydrostatic pressure [28]. Early stage microaneurysms may be extensively infiltrated with large numbers of monocyte and polymorphonuclear cells (Figure 36.6) [28].

### Smooth muscle death

Progressive death of vascular smooth muscle cells in the retinal arteries and arterioles has been established in the diabetic human retina [29].

### Capillary weakening

Increasing closure of capillaries may be linked with the occurrence of intraretinal microvascular abnormalities (IRMA). These structures contain large numbers of endothelial-like cells and occur in association with acellular capillaries close to the arterial side of the circulation [29].

### Retinal blood flow

Most clinical hemodynamic studies in diabetes conclude that increased blood flow and impaired autoregulation are features of DR [30]. Persistent dilatation of retinal arterioles is a well-known phenomenon in diabetes [31]. As DR progresses, increasingly large and widespread areas of retinal ischemia develop, caused by capillary occlusion and intravascular coagulation, which is considered to be enhanced by increased platelet stickiness in some studies [32], but not others [33].

### The consultation

A carefully taken history and high quality clinical examination is a vital component of the care of any patient with DR.

### Practical assessment

- History, which includes past ocular, diabetes, medical, family, drug and psychosocial history.
- Eye examination, which includes assessment of visual acuity and, where appropriate, color vision, inspection of external structures, visual fields to confrontation, ocular movement, pupillary reactions to light and accommodation, red reflex with an ophthalmoscope and slit-lamp biomicroscopy of the anterior eye.
- Both pupils are dilated with 1% tropicamide and in many patients 2.5% phenylephrine as well.
- Direct ophthalmoscopy has a limited two-dimensional field of view and has been shown to have a limited sensitivity and specificity for the detection of sight-threatening DR but is useful for ad hoc detection of DR.
- Slit-lamp biomicroscopy of the retina is the most common method employed by ophthalmologists to diagnose and monitor retinal disease using condensing lenses or fundus contact lenses (contact lens biomicroscopy).
- Binocular indirect ophthalmoscopy is useful for evaluating the posterior segment and retinal periphery. A larger area can be viewed than with slit-lamp biomicroscopy but this view is less magnified.

### Multidisciplinary management

It is very important for an ophthalmologist to be aware of the control of risk factors in the individual patient and to have good communication with the diabetic physician or general practitioner who is looking after this aspect of the patient's management.

### Investigative techniques to assess diabetic retinopathy

#### Retinal photography

Digital color retinal photography is increasingly being used as a record of retinal lesions.

#### Fundus fluorescein angiography

This is a diagnostic procedure, when sodium fluorescein injection is given rapidly into the arm and the fluorescence of the dye in

**Figure 36.7** Fundus fluorescein angiography. (a) Choroidal flush. (b) Retinal arterial stage with very early signs of fluorescein in veins. (c) Arteriovenous phase. (d) Venous phase.

blue light enables photographs to be taken as it appears in the retina (Figure 36.7). The fluorescein dye causes a few side effects such as nausea, vomiting, occasional syncope, skin rashes and itching. More serious side effects of bronchospasm, anaphylactic shock and cardiac arrest are extremely rare.

#### **Optical coherence tomography**

Optical coherence tomography (OCT) is an imaging technique that interprets reflected optical waves using interferometry. OCT images can be presented as either cross-sectional images or as topographic maps (Figure 36.8).

#### **Ultrasound B scan examination**

Ultrasound B scan examination uses high frequency ultrasound to examine the density and extent of a vitreous hemorrhage and the presence or absence of a retinal detachment where the retinal view is obscured.

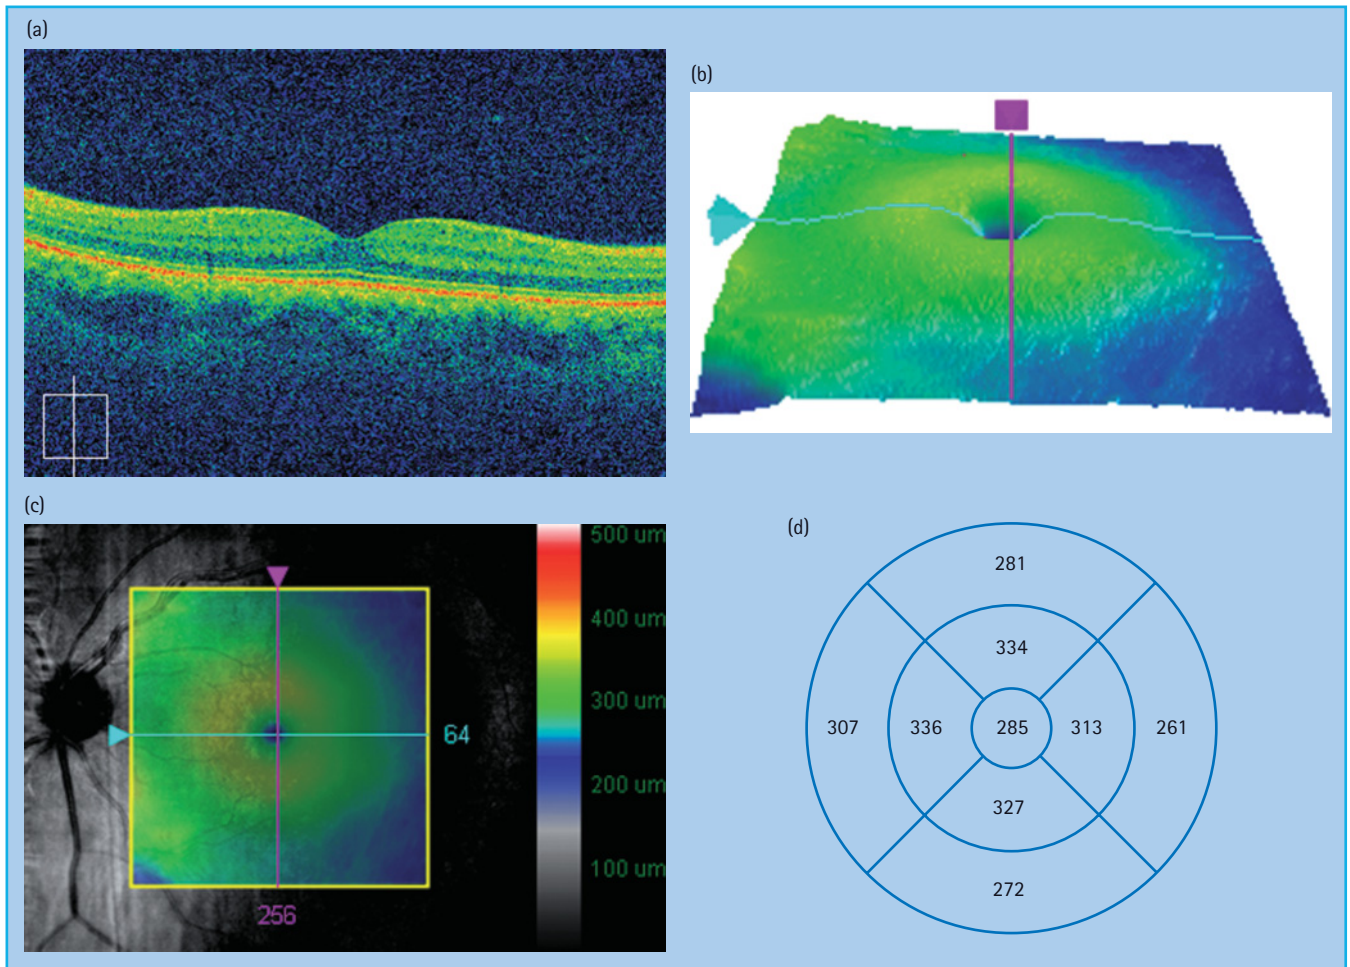

#### **Perimetry**

Perimetry is the systematic measurement of differential light sensitivity in the visual field by the detection of the presence of test targets on a defined background in order to map and quantify the visual field, normally testing each eye independently but binocularly for driving field assessment.

---

### **Screening for diabetic retinopathy**

The definition of screening that was adapted by the World Health Organization (WHO) [34] in 1968 was “the presumptive identification of unrecognized disease or defect by the application of tests, examinations or other procedures which can be applied rapidly. Screening tests sort out apparently well persons who probably have a disease from those who probably do not. A screening test is not intended to be diagnostic. Persons with posi-

**Figure 36.8** (a) Normal cross-sectional optical coherence tomography (OCT) image. (b) Topographic map of macular area. (c) Topographic map superimposed on red free image of macular area. (d) Measurements of thickness in macular area.

tive or suspicious findings must be referred to their physicians for diagnosis and necessary treatment.”

Applying this definition to DR demonstrates that it is a very suitable condition for screening:

- Sight-threatening DR is an important public health problem [35,36].
- The incidence of sight-threatening DR is going to become an even greater public health problem; the International Diabetes Federation (IDF) has predicted a worldwide increase in diabetes and DR.
- Sight-threatening DR has a recognizable latent stage [19,37].
- Laser treatment for sight-threatening DR is effective [38,39] and agreed universally. Favorable long-term visual results have been reported [40–42] and there is also evidence that intensive control of blood glucose control [6,19] and systemic hypertension [10] reduces the risk of new onset DR and slows the progression of existing DR.
- A suitable and reliable screening test is available (digital photography) for sight-threatening DR [43–46], and is acceptable to both health care professionals and to the public.

- The costs of screening and effective treatment of sight-threatening DR balance economically in relation to total expenditure on health care [47–50], including the consequences of leaving the disease untreated.

## Lesions and classifications of diabetic retinopathy

### Microaneurysms and retinal hemorrhages

The lesions that the Early Treatment Diabetic Retinopathy Study (ETDRS) (Table 36.1) [51] described as critical to the stages of progression of DR were:

- *Microaneurysms* – a microaneurysm is defined as a red spot <125 $\mu$ m (approximate width of vein at disc margin) and sharp margins.
- *Small retinal hemorrhages* – a hemorrhage is defined as a red spot, which has irregular margins and/or uneven density, particularly when surrounding a smaller central lesion considered to be a microaneurysm.

**Figure 36.9** An example of the venous phase of a fluorescein angiogram showing small hemorrhages (dark), microaneurysms fluorescing, some of which are leaking shown by the fluffy edge.

**Figure 36.11** An example of exudates in the right macular area.

**Figure 36.10** An example of more elongated lighter red flame hemorrhages and more oval and darker red blot hemorrhages.

- *Hemorrhage/microaneurysm (HMa)* – because the ETDRS recognized that it was very difficult to differentiate between microaneurysms and small hemorrhages, the concept of HMa was introduced, which is a small hemorrhage or microaneurysm (Figure 36.9).

#### Other larger retinal hemorrhages

- *Flame hemorrhages* – superficial hemorrhages just under the nerve fiber layer (Figure 36.10).

**Figure 36.12** An example of cotton wool spots. Reproduced from Scanlon PH, Wilkinson CP, Aldington SJ, Matthews DR. *A Practical Manual of Diabetic Retinopathy Management*. Published 2009 by Blackwell Publishing.

- *Blot hemorrhages* – deeper hemorrhages, which are a sign of retinal ischemia in the area of the retina in which they occur.

#### Hard exudates

Hard exudates (sometimes now just referred to as exudates) are defined as small white or yellowish-white deposits with sharp margins, located typically in the outer layers of the retina, but they may be more superficial, particularly when retinal edema is present (Figure 36.11).

#### Cotton wool spots

Cotton wool spots (referred to as soft exudates in the ETDRS, but this term is now rarely used) are fluffy white opaque areas caused by an accumulation of axoplasm in the nerve fiber layer of the retina, which is caused by an arteriolar occlusion in that area of retina that is apparent on a fluorescein angiogram (Figure 36.12).

**Figure 36.13** An example of intraretinal microvascular abnormality (IRMA) in the temporal retina of the right eye (the right macula is seen in the right side of this red free photograph).

#### Intraretinal microvascular abnormalities

IRMA are defined as tortuous intraretinal vascular segments, varying in caliber, derived from remodeling of the retinal capillaries and small collateral vessels in areas of microvascular occlusion and are therefore a sign of retinal ischemia (Figure 36.13).

#### Venous abnormalities

- *Venous loops* – abrupt curving deviations of a vein from its normal path (Figure 36.14).
- *Venous beading* – in the ETDRS, venous beading is described as a localized increase in caliber of the vein and the severity is dependent on the increase in caliber and the length of vein involved. It is associated with retinal ischemia (Figure 36.15).

Other venous changes that occur in DR are as follow:

- Venous dilatation;
- Venous narrowing;
- Opacification of the venous wall; and
- Perivenous exudate.

#### Arteriolar abnormalities

Other arteriolar changes that occur in DR are as follow:

- Arteriolar narrowing;
- Opacification of arteriolar walls; and
- Arteriovenous nipping.

#### Fibrous proliferation at the disc

Fibrous proliferation at the disc (FPD) usually occurs when new vessels at the disc start to regress and fibrosis occurs.

#### Fibrous proliferation elsewhere

Fibrous proliferation elsewhere (FPE) usually occurs when new vessels elsewhere start to regress and fibrosis occurs.

**Figure 36.14** An example of a venous loop.

**Figure 36.15** A fluorescein angiogram showing venous beading adjacent to an ischemic area of retina. Reproduced from Scanlon PH, Wilkinson CP, Aldington SJ, Matthews DR. *A Practical Manual of Diabetic Retinopathy Management*. Published 2009 by Blackwell Publishing.

#### New vessels on and/or within 1 disc diameter of the disc

For new vessels on and/or within 1 disc diameter (DD) of the disc (NVD), see Figure 36.16.

#### New vessels elsewhere

For new vessels elsewhere (NVE), see Figure 36.17.

#### Vitreous hemorrhage

Vitreous hemorrhage (VH) is a hemorrhage that is in the vitreous gel.

#### Preretinal hemorrhage

Preretinal hemorrhages (PRH) are boat-shaped hemorrhages and roughly round, confluent or linear patches of hemorrhage just anterior to the retina or under the internal limiting membrane (Figure 36.18).

**Figure 36.16** An example of new vessels on disc (NVD).

#### Post laser treatment

Photocoagulation laser scars may be seen both after macular or panretinal laser treatment (Figure 36.19; Tables 36.1–36.4).

### Maculopathy

#### Clinical classification of diabetic maculopathy

Diabetic maculopathy may be classified into focal (subdivided into focal exudates and focal/multifocal edema), diffuse and ischemic diabetic maculopathy (Tables 36.2 and 36.4).

#### Pathophysiology of macular edema

In focal macular edema, focal leakage tends to occur from microaneurysms, often with extravascular lipoprotein in a circinate pattern around the focal leakage [57].

In diffuse macular edema, there is a generalized breakdown of the blood–retina barrier and profuse early leakage from the entire capillary bed of the posterior pole [58] causing extracellular fluid accumulation, often accompanied by cystoid macular edema [57], which is caused by cellular swelling. In ischemic maculopathy, enlargement of the foveal avascular zone as a result of capillary closure is found.

#### The fluorescein angiographic appearance

In diabetic maculopathy, most leakage occurs in the venous phase of the angiogram and hence examples of venous phase angiograms are shown in Figure 36.20.

**Figure 36.17** An example of new vessels elsewhere (NVE).

**Figure 36.18** An example of preretinal hemorrhage.

#### Optical coherence tomography

An example of diabetic maculopathy is shown in Figure 36.21. Macular traction can occur from contracture of fibrotic proliferations, particularly as new vessels regress after panretinal photocoagulation, and also from a taut posterior hyaloid. If macular traction is severe, surgical intervention is required (Figure 36.22).

#### Laser treatment for diabetic maculopathy

In 1985, the ETDRS [59] demonstrated that focal (direct/grid) laser photocoagulation reduces moderate vision loss caused by

**Table 36.1** Early Treatment Diabetic Retinopathy Study (ETDRS) Research Group diabetic retinopathy classification of progression to proliferative diabetic retinopathy based on 7 × 30° field stereo photographs of each eye.

ETDRS final Retinopathy Severity Scale [37]	ETDRS (final) grade	Lesions	Risk of progression to PDR in 1 year (ETDRS Interim)	Practical clinic follow-up intervals (not ETDRS)
No apparent retinopathy	10	DR absent		1 year
Mild NPDR	14, 15	DR questionable		1 year
	20	Microaneurysms only		6–12 months
	35	One or more of the following:	Level 30 = 6.2%	
	a	Venous loops ≥ definite in 1 field		
	b	SE, IRMA, or VB questionable		
	c	Retinal hemorrhages present		
	d	HE ≥ definite in 1 field		
	e	SE ≥ definite in 1 field		
Moderate NPDR	43a	H/Ma moderate in 4-5 fields or severe in 1 field <i>or</i>	Level 41 = 11.3%	6 months
	b	IRMA definite in 1–3 fields		
Moderately severe NPDR	47	Both level 43 characteristics – H/Ma moderate in 4–5 fields	Level 45 = 20.7%	4 months
	a	<i>or</i> severe in 1 field and IRMA definite in 1–3 fields		
	b	<i>or</i> any one of the following:		
	c	IRMA in 4–5 fields		
	d	HMa severe in 2–3 fields		
		VB definite in 1 field		
Severe NPDR	53	One or more of the following:	Level 51 = 44.2%	3 months
	a	≥2 of the 3 level 47 characteristics		
	b	H/Ma severe in 4–5 fields		
	c	IRMA ≥ moderate in 1 field	Level 55 = 54.8%	
	d	VB ≥ definite in 2–3 fields		
Mild PDR	61a	FPD or FPE present with NVD absent <i>or</i>	1976. Diabetic Retinopathy Study [52] protocol	
	b	NVE = definite	changed to treat untreated eyes with high risk	
Moderate PDR	65a	<b>1</b> NVE ≥ moderate in 1 field or definite NVD with VH and	characteristics	
		PRH absent or questionable <i>or</i>		
	b	<b>2</b> VH or PRH definite and NVE < moderate in 1 field and	1981. Diabetic Retinopathy Study [53]	
		NVD absent	recommendation to treat – eyes with new vessels	
High risk PDR	71	Any of the following:	on or within 1 DD of the optic disc (NVD) ≥0.25	
	a	<b>1</b> VH or PRH ≥ moderate in 1 field	–0.33 disc area, even in the absence of preretinal	
	b	<b>2</b> NVE ≥ moderate in 1 field and VH or PRH definite in	or vitreous hemorrhage. Photocoagulation, as	
		1 field	used in the study, reduced the risk of severe	
	c	<b>3</b> NVD = 2 and VH or PRH definite in 1 field	visual loss by 50% or more	
	d	<b>4</b> NVD ≥ moderate		
High risk PDR	75	NVD ≥ moderate and definite VH or PRH		
Advanced PDR	81	Retina obscured due to VH or PRH		

DD, disc diameter; DR, diabetic retinopathy; HE, hard exudate; HMa, small hemorrhage or microaneurysm; IRMA, intraretinal microvascular abnormality; NPDR, non-proliferative DR; NVD, new vessels on disc; NVE, new vessels elsewhere; PDR, proliferative diabetic retinopathy; PRH, preretinal hemorrhage; SE, soft exudate, a term that has now been replaced by cotton wool spot; VB, venous beading; VH, vitreous hemorrhage.

**Table 36.2** Early Treatment Diabetic Retinopathy Study (ETDRS) maculopathy classification.

ETDRS	Outcome
Clinically significant macular edema [54] as defined by:	
• A zone or zones of retinal thickening one disc area or larger, any part of which is within one disc diameter of the center of the macula	Consider laser
• Retinal thickening at or within 500 μm of the center of the macula	Consider laser
• Hard exudates at or within 500 μm of the center of the macula, if associated with thickening of the adjacent retina (not residual hard exudates remaining after disappearance of retinal thickening)	Consider laser

Because of the difficulty in correlating 7 field stereo-photography to the clinical setting, two further simplified classifications have been developed (International Classification and the English Screening Classification).

**Table 36.3** International and English retinopathy classifications.

International clinical classification of diabetic retinopathy severity or diabetic macular edema [55]	Recommended International outcome	English Screening program levels [56] and recommended outcome
Microaneurysms only	Optimize medical therapy, screen at least annually	<b>R0:</b> no DR Outcome: currently screen annually
More than just microaneurysms but less severe than severe NPDR	Refer to ophthalmologist	<b>R1:</b> background DR Microaneurysm(s) Retinal hemorrhage(s) ± any exudate Outcome: currently screen annually
Severe NPDR Any of the following: (a) Extensive intraretinal hemorrhage (>20) in 4 quadrants (b) Definite venous beading in 2+ quadrants (c) Prominent IRMA in 1+ quadrant and no signs of PDR	Consider scatter photocoagulation for T2DM	<b>R2:</b> preproliferative DR venous beading venous loop or reduplication IRMA, multiple deep, round or blot hemorrhages Outcome: refer to ophthalmologist
Neovascularization Vitreous/preretinal hemorrhage	Scatter Photocoagulation without delay for patients with vitreous hemorrhage or neovascularization within 1 DD of the optic nerve head	<b>R3:</b> proliferative NVD NVE Preretinal or vitreous hemorrhage Preretinal fibrosis ± tractional retinal detachment Outcome: urgent referral to ophthalmologist

DD, disc diameter; DR, diabetic retinopathy; IRMA, intraretinal microvascular abnormality; NPDR, non-proliferative DR; NVD, new vessels on disc; NVE, new vessels elsewhere; PDR, proliferative diabetic retinopathy.

**Figure 36.19** (a,b) Right macular and nasal views following panretinal photocoagulation to show laser treatment scars in the superior, inferior, temporal and nasal retina.

**Table 36.4** International and English maculopathy classification.

International classification [55]	Outcome	English classification [56]	Outcome
Diabetic macular edema present as defined by some retinal thickening or hard exudates in the posterior pole and subclassified into: Mild diabetic macular edema: Some retinal thickening or hard exudates in the posterior pole but distant from the macula	Referral	Circinate or group of exudates within the macula (The macula is defined as that part of the retina that lies within a circle centered on the fovea whose radius is the distance between the center of the fovea and the temporal margin of the disc) Any microaneurysm or hemorrhage within 1 DD of the center of the fovea only if associated with a best VA of $\leq 6/12$ (if no stereo)	Referral Referral
Moderate diabetic macular edema: Retinal thickening or hard exudates approaching the center of the macula but not involving the center	Referral	Exudate within 1 DD of the center of the fovea	Referral
Severe diabetic macular edema: Retinal thickening or hard exudates involving the center of the macula	Referral	Retinal thickening within 1 DD of the center of the fovea (if stereo available)	Referral

DD, disc diameter; VA, visual acuity.

diabetic maculopathy edema by 50% or more. It also described “clinically significant macular edema,” which defined the parameters for treatment as [54]:

- Thickening of the retina at or within 500 $\mu$ m of the center of the macula;
- Hard exudates at or within 500 $\mu$ m of the center of the fovea, if associated with thickening of the adjacent retina (not residual hard exudates remaining after disappearance of retinal thickening);
- A zone or zones of retinal thickening 1 disc area or larger, any part of which is within 1 DD of the center of the macula (Figure 36.23).

#### Mechanisms of action of laser for macular edema

The effectiveness of focal laser treatment may be caused, in part, by the closure of leaky microaneurysms. Other methods suggested have been histopathologic changes [60], biochemical

changes [61] and the application of Starling’s law and improved oxygenation [62].

#### Adverse effects of macular laser treatment

Potential side effects specific to macular laser are:

- Laser close to the central fovea, resulting in a drop in visual acuity. Laser burns may be associated with paracentral scotomas and may become larger than the original spot size [63] and encroach on fixation.
- Choroidal neovascular membrane developing in an area that has received laser treatment – this complication is extremely rare.

#### Intravitreal triamcinolone

Promising results in the short term for improving the vision in eyes with chronic diabetic macular edema unresponsive to conventional laser treatment, reducing macular thickness and induc-

ing reabsorption of hard exudates, have been described in numerous studies [64–67]. The effects are reported to last for 3–8 months, which may be partially dependent on the dose given, varying between 1 and 25 mg.

Serious side effects, however, have been reported such as early rapid increases in intraocular pressure requiring surgical intervention [68] and infectious endophthalmitis [69]. Randomized controlled trials utilizing varying doses of steroid are now required to assess the long-term efficacy, safety and to define optimum treatment regimens.

### Vascular endothelial growth factor treatments

For anti-vascular endothelial growth factor (anti-VEGF) treatments, see the section on the use of intravitreal vascular endothelial growth factor inhibitors later in this chapter.

---

## Mild non-proliferative diabetic retinopathy (ETDRS & International) and background diabetic retinopathy (English Screening)

The earliest sign of mild non-proliferative DR (mild NPDR) or background DR is microaneurysms.

### Microaneurysms

Patients with no DR and microaneurysms only were not included in the ETDRS study. In the Wisconsin Epidemiological Study of Diabetic Retinopathy, the rate of progression to proliferative retinopathy 4 years after the initial evaluation showed “no DR” was 0.4% for young patients <30 years with T1DM, 0% for older patients ≥30 years with diabetes taking insulin and 0.6% for those not using insulin. For those with microaneurysms or one hemorrhage in one eye only, the rate of progression to proliferative retinopathy 4 years after the initial evaluation was 3.0% for young patients <30 years with T1DM, 0% for older patients ≥30 years with T1DM and 1.5% for those not using insulin.

The other signs of mild NPDR are one or more of the following:

- *Retinal hemorrhages.* In mild NPDR, retinal hemorrhages are usually small dot hemorrhages or flame-shaped hemorrhages (Figures 36.9 and 36.10). Because small retinal hemorrhages can be difficult to differentiate from microaneurysms they are commonly referred to as HMA.
- *Exudates* (or hard exudates) are a feature of mild NPDR (Figure 36.11).
- *Cotton wool spots* may be present in mild NPDR or background DR but are caused by an arteriolar occlusion in that area of retina, but despite this being the underlying cause, they are not a good sign of increasing retinal ischemia. They are often associated with hypertension (Figure 36.12).
- *A single venous loop.* The ETDRS included a single venous loop in their classification of mild NPDR; however, this rarely occurs in isolation without other significant signs of retinal ischemia and

**Figure 36.24** Red free photograph showing microaneurysms, hemorrhages, hard exudates and cotton wool spots.

a venous loop is therefore not a feature of the English Screening definition of background DR (Figure 36.14).

For mild NPDR, there is a 6.2% risk of progression to proliferative retinopathy within 1 year.

The International classification of DR recommends that anyone who has a more severe disorder than microaneurysms is referred to an ophthalmologist [55]. In the UK, patients who are screened and who show signs of background DR are only rescreened annually. For the purposes of the English National Screening Programme, background DR is defined by the following lesions [56]:

- Microaneurysm(s); and
- Retinal hemorrhage(s) with or without any exudate (Figure 36.24).

---

## Moderate and severe non-proliferative diabetic retinopathy (ETDRS & International) and pre-proliferative diabetic retinopathy (English Screening)

The main features that warrant classifying a DR level in the higher levels of moderate and severe NPDR [55] (or pre-proliferative DR [56]) are increasing signs of retinal ischemia.

Lesions associated with increasing retinal ischemia:

- Retinal hemorrhages especially blot hemorrhages (Figure 36.25).
- Intraretinal microvascular abnormality (Figure 36.25). Intraretinal microvascular abnormalities are derived from remodeling of the retinal capillaries and small collateral vessels in

**Figure 36.25** Photograph showing venous beading, intraretinal microvascular abnormality, perivenous exudate and a small number of blot hemorrhages. Reproduced from Scanlon PH, Wilkinson CP, Aldington SJ, Matthews DR. *A Practical Manual of Diabetic Retinopathy Management*. Published 2009 by Blackwell Publishing.

areas of microvascular occlusion. They are usually found on the borders of areas of non-perfused retina.

- Venous beading (VB; Figure 36.25) is found to be associated with retinal ischemia and is used for assessment of severity of DR.

With increasing ischemia, there is an increasing risk of progression to proliferative in 1 year. The risk increases from approximately 11.3% in the lower levels of moderate NPDR to 54.8% progression to proliferative in 1 year in the most severe NPDR level.

ETDRS definitions have been simplified to make them easier for everyday clinical use both in the International classification and in the English classification for screening.

The ETDRS “4:2:1 rule” indicates that the presence of severe hemorrhages in four quadrants ( $\geq 20$ ), VB in two quadrants or IRMA in a single quadrant represents this severity of retinopathy, severe NPDR.

In the International classification, severe NPDR is defined by any of the following:

- Extensive intraretinal hemorrhages ( $>20$ ) in four quadrants;
- Definite VB in two or more quadrants;
- Prominent IRMA in one or more quadrant, and no signs of PDR.

Moderate NPDR is classified in the International classification as more than “microaneurysms only” and less severe than the 4:2:1 rule.

In the English Screening classification, pre-proliferative DR is defined by any of the following:

- VB;
- Venous loop or reduplication;
- IRMA; or
- Multiple deep, round or blot hemorrhages.

**Figure 36.26** Profuse leakage of fluorescein from new vessels on disc (NVD) and new vessels elsewhere (NVE) in the arteriovenous phase of this angiogram.

## Proliferative diabetic retinopathy and advanced diabetic retinopathy

### Pathogenesis of retinal angiogenesis (new vessel formation)

New vessels arise from the post capillary venule in areas of ischemic retina. New vessel growth originates either within 1 DD of the optic disc (new vessels at the disc [NVD]) or developing from retinal vessels more than 1 DD away from the edge of the optic disc (new vessels elsewhere [NVE]).

The central role of growth factors in retinal neovascularization was suggested as early as 1948 by Michaelson [70], who proposed that a diffusible factor released from the ischemic retina was responsible for angiogenesis. The growth factors that have been extensively studied are fibroblast-derived growth factor (FDGF) [71], insulin-like growth factor I (IGF-I) [72], platelet-derived growth factor (PDGF) [73], hepatocyte growth factor (HGF) [74] and VEGF [75]. Another consequence of generalized retinal ischemia can be neovascularization in the anterior chamber on the iris (rubeosis iridis).

### Fluorescein angiographic appearance

The characteristic appearance of new vessels on the fluorescein angiogram, once they have penetrated the internal limiting membrane, is leakage appearing in the arteriovenous phase of the angiogram and increasing through the angiogram (Figure 36.26).

### Presentation

Some patients present asymptotically from screening, others with visual loss arising from hemorrhage from new vessels.

### Laser treatment for proliferative diabetic retinopathy

For laser treatment for proliferative diabetic retinopathy (PDR), see Figure 36.27.

**Figure 36.27** Disc and macular photographs taken immediately after panretinal laser treatment on a patient with proliferative diabetic retinopathy. Reproduced from Scanlon PH, Wilkinson CP, Aldington SJ, Matthews DR. *A Practical Manual of Diabetic Retinopathy Management*. Published 2009 by Blackwell Publishing.

### Diabetic Retinopathy Study

The Diabetic Retinopathy Study (DRS) [53] recommended prompt treatment in the presence of DRS high-risk characteristics, which reduced the 2-year risk of severe visual loss by 50% or more and were defined by:

- Presence of preretinal or vitreous hemorrhage;
- Eyes with NVD equalling or exceeding one-quarter to one-third disc area in extent with no hemorrhage;
- NVE equalling more than half disc area with hemorrhage.

Untreated, eyes with high risk characteristics had a 25.6–36.9% chance of severe visual loss within 2 years, depending on the size and location of the new vessels and whether or not hemorrhage was present.

### “Low risk” proliferative patients

In eyes with PDR without high risk characteristics, there were still the following risks of severe visual loss:

- Untreated: 2 year 7.0%, 4 years 20.9%;
- Treated: 2 year 3.2%, 4 years 7.4%.

These risks need to be balanced against the potential adverse effects of laser treatment.

### Adverse effects of laser treatment

Adverse effects of laser treatment described in the DRS [76] and other studies are as follow:

- Loss of peripheral areas of visual field was attributed to argon laser in approximately 10% of eyes and field loss was nearly three times more common in the xenon arc treated group.
- Visual acuity loss at the 6-week follow-up visit was assumed to be brought about by treatment. Among eyes with NPDR, 14.3% more argon-treated and 29.7% of xenon-treated eyes than control subjects had an early persistent loss of one or more lines.

Other possible adverse effects of panretinal laser treatment are as follow:

- Unintended laser absorption (e.g. to the lens) or uptake of laser from a flame-shaped hemorrhage, which may result in a burn and destruction of the nerve fiber layer that lies on its surface.
- Inadvertent coagulation (e.g. to the fovea).
- Choroidal detachment is usually as a result of a large dose of laser treatment being applied in a single session, which usually resolves spontaneously within 10 days.

### Risks to the ophthalmologist

There has been some concern in the past that the ophthalmologist is exposed to excessive amounts of reflected light, particularly blue light; however, modern technology with appropriate filters has significantly reduced this risk.

### Risks to an observer

The risk to an observer is extremely small but, as a precaution, it is advised that any observer wears the appropriate spectacle protection.

### Factors other than high risk characteristics influencing the decision to laser

#### Anterior segment neovascularization

Extensive neovascularization in the anterior chamber angle is an urgent indication for scatter laser photocoagulation, if it is feasible (Figure 36.28).

#### Signs of ischemia

Large IRMA, VB in more than one quadrant, extensive retinal hemorrhages and opaque small arteriolar branches are signs suggesting severe retinal ischemia.

**Figure 36.28** Iris neovascularization.

#### Macular edema

See the section on laser for PDR and concurrent diabetic maculopathy.

#### Pregnancy

See the section on pregnancy and DR (below).

#### Renal failure

Treatment needs to coincide with renal dialysis or transplantation. It is also important to control hypertension.

#### Past history

The past history of retinopathy, both in the eye for which scatter laser photocoagulation and in the fellow eye, needs to be considered.

#### Duration of the laser burn

There has been an increasing tendency in the last year for operators to reduce the duration of the burn and increase the power to produce an apparently similar mild bleaching because of the clinical impression that this is more comfortable for the patient.

#### Pattern scan laser

With conventional methods of retinal laser photocoagulation, the ophthalmologist uses a mechanical joystick and foot pedal to deliver single 100-ms laser pulses to the peripheral retina. With the pattern scan laser, the laser pulse time is reduced from 100 ms to just 10–20 ms, and automated multiple spots are produced with each depression of the foot pedal. Higher power is required for shorter burns. Predetermined pattern types can administer up to 25 spots at a time for scatter laser treatment.

### Stage R3 with M1: proliferative diabetic retinopathy with maculopathy

The ETDRS [77] compared giving immediate panretinal photocoagulation with either simultaneous or delayed focal treatment.

**Figure 36.29** Proliferative diabetic retinopathy and concurrent maculopathy.

The conclusion was that, where possible, clinically significant macular edema should be treated by applying focal/grid photocoagulation for macular edema before beginning scatter laser treatment. When the risk of vitreous hemorrhage or neovascular glaucoma seems high, combine treatment of clinically significant macular edema by applying focal/grid photocoagulation for macular edema with panretinal photocoagulation to the inferior half of the peripheral retina, followed 2 weeks later by panretinal photocoagulation to the superior half.

Hamilton *et al.* [78] recommended an exception to this approach for young patients with T1DM who have rapidly accelerating peripheral ischemia associated with macular edema that may resolve following panretinal photocoagulation (Figure 36.29).

### Use of intravitreal vascular endothelial growth factor inhibitors

Ocular neovascularization (angiogenesis) and increased vascular permeability have been associated with VEGF, which does also has a neuroprotective effect. There are three potential VEGF inhibitors:

- 1 Pegaptanib (Macugen);
- 2 Ranibizumab (Lucentis);
- 3 Bevacizumab (Avastin).

Ranibizumab (Lucentis) is an antibody fragment derived from bevacizumab (Avastin), which is a full-length humanized monoclonal antibody against human VEGF.

There are reports of reduction in macular thickness using intravitreal injections of these agents [79]; however, the effect does not last and repeated injections would be required to sustain any beneficial effects.

Favorable results have been reported with some regression of neovascularization and reduction in fluorescein leakage in some studies using bevacizumab [80,81] and using pegaptanib [82] but the effect is only transient (2–11 weeks [81]).

**Figure 36.30** Vitrectomy for tractional detachment shown in (a–c) with postoperative photograph in (d). Reproduced from Scanlon PH, Wilkinson CP, Aldington SJ, Matthews DR. *A Practical Manual of Diabetic Retinopathy Management*. Published 2009 by Blackwell Publishing.

Intravitreal injection is an effective means of delivering anti-VEGF drugs to the retina but has the potential complications of endophthalmitis and retinal detachment. Randomized controlled trials utilizing varying doses of the VEGF inhibitors are required to assess the long-term efficacy, safety and to define optimum treatment regimens.

## Vitrectomy

Smiddy and Flynn [83] wrote an excellent review where they noted that, according to the ETDRS, at least 5% of eyes receiving optimal medical treatment will still have progressive retinopathy that requires laser treatment and pars plana vitrectomy.

Two recent reports of vitrectomy case series have demonstrated that the most common reason for vitrectomy for DR is vitreous hemorrhage [84,85]. In the latter study, the indications for vitrectomy were:

- Vitreous hemorrhage in 80 patients (86.1%);
- Tractional retinal detachment in three patients (3.2%); and
- Vitreous hemorrhage associated with tractional retinal detachment in 10 patients (10.7%).

Lewis [86] suggested that for clinically significant macular edema, OCT should be performed to test for posterior hyaloid thickening and vitrectomy should be considered when a shallow macular detachment is found. Studies by Okamoto *et al.* [87] and Emi *et al.* [88] have shown that vitrectomy is effective in increasing the quality of life of patients with DR (Figure 36.30).

## Pregnancy and the diabetic eye

### Risk factors for progression of diabetic retinopathy in pregnancy

The known risk factors for progression of DR in pregnancy are:

- Pregnancy itself is independently associated with progression of DR [89,90];
- Baseline severity of DR [91–93];
- Poor metabolic control at conception [91];
- Rapid improvement of glycemic control [90–93];
- Poor metabolic control during pregnancy or the early postpartum period [89,90,93,94];
- Duration of diabetes [93,95,96]; and
- Chronic hypertension and pregnancy-induced hypertension [93].

### Recommendations for patients

- Plan pregnancies early in life – women with T1DM should be encouraged to plan pregnancies early in life [94].
- Improving metabolic control before conception is recommended both for the mother and infant [91].
- Improving metabolic control during pregnancy is recommended both for the mother and infant [89,90,93,94].
- Control of hypertension both before conception and during pregnancy is recommended both for the mother and infant [93].
- Photocoagulation before conception and during pregnancy [95]. It is recommended that, if a patient is found to have significant retinopathy before conception, pregnancy is delayed where possible until appropriate laser treatment has been applied and good metabolic control has been achieved for a 9-month period to overcome any effects of the early worsening phenomenon [7]. Photocoagulation before pregnancy may protect against rapidly progressive PDR. Aggressive treatment of PDR developing in pregnancy may prevent further progression of the disease.

### Low vision and blindness from diabetic retinopathy

In 2001, Cunningham [97] reported that 45 million people worldwide fulfil the WHO criteria for blindness. Twenty-four percent of all blindness, affecting people in both developed and developing nations, is caused by a combination of DR and macular degeneration with a small contribution from other eye diseases. In 2002, Kocur and Resnikoff [36] reported that in people of working age in Europe, DR is the most frequently reported cause of serious visual loss, confirmed in the UK by two studies [98,99].

In 2004, Fong *et al.* [100] reported that DR is a leading cause of adult blindness in the USA, resulting in blindness for more than 10 000 people per year.

The most progress in reduction of blindness has been made in Iceland [2] where the prevalence of legal blindness from DR dropped from 4.0% to 0.5% over 15 years, beginning in 1980.

## Diabetic Nephropathy

Sally M. Marshall<sup>1</sup> & Allan Flyvbjerg<sup>2</sup>

<sup>1</sup>Diabetes Research Group, Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK

<sup>2</sup>Department of Endocrinology and Internal Medicine, Aarhus University Hospital – Aarhus University, Aarhus, Denmark

### Keypoints

- Diabetic nephropathy is characterized by gradually increasing urine albumin excretion (UAE) over many years, accompanied by slowly rising blood pressure (BP); the decline in glomerular filtration rate (GFR) occurs late.
- Individuals with nephropathy are at greatly increased risk of other microvascular and macrovascular complications of diabetes.
- The risk of cardiovascular disease increases as UAE increases and as GFR decreases.
- Approximately 30–50% of Caucasian people with diabetes will develop microalbuminuria; the prevalence is higher in non-Caucasians.
- One-third of people with diabetes will progress to proteinuria and be at high risk of end-stage renal disease (ESRD).
- Factors most closely associated with progression of nephropathy are poor glucose and BP control, and baseline UAE.
- Screening for diabetic nephropathy should be performed annually, by measuring urine albumin:creatinine ratio and estimated GFR (eGFR).
- Good blood glucose and BP control are key to prevention of nephropathy.
- If UAE is raised, an inhibitor of the renin angiotensin system should be commenced and titrated up to the maximum tolerated dose.
- Maintaining BP <125/75 mmHg will reduce the rate of decline of GFR from 10–12 to 3–5 mL/min/1.73 m<sup>2</sup>.
- Reducing dietary protein intake to 0.7–1.0 g/kg body weight per day may slow the deterioration in renal function.
- Aggressive management of other cardiovascular risk factors and prescription of aspirin reduces the incidence of cardiovascular events and of progression to nephropathy by around 60%.
- Renal failure from diabetes is the most common single cause of entry to renal replacement programs worldwide; the majority of patients have type 2 diabetes plus major co-morbidities.
- Patients with ESRD and significant co-morbidities should be offered dialysis. Fitter patients benefit from kidney or kidney–pancreas transplantation, but need full cardiovascular assessment and treatment before transplantation if necessary.

### Introduction

Diabetic nephropathy remains an important common complication of diabetes. End-stage renal disease (ESRD) is devastating to the individual and of enormous financial and social consequences to society. In 2006, the proportion of individuals with diabetes beginning renal replacement therapy (RRT) was 20–44% in most countries reporting to the US Renal Disease Registry [1]. The number of people with diabetes requiring RRT in the USA increased 50% between 1996 and 2006. The increasing numbers are accounted for primarily by individuals with type 2 diabetes mellitus (T2DM), often with severe co-morbidities [2]. A European report covering 1998–2002 demonstrated a 9.9% per year increase in the numbers of European patients with T2DM beginning RRT, with no change in non-European populations [3].

ESRD caused by T2DM currently is uncommon before age 45 years, although the annual increase in patients with diabetes beginning RRT may be greatest in this age group [4]. The numbers of patients with type 1 diabetes mellitus (T1DM) entering RRT has not changed dramatically over the same time [2,3].

### Definitions

Classic diabetic nephropathy is a chronic condition developing over many years, characterized by gradually increasing urinary albumin excretion (UAE) and blood pressure (BP). Declining glomerular filtration rate (GFR) is a relatively late event. As nephropathy progresses, the risk of other chronic complications of diabetes increases, so that if other complications of diabetes are absent, an alternative cause of the renal disease should be considered. In particular, the risk of cardiovascular disease (CVD) increases dramatically as renal disease progresses.

Kidney disease is staged on the basis of both the level of UAE and GFR. In diabetic nephropathy, UAE increases gradually from

**Table 37.1** Definitions of normal urinary albumin excretion (UAE), microalbuminuria and proteinuria.

	Normal UAE	Microalbuminuria	Proteinuria
Albumin:creatinine ratio (mg/mmol)	<3.5 (female) <2.5 (male)	3.5–30.0 (female) 2.5–30.0 (male)	>30
Timed overnight urine albumin excretion rate (µg/min)	<20	20–200	>200
24-hour urine collection (mg/24 h)	<30	30–300	>300

**Table 37.2** Staging of chronic kidney disease on the basis of estimated glomerular filtration rate (eGFR) and urine albumin excretion (UAE).

Stage	eGFR description	UAE
Normal	GFR >90 mL/min/1.73 m <sup>2</sup>	Normal
1	GFR >90 mL/min/1.73 m <sup>2</sup> with other evidence of kidney disease*	Normal / micro / proteinuria
2	Mild impairment; GFR 60–90 mL/min/1.73 m <sup>2</sup> with other evidence of kidney disease*	Normal / micro / proteinuria
3a	Moderate impairment; GFR 45–59 mL/min/1.73 m <sup>2</sup>	Normal / micro / proteinuria
3b	Moderate impairment; GFR 30–44 mL/min/1.73 m <sup>2</sup>	Normal / micro / proteinuria
4	Severe impairment; GFR 15–29 mL/min/1.73 m <sup>2</sup>	Normal / micro / proteinuria
5	Established renal failure; GFR <15 mL/min/1.73 m <sup>2</sup> or on dialysis	Normal / micro / proteinuria

\*Other evidence of kidney disease may be: microalbuminuria, persistent proteinuria, persistent hematuria after exclusion of all other causes, structural abnormalities of the kidney demonstrated on ultrasound, or biopsy-proven glomerular nephritis.

normal, through microalbuminuria to proteinuria. Consensus definitions of normal UAE, microalbuminuria and proteinuria are given in Table 37.1.

Serum creatinine is a relatively poor reflection of GFR, but more precise direct measures of GFR are inappropriate in routine clinical practice. Calculation of an “estimated” GFR (eGFR) is now recommended, using the four variable Modification of Diet in Renal Disease study equations [5]. The agreed staging of chronic kidney disease (CKD) on the basis of the eGFR and UAE is shown in Table 37.2.

### Natural history

The development of diabetic nephropathy generally takes at least 20 years. Gradually increasing UAE is the hallmark (Figure 37.1).

**Figure 37.1** Development of diabetic nephropathy. Micro-, microalbuminuria; Normo-, normal urine albumin excretion.

### Type 1 diabetes

During the acute presentation of T1DM, UAE and GFR may both be increased above normal. With insulin therapy, UAE returns to normal in most if not all individuals. GFR also returns to normal in the majority, but remains above normal in 25–40%. The implications of this have long been debated. A recent meta-analysis of 10 cohort studies concluded that individuals with persistently elevated GFR were at increased risk of progression to diabetic nephropathy [6].

In those patients who will never develop nephropathy, UAE remains normal, except during periods of particularly poor glucose control, or during acute intercurrent illness, when a transient increase in UAE may occur. In those who will develop diabetic nephropathy, UAE increases gradually, with microalbuminuria usually appearing within 5–15 years of diabetes. Untreated, the mean increase in UAE is 20% per year. Patients may go through a phase of “transient microalbuminuria” as they approach the cut-off, when sequential samples may vary from normal to microalbuminuria, but eventually they become persistently microalbuminuric. In patients with normal UAE, approximately 1.5–2.5% per year develop microalbuminuria [7,8], and 50% develop persistent microalbuminuria at some point in their life [9–11]. One recent study reported an estimated cumulative incidence of microalbuminuria of 25.4% after 40 years of diabetes, suggesting that the incidence of microalbuminuria may be falling [12]. Approximately one-third of patients with T1DM microalbuminuria will progress gradually over a further 5–15 years to proteinuria, one-third will remain microalbuminuric and one-third will revert to normal UAE (Figure 37.2) [13–15]. In the short term, reversion from microalbuminuria to normal UAE may be even more common, one study reporting regression in 58% of patients over 6 years [16]. Short-duration microalbuminuria, and lower HbA<sub>1c</sub>, systolic BP, total cholesterol and triglycerides were all independently associated with regression. The eventual outcome in those who regress, or who do not initially progress, remains unclear; however, they probably remain

**Figure 37.2** Progression of albuminuria in type 1 diabetes mellitus (T1DM). Approximately 50% of individuals with T1DM will develop microalbuminuria at some time. Of these, around one-third will regress to normal urinary albumin excretion (UAE), at least temporarily, one-third will remain microalbuminuric and one-third will progress to proteinuria. Once proteinuria is present, progression to end-stage renal disease (ESRD) is usually inevitable. BP, blood pressure; CVD, cardiovascular disease. Reproduced from Marshall SM, Flyvbjerg A. Prevention and early detection of vascular complications of diabetes. *Br Med J* 2006; **333**:475–480, with permission.

at increased risk of nephropathy compared to individuals who have never had microalbuminuria.

Older data suggest that the cumulative incidence of proteinuria is around 40%, but in several Scandinavian studies, the cumulative incidence has fallen in individuals diagnosed after 1970 to around 10–14% after 20–25 years' duration [17,18]. In the Pittsburgh cohort, the incidence has remained relatively steady at 32% after 25 years [19]. Almost all patients with T1DM with proteinuria eventually progress to ESRD, if untreated in a mean time of 9 years. GFR is generally relatively stable in microalbuminuria but begins to fall when proteinuria develops, with a mean annual rate of decline in GFR of 10–12 mL/min/1.73 m<sup>2</sup> in a patient without good BP control. Low eGFR occurs very rarely without preceding microalbuminuria in patients with T1DM [20].

Several countries report a declining incidence of ESRD in T1DM. In Sweden, at a maximum duration of diabetes of 27 years (mean 21 years), only 33 of 12032 cases with childhood-onset diabetes had developed ESRD, all with diabetes duration >15 years [21]. With diabetes duration >15 years, the cumulative incidence of ESRD was 0.7%. Data from the Pittsburgh Epidemiology of Diabetes Complications Study also suggests a declining incidence, but after 30 years' duration, the cumulative incidence remained higher at 18% in those diagnosed 1965–1969 [19]. Analyses of data combined from several individual registries confirms that between 1991 and 2000, the numbers of people with T1DM entering RRT has either remained static [2] or even decreased slightly [3], at a time when the incidence of T1DM is rising. Survival once ESRD has developed may also have improved [22,23].

Thus, the incidence of all stages of diabetic nephropathy may be declining, at least in some centers. Whether this represents true prevention, or perhaps more likely delay in progression, remains to be seen.

## Type 2 diabetes

### Classic diabetic nephropathy

The natural history of nephropathy in T2DM is not unlike that of T1DM, with some notable exceptions. At diagnosis, UAE may be raised but with good glycemic control generally returns to normal; however, in 10–48% microalbuminuria persists [24,25]. Those with persistently raised UAE probably have had diabetes for some time before diagnosis, and have established kidney changes. The reported prevalence of hyperfiltration at diagnosis of T2DM varies between studies, reflecting diabetes undiagnosed for some time and the presence of co-morbidities including pre-existing hypertension.

Longitudinal studies in the Pima Indians show that GFR is generally increased in subjects with impaired glucose tolerance (IGT) who later progress to frank diabetes [26]. In one study, 16% of newly diagnosed patients had hyperfiltration [27]. After 6 months' treatment, GFR fell significantly only in those with GFR initially >120 mL/min [28]. GFR remains stable with the onset of microalbuminuria, only beginning to decline when proteinuria develops [26,29]. No relationship of hyperfiltration at diagnosis to subsequent nephropathy has been found.

In cross-sectional studies in established diabetes, the prevalence of microalbuminuria is 10–42%, depending on population selection [30–36]. Higher prevalences are reported in UK Asians [31], Pima Indians [35], African-Americans [37] and in Maori and Pacific Islanders [33] than European patients. The relationship of microalbuminuria to duration of T2DM is not as strong as in T1DM. Many longitudinal studies suggest that the rate of progression from normal UAE to microalbuminuria is 3–4% per annum which is at least as high as, if not higher than, in T1DM [35,38–41].

In Caucasian populations, approximately 7% of microalbuminuric patients with T2DM develop proteinuria per year [42–44]. In an older study, after 20 years' duration of T2DM, the cumulative incidence of proteinuria was 27%, similar to that in T1DM [45]. In the Pima Indians, more than 50% develop proteinuria within 20 years [26]. In contrast to the decline in the cumulative incidence of proteinuria in T1DM, the incidence has doubled in Pima Indians in the last 40 years [46], despite improvements in glucose and BP control and probably as a consequence of increasing survival and therefore duration of diabetes [47].

Once proteinuria develops, the untreated rate of decline of GFR is similar to that in T1DM at 10–12 mL/min/1.73 m<sup>2</sup> [45,48], although it may be greater in non-European subjects [49]. Rates for acceptance on to RRT are higher in African-Caribbean and Indo-Asian than European people with diabetes [50–52]. In the Pima Indians, the age- and sex-adjusted incidence of ESRD has declined since 1990, suggesting slowing of progression [47].

Overall, the course of nephropathy in Euroid T2DM is similar to that in T1DM, the differences probably relating to delayed diagnosis, older age and more CVD of the subjects with T2DM. In the ethnic minorities, the prevalence of nephropathy is higher, and progression to ESRD may be faster.

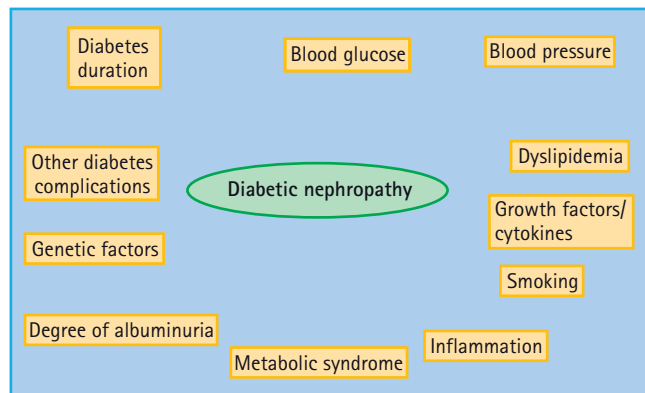

### Non-classic diabetic nephropathy

One-third of Euroid patients with T2DM with raised UAE do not have classic histologic changes of diabetic glomerulosclerosis; arterial hyalinization is the most common abnormality. Conversely, some patients with T2DM with a progressive decline in GFR have normal albumin excretion or only low levels of microalbuminuria which do not progress. In the UK Prospective Diabetes Study (UKPDS), 51% of those who developed renal impairment did not have preceding albuminuria [53]. Identification of patients with non-diabetic changes on the basis of clinical features, including the absence of diabetic retinopathy [54,55], is difficult. The underlying disease process probably reflects a combination of diabetes, hypertension and atherosclerotic vascular disease, or a specific obesity-related glomerulopathy [56].

### Risk factors for diabetic nephropathy

Diabetes duration is one of the strongest risk factors for nephropathy, along with glycemic control, BP and blood lipid levels (Figure 37.3) [12]. “White coat” hypertension, reflecting higher 24-hour BP, doubles the risk of proteinuria [57] and, in young people, microalbuminuria is associated with higher nocturnal diastolic BP and loss of diastolic dipping [58]. Although blood lipids contribute to the development and progression of nephropathy, the lipid phenotype alters as nephropathy progresses [59,60]. Current smoking also predicts the development of albuminuria [61].

Both patients with T1DM and T2DM with nephropathy are more likely to have the metabolic syndrome [62–65].

**Figure 37.3** Factors associated with the development and/or progression of diabetic nephropathy.

The degree of albuminuria is also an independent predictor at each stage of nephropathy; thus, the higher the UAE within the normal range, the higher the risk of developing microalbuminuria [66]. Likewise, the higher the level of microalbuminuria, the higher the risk of developing proteinuria. Baseline albuminuria was the strongest predictor of ESRD in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study [67].

Several lines of evidence suggest a genetic susceptibility to diabetic nephropathy in T1DM, as only 40% of patients are at risk. If one sibling with diabetes has nephropathy, the risk to a second sibling is increased four- to eightfold compared to siblings where neither has nephropathy [68]. The clustering of conventional cardiovascular risk factors and CVD in patients with diabetes and nephropathy also occurs in their parents [69]. This suggests that the genetic susceptibility to nephropathy also influences the development of CVD. Multiple genes are likely to be involved and different loci may influence UAE and GFR separately [70]. Many candidate genes suggested in small studies have not been confirmed in adequately powered cohorts.

Other possible risk factors for nephropathy include pre-eclampsia, but not pregnancy-induced hypertension [71], inflammatory markers [72], cytokines and growth factors [73] and periodontitis [74]. High levels of mannose-binding lectin (MBL) predict progression from normoalbuminuria to micro- and/or macro-albuminuria in T1DM and T2DM [75,76]. In patients with T1DM, higher baseline levels of the bone-related peptide osteoprotegerin (OPG) [77] predicted higher risk of progression to ESRD. Patients with T2DM and non-alcoholic fatty liver disease are more likely to have CKD [78].

### Association of diabetic nephropathy with other complications of diabetes

The prognosis for diabetic patients with any degree of diabetic nephropathy is much poorer than for individuals without nephropathy. The risk of CVD and of other microvascular complications is greatly increased. Indeed, diabetic nephropathy may be a vascular disease [79].

#### Cardiovascular disease

In T1DM, the relative risk of CVD is 1.2-fold in microalbuminuric [80,81] and 10-fold higher in proteinuric than normoalbuminuric patients (Figure 37.4) [82,83]. The cumulative incidence of CVD by the age of 40 years is 43% in patients with T1DM with diabetic nephropathy, compared to 7% in patients without diabetic nephropathy, with a 10-fold increased risk of coronary heart disease and stroke. In ESRD the risk is even higher.

In T2DM, with microalbuminuria, the risk is increased two- to fourfold [84] and with proteinuria ninefold [85]. Once serum creatinine is outwith the normal range, cardiovascular risk increases exponentially [86,87]. Survival with ESRD is very limited: 20–25% of individuals with T2DM die in the first year of dialysis, and almost all are dead within 4–5 years.

**Figure 37.4** Increasing cardiovascular risk with the development of nephropathy in type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM). Compared with normoalbuminuric individuals with T1DM, cardiovascular disease (CVD) risk is increased 1.2-fold in microalbuminuria, 10-fold in proteinuria and at least 20-fold in patients with T1DM with declining glomerular filtration rate (GFR). In T2DM, the risk is increased 2-4 fold in microalbuminuria, 10-fold in proteinuria and at least 20-fold in those with declining GFR.

In both T1DM and T2DM, all-cause and cardiovascular mortality increases as eGFR decreases [88]. UAE and declining GFR may have independent effects [89–91].

### Hypertension

Hypertension is an invariable accompaniment of persistent proteinuria and ESRD. The excess prevalence of hypertension in T1DM is confined to patients with nephropathy, individuals with normal UAE having a prevalence of hypertension similar to the non-diabetic population [92]. This suggests that hypertension is an integral part of diabetic nephropathy, perhaps arising from the same underlying mechanisms. In support of this, BP rises very early in the development of nephropathy. Accordingly, patients with UAE in the high normal range, who are at increased risk of progression to microalbuminuria, have a higher BP than those with lower UAE [7,93]. Changes in BP are very subtle at this stage and may only be documented on 24-hour BP monitoring, perhaps as reduced dipping in nocturnal diastolic BP [94].

In most cross-sectional studies, patients with T1DM with microalbuminuria have higher BP than those with normal UAE, although the levels may not meet a formal definition of hypertension. Once proteinuria is present, untreated BP is >140/90 mmHg in over 80% of patients, and in ESRD hypertension is almost universal.

In T2DM, because hypertension is common, the link between hypertension and renal disease is less striking; however, almost all patients with microalbuminuria or more severe renal disease have hypertension, and the more severe the renal disease, the higher the BP.

### Other microvascular complications

Patients with nephropathy are also much more likely to have other microvascular complications. Indeed, the absence of other

microvascular disease should make one question the diagnosis of diabetic nephropathy as the cause for the renal disease. Significant retinopathy is almost invariably present in patients with T1DM with microalbuminuria or more severe renal disease. In patients with T2DM, the relationship is less clear-cut. Those with classic nephropathy and progressively increasing UAE usually have significant retinopathy. In those with non-classic disease, with non-progressive low levels of microalbuminuria, retinopathy may be absent.

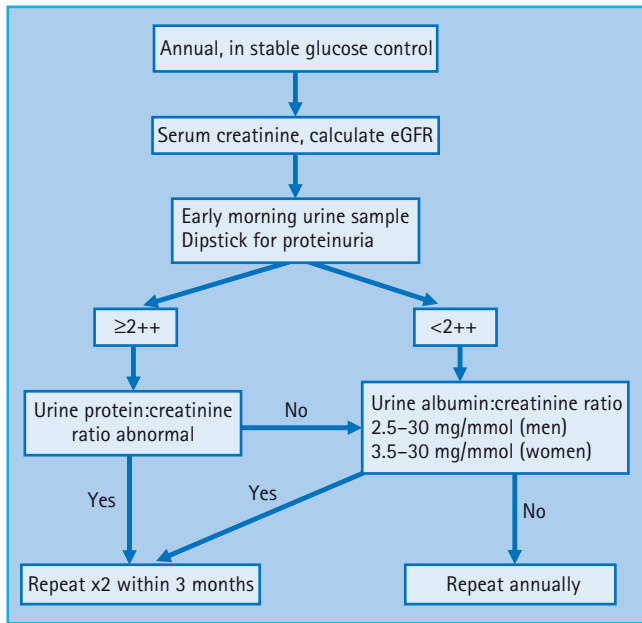

Peripheral neuropathy is also more common in patients with diabetes and renal disease, associating with both albuminuria and declining GFR [95]. Autonomic neuropathy, perhaps relating to loss of nocturnal BP dipping, occurs frequently [96,97].

## Testing for kidney disease in diabetes

### Screening

Early identification of CKD in people with diabetes allows intensification of therapy to slow the progression of the kidney disease and to manage the increased risk of other complications, particularly CVD. All guidelines suggest systematic screening, generally as part of the “annual review.” Both UAE and GFR should be measured, as the combination improves prediction of ESRD [98]. Screening should be undertaken when the person is free of acute illness and in stable glucose control, because many acute illnesses and acute hyperglycemia increase UAE temporarily.

As UAE may increase in the upright posture and with exercise, measurements are best made in an early morning urine sample; however, a spot urine sample can be used if there is no alternative. Timed overnight or 24-hour urine collections are only required for research purposes. A plan for screening is shown in Figure 37.5. Urine albumin is stable at room temperature; the patient

**Figure 37.5** A suggested plan for annual screening for kidney disease in diabetes. eGFR, estimated glomerular filtration rate. Adapted from Marshall SM, Flyvbjerg A. Prevention and early detection of vascular complications of diabetes. *Br Med J* 2006; **333**:475–480.

can collect two or three early morning urine samples on consecutive days and return them all at the same time. Because of the high day-to-day variation in UAE, at least two out of three measurements should be abnormal before a diagnosis of microalbuminuria or proteinuria is made.

Serum creatinine should also be measured annually, using an accredited assay standardized to the recommended isotope dilution mass spectrometry reference method. Using the four variable Modification of Diet in Renal Disease equations, which adjust for age, sex and ethnicity, eGFR is calculated from the serum creatinine [99]. Although the validity of this equation in diabetes has been debated, there is general agreement that it provides information that is more reliable than serum creatinine and is sufficiently accurate for clinical use when eGFR is <60 mL/min/1.73 m<sup>2</sup> [100–103]; however, the equation underestimates the rate of change of GFR at higher levels and is not a good indicator of hyperfiltration [104,105].

The final screening stage should indicate both the GFR and UAE status, as in Table 37.2. For example, stage 3 CKD with proteinuria or stage 2 CKD with microalbuminuria.

Serum cystatin C has been suggested as an alternative to creatinine. Cystatin C is a naturally circulating protein that is freely filtered by the glomerulus and almost completely reabsorbed and catabolized by tubular cells. Although levels reflect trends in GFR <40 mL/min/1.73 m<sup>2</sup>, there is doubt about its ability to detect changes in GFR before the serum creatinine has risen [105–108]. Thus, it seems premature to use cystatin C as a marker of GFR.

**Figure 37.6** Monitoring changes in estimated glomerular filtration rate (eGFR). Solid black line: end-stage renal disease (ESRD). Blue line: actual linear decline in eGFR of 5–6 mL/min/1.73 m<sup>2</sup> in an individual with modest blood pressure (BP) control. Green dotted line: estimated further fall in eGFR in the same individual in the blue line, showing that they will reach ESRD in 9–10 years. Red line: fall in eGFR in an individual whose BP control was tightened between years 2 and 3. The rate of decline of eGFR is reduced, delaying ESRD by at least 5 years (illustrated by thick, black, double-headed arrow).

### Excluding other treatable causes of kidney disease

It is uncommon to find a specific treatable cause of CKD if the natural history is classic, with slowly progressive rise in albuminuria and BP in the presence of retinopathy; however, if there is doubt, ultrasound of the renal tract and measurement of autoantibodies and immunoglobulins may help. If the diagnosis remains unclear, referral to a nephrologist is appropriate.

### Monitoring kidney disease

Once abnormal UAE has been detected, the albumin:creatinine ratio should be measured every 3 months, preferably on the three consecutive mornings before the clinic visit. This provides sufficient information to identify true changes in UAE with time, as opposed to day-to-day variation. Serum creatinine and eGFR should also be measured 3–6 monthly. Once renal function begins to decline, there is a linear relationship between eGFR, or the inverse of the serum creatinine, which is useful in assessing changes in rate of decline of GFR in response to therapy and to estimate when an individual will reach ESRD (Figure 37.6).

### Prevention of kidney disease

Prevention of kidney disease is crucial (Table 37.3). Although much can be done to slow progression when UAE is raised or GFR has begun to decline, it may not be possible to avoid ESRD. The risk of developing diabetic nephropathy is greatly reduced by good blood glucose control. In T2DM, BP control is also crucial. Studies have generally used the development of microalbuminuria as their primary endpoint, with data on preservation of GFR being limited.

**Table 37.3** Factors important in prevention of nephropathy in T1DM and T2DM.

	T1DM	T2DM
Blood glucose control	Yes	Yes
Hypertension	Probably	Yes
RAS inhibition in “normotension”	No	Yes
Dyslipidemia treatment	Possibly	Possibly
Smoking cessation	Possibly	Possibly

RAS, renin angiotensin system.

## Prevention in type 1 diabetes

### Glucose control

In initially normoalbuminuric patients in the Diabetes Control and Complications Trial (DCCT), the relative risk reduction for development of microalbuminuria was 39% and for proteinuria 54% in those allocated to the intensively treated group compared to those in the conventionally managed group over the 6.5-year study [109]. Mean achieved HbA<sub>1c</sub> was approximately 7.0% (53 mmol/mol) and 9.1% (76 mmol/mol), respectively. There is no HbA<sub>1c</sub> threshold below which risk is not reduced, implying that the lower the HbA<sub>1c</sub>, the lower the risk of nephropathy [110]. Thus, any reduction in HbA<sub>1c</sub> is beneficial.

In the open follow-up of the DCCT cohort, the Epidemiology of Diabetes Interventions and Complications (EDIC) study, the difference in HbA<sub>1c</sub> between the previously intensively and conventionally managed groups narrowed over 4 years of follow-up to a mean of 7.9% (63 mmol/mol) and 8.2% (66 mmol/mol), respectively [111]. Despite this, after 8 years, 6.8% in the intensively treated group and 15.8% in the conventionally treated group had developed new microalbuminuria, a 59% reduction in odds [112]. The 84% reduction in new proteinuria was even more impressive: 1.4 vs 9.4%. In addition, fewer participants in the intensive group developed hypertension (29.9 vs 40.3%) and serum creatinine >176 μmol/L (5 vs 19 patients; *P* = 0.004). Thus, the beneficial renal effects of intensive glucose therapy extend far beyond the actual period of good control, a phenomenon termed “metabolic memory.”

### Blood pressure control

No trials have specifically addressed the question of whether improved control of hypertension in patients with T1DM reduces the risk of renal disease, but given the weight of evidence in the general population, this would seem likely. Two trials have explored the effects of renin angiotensin system (RAS) inhibitors in patients with T1DM with normal UAE and BP [113,114]. In the Eurodiab Controlled Trial of Lisinopril in Insulin-Dependent Diabetes Mellitus (EUCLID) study, patients with T1DM receiving lisinopril for 2 years had significantly lower UAE than those receiving placebo [113]; however, the clinical relevance of the small difference (1 μg/min) is questionable. In the The DIabetic RETinopathy Candesartan Trials (DIRECT) study, candesartan 32 mg/day for 4.7 years did not prevent microalbuminuria [114].

Thus, there is no evidence that in normotensive patients with T1DM, prescription of agents that block the RAS prevents the onset of microalbuminuria.

## Prevention in type 2 diabetes

### Glucose control

In the UKPDS, although the mean achieved HbA<sub>1c</sub> in the intensively managed group was 7.0% (53 mmol/mol), compared to 7.9% (63 mmol/mol) in the less strictly managed group, there was a reduction in the relative risk of developing microalbuminuria and proteinuria of approximately 30% after 9–12 years [115]. Different glucose lowering therapies had similar effects, although the UKPDS was not powered to detect small differences between therapies. As in the DCCT, no threshold of HbA<sub>1c</sub> and risk was observed, again suggesting that the lower the HbA<sub>1c</sub>, the lower the risk of nephropathy. For a 1% (11 mmol/mol) reduction in HbA<sub>1c</sub>, there was a 37% reduction in the risk of microvascular complications [116]. In the open follow-up of the UKPDS cohort, HbA<sub>1c</sub> was similar in the previously intensively and conventionally managed groups after 1 year [117]. Despite this, microvascular risk remained lower, confirming the “metabolic memory” seen in the DCCT/EDIC study.

In the Action in Diabetes and Vascular Disease: Preterax and Diamicon MR Controlled Evaluation (ADVANCE) study, intensive therapy was based on modified release gliclazide, with other agents added if the target HbA<sub>1c</sub> of 6.5% (48 mmol/mol) was not reached [118]. The lower HbA<sub>1c</sub> in the intensive group (6.5% [48 mmol/mol] compared to 7.3% [56 mmol/mol] in the standard group) was associated with a 9% relative risk reduction in new onset microalbuminuria over 5 years.

### Blood pressure control

Control of hypertension reduces the risk of developing microalbuminuria. In the UKPDS [119], tight BP control (achieved mean 144/82 mmHg) compared to less tight control (achieved mean 154/87 mmHg) resulted in a 29% reduction in risk of microalbuminuria over 6 years. There is no BP level below which risk rises again (i.e. no “J” shape) [120]. Treatment with captopril and atenolol was equally effective, although the study was not powered to detect differences between treatment modalities [121]. In the subset of normoalbuminuric patients with diabetes in the Heart Outcomes Prevention Evaluation (HOPE) study [122], addition of ramipril to background antihypertensive therapy reduced the risk of developing proteinuria, compared to the addition of placebo. In the Bergamo Nephrologic Diabetes Complications Trial (BENEDICT) study, hypertensive (BP > 130/85 mmHg), but normoalbuminuric patients with T2DM receiving trandolapril alone or in combination with verapamil were approximately 50% less likely to develop microalbuminuria than subjects taking verapamil alone or placebo [41]. In the ADVANCE trial, there was a significant 17% reduction in the incidence of microalbuminuria in those receiving perindopril indapamide [123]. Thus, there may be a particular benefit of RAS

inhibition in prevention of nephropathy, as seen in a meta-analysis [124].

Overall, there is no doubt that tight BP control (achieved BP of approximately 140/80 mmHg) reduces the risk of microalbuminuria in T2DM. First-line therapy with RAS inhibitors may be most effective, but lowering BP sufficiently is more important than the type of first line agent used. Many guidelines now suggest a BP target of 130/80 mmHg for people with T2DM, based on the evidence around prevention of CVD events and not on renal outcomes; of note, achieved BP in the specific renal studies has been around 140/80 mmHg.

In contrast to the “metabolic memory” demonstrated with glucose control, the benefits of BP reduction are lost when BP control deteriorates [125]. Tight BP control must be continued long-term if the benefits are to be maintained.

### Management of diabetic kidney disease

Rigorous intervention, particularly to control BP tightly, can alter the gloomy prognosis in diabetic nephropathy (Table 37.4). Conservative estimates suggest that good management can double the time taken from first appearance of proteinuria to need for RRT, from a mean of 9 years to a mean of 18 years. More optimistically, improved management of microalbuminuria may prevent progression to proteinuria.

#### Type 1 diabetes

##### Glucose control

Once UAE is abnormal, there is little evidence that tight blood glucose control influences progression. The studies that have been performed were all small, of short duration or did not achieve sufficiently tight glucose control [13,14,126–128]. In a

highly selected group of patients undergoing serial renal biopsies after pancreas transplantation, renal structural changes regressed [129], but only after 10 years. Thus, very prolonged periods of extremely good control may be necessary to reverse renal structural changes, indicated by microalbuminuria or proteinuria.

##### Inhibition of the RAS in microalbuminuria and proteinuria

A meta-analysis of 12 studies (698 individuals) summarized the effects of treatment with angiotensin-converting enzyme (ACE) inhibitors in microalbuminuric patients with T1DM [130]. The odds ratio of progression to persistent proteinuria was reduced by ACE inhibition to 0.35, and the odds ratio for regression to normal UAE increased to 3.07, compared to placebo treatment. After 2 years’ treatment, the mean reduction in UAE was 50.5% with ACE inhibition. The reduction in UAE was greatest in those with highest baseline UAE, but the response to treatment plateaued with time, suggesting that treatment delays, rather than prevents, progression.

Addition of an ACE inhibitor to non-ACE inhibitor antihypertensive therapy reduced the risk of a doubling of the serum creatinine by 48% and the composite endpoint of death, need for dialysis or renal transplantation by 50%, in patients with T1DM with proteinuria and hypertension [131]. Both benefits were independent of BP. In short-term studies, the effects of angiotensin II receptor blockers (ARBs) on BP and UAE are similar to those of ACE inhibitors in proteinuric patients with T1DM [132].

For a similar reduction in BP, there is a greater reduction in protein excretion using ACE inhibitors compared with other classes of antihypertensive agents [133]. This may be especially beneficial, as the passage of protein across the glomerular filtration barrier may accelerate the progression of nephropathy [134].

On the basis of the above, and of animal data showing preferential reduction in intraglomerular pressure with ACE inhibitors [135], ACE inhibitors should be offered to all patients with T1DM with abnormal UAE, even if BP is normal. The dose should be titrated up to the maximum recommended or tolerated doses, to obtain maximal antiproteinuric effect.

##### Blood pressure control

Tight BP control is crucial in slowing the progression of diabetic kidney disease. GFR and renal structural variables remain relatively stable in proteinuric patients with T1DM who do not have hypertension [136,137]. Reduction of BP to <140/80 mmHg reduces the rate of decline of GFR from 10–12 mL/min/year untreated to <5 mL/min/year [138]. Regression from persistent proteinuria to microalbuminuria has been reported, with the fall in GFR reduced to <1 mL/min/year for a substantial time in a significant number of patients [139].

If BP remains >125/75 mmHg on maximum dose of ACE inhibitor or ARB, antihypertensive therapy should be intensified. The choice of agent should be made on an individual basis, as there is no evidence in T1DM that any one add-on agent is better

**Table 37.4** Factors important in delaying progression of nephropathy in T1DM and T2DM.

Factor	Target
Glucose control	HbA <sub>1c</sub> as low as possible without undue hypoglycemia
RAS inhibition	For all, unless absolutely contraindicated
Blood pressure	As low as possible; <125/75 mmHg if proteinuric or eGFR <60 mL/min/1.73 m <sup>2</sup> ; others <130/80 mmHg
Lipids	Statin for all; additional therapy if total cholesterol >4.0 mmol/L or LDL cholesterol >2.0 mmol/L or triglycerides >2.1 mmol/L
Aspirin	75 mg/day for all
Smoking	Stop
Weight	BMI <25.0 kg/m <sup>2</sup>
Dietary protein intake	If proteinuria: 6-month trial of reduction to 0.9 g/kg body weight per day

BMI, body mass index; eGFR, estimated glomerular filtration rate; LDL, low density lipoprotein; RAS, renin angiotensin system.

than any other. In the short term, addition of an ARB to therapy with an ACE inhibitor gives further reduction in BP and UAE [140,141], in line with a systematic review of data in proteinuric patients generally [142]; however, there is no evidence of long-term benefit, and some concern about hyperkalemia [142]. Addition of spironolactone to other antihypertensive therapy, including RAS blockade, reduces UAE in the short term [143]. There are no good data on direct renin inhibition in T1DM.

## Type 2 diabetes

### Glucose control

There is some evidence that improved glucose control delays progression of microalbuminuria. In the ADVANCE study, a difference in HbA<sub>1c</sub> of 6.5% (48 mmol/mol) vs 7.3% (56 mmol/mol) over 5 years was associated with a relative risk reduction in the development of proteinuria of 21% [118]. In a small study of Japanese patients with T2DM, with normal UAE or microalbuminuria at baseline, the proportion of patients with worsening of nephropathy (an increase of one or more steps in the three stages of normoalbuminuria, microalbuminuria and proteinuria), was significantly lower after 6–8 years of intensive glucose management [144,145].

### Inhibition of RAS

As with T1DM, there is now good evidence in T2DM that inhibition of the RAS should be the backbone of therapy. In microalbuminuric patients with T2DM with BP > 135/85 mmHg, a large randomized controlled study compared the ARB irbesartan, 150 or 300 mg/day, with placebo [44]. Over 2 years, the proportion of patients developing persistent proteinuria was as follows: high dose irbesartan 5.2% (hazard ratio 0.30); low dose irbesartan 9.7% (hazard ratio 0.61) and placebo 14.9%. The proportion of patients becoming normoalbuminuric was 34%, 24% and 21%, respectively. A much smaller study in similar patients demonstrated that ACE inhibition reduces the rise in UAE and stabilized serum creatinine over 4 or 5 years [146,147]. Thirty-two percent of the patients with T2DM in the HOPE study had microalbuminuria [122]. There was a significant reduction in the risk of developing proteinuria in those receiving ramipril, independent of BP.

Two large studies of patients with T2DM with advanced nephropathy have been conducted [148,149]. In the RENAAL study [148], the effects of the ARB losartan were compared with placebo, in addition to conventional antihypertensive therapy. In the group taking losartan, 43.5% reached the primary outcome (doubling of serum creatinine, ESRD or death), compared to 47.1% in the control group, a 16% risk reduction. In the second study, another ARB, irbesartan, was compared with the calcium-channel blocking agent amlodipine and placebo, in addition to conventional antihypertensive therapy [149]. Treatment with irbesartan was associated with a 20% reduction in the primary endpoint (doubling of serum creatinine, ESRD or death) compared to placebo and 23% compared to amlodipine.

Direct comparisons of ACE inhibitors and ARBs in microalbuminuric patients with T2DM suggest no clinically important dif-

ferences in renal outcomes [150–152]; however, even the largest of these was not powered to detect small differences [150]. Thus, as in T1DM, patients with T2DM with high UAE should be prescribed an RAS inhibitor, which should be titrated up to the maximum tolerated dose.

### Blood pressure control

Most patients with T2DM with elevated UAE will require additional antihypertensive therapy. The guideline target BP in proteinuric patients of <125/75 mmHg is extremely difficult to reach. The choice of additional agents should be made on an individual basis, with diuretics and calcium-channel blockers often being appropriate. A direct renin inhibitor, aliskiren, added to 100 mg/day losartan in hypertensive patients with T2DM with nephropathy, reduced UAE by 20% compared to placebo, with no increase in adverse events [153]. Spironolactone, with or without background ACE inhibitor or ARB, reduces UAE and BP but may cause glycemic control to deteriorate [154,155].

Short-term studies have suggested greater reduction in BP and UAE when ACE inhibitors and ARBs are used in combination than when they are used separately [152]; however, in a study designed to assess CVD outcomes, and which included individuals with diabetes, combination therapy with an ACE inhibitor and ARB did not improve CVD outcomes, and was associated with more adverse events [156]. In particular, the incidences of renal dysfunction and renal failure were higher in those on combination therapy than those taking ACE inhibitor or ARB monotherapy. Thus, combination therapy is not advisable.

---

## Low protein diet

A Cochrane meta-analysis concluded that reducing dietary protein intake non-significantly reduces progression to ESRD [157]. Questions about the level of protein intake required and compliance with diet were raised. Large variability between patients was seen, so that a 6-month trial of dietary restriction might be appropriate, with only those patients who respond continuing thereafter. Dietary protein intake should not be restricted to <0.7 g/kg body weight/day.

---

## Cardiovascular risk: smoking, lipids, aspirin

The above measures, particularly RAS blockade and controlling BP, reduce both CVD and renal risk. There are no good trials of smoking cessation, lipid control and use of aspirin individually in diabetic kidney disease, but the Steno-2 study in patients with T2DM and microalbuminuria addressed all modifiable CVD risk factors aggressively [158,159]. Although the proportion of patients reaching these strict targets was disappointing low, there was a large reduction in the proportion of the intensively managed group having a CVD event. The risk of developing proteinuria was also reduced (relative risk 0.39 [0.17–0.87];

**Table 37.5** The Steno-2 study. Aggressive multifactorial management in patients with T2DM and microalbuminuria. Outcomes after 7.8 years of intensive or conventional management, plus 5.5 years observational follow-up.

Event	Intensive group	Conventional group
Proteinuria	20	37
Dialysis	1	6
Laser therapy	14	27
All deaths	24	40
CVD deaths	9	19
CVD events	42	139

CVD, cardiovascular disease. Figures are number of patients.

$P = 0.003$ ), as was the risk of retinopathy and autonomic neuropathy.

After the 8-year randomized trial, participants were followed observationally for a further 5.5 years [160]. Twenty four patients in the initially intensively managed group died, compared to 40 in the conventional therapy group (hazard ratio 0.54 [0.32–0.89];  $P = 0.02$ ). The risk of cardiovascular death and of cardiovascular events was significantly lower in the intensively treated group. One patient in the intensive group compared to six in the conventional group developed ESRD. Thus, intensive intervention with lifestyle modification and multiple drug combinations had sustained beneficial effects on both cardiovascular and renal outcomes (Table 37.5).

## Management of chronic kidney disease stage 3 or poorer

### Monitoring renal function

Serum creatinine, eGFR and UAE should be measured every 3 months, and more often if clinically indicated. In progressive CKD from stage 3 onwards, bone chemistry, full blood count and iron stores should be assessed 3–6 monthly.

### Monitoring glucose control

Red blood cell turnover is abnormal in CKD, so that HbA<sub>1c</sub> results may be misleading. One uncontrolled study suggested HbA<sub>1c</sub> values fell by approximately 1% (11 mmol/mol) when hemoglobin rose from 10.6 to 11.8 g/dL with treatment with erythropoietin [161]. Thus, more reliance should be placed on self-monitoring of blood glucose and continuous glucose monitoring. As albumin turnover is also abnormal, interpretation of fructosamine is difficult.

### Glucose control

Metformin is excreted mainly by the kidney (Table 37.6). In renal failure, metformin accumulates and inhibits oxidation of lactate. Lactic acidosis arises and may be fatal. Metformin should therefore be used cautiously in patients with eGFR <40 mL/min/1.73 m<sup>2</sup>, and stopped completely when eGFR <35 mL/min/1.73 m<sup>2</sup>.

**Table 37.6** Managing glucose control in chronic kidney disease.

Drug	Comment
Metformin	Risk of accumulation and lactic acidosis; Caution when eGFR <40 mL/min/1.73 m <sup>2</sup> ; Stop when eGFR <35 mL/min/1.73 m <sup>2</sup>
Sulfonylureas	Glibenclamide, gliclazide and tolbutamide predominantly renally excreted; may need to reduce dose
Meglitinides	~10% excreted via kidney; usually safe
Thiazolidenediones	Predominantly hepatic metabolism; use may be limited by fluid retention
DPP-4 inhibitors	Sitagliptin: 80% renally excreted, may need to reduce dose Vildagliptin: hepatic metabolism; probably safe
GLP-1 analogs	Exenatide: renal excretion; contraindicated in ESRD Liraglutide: no renal excretion; probably safe
Insulin	Excreted by kidney; may need to reduce dose and/or switch to shorter-acting preparations

DPP-4, dipeptidyl peptidase 4; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; GLP-1, glucagon-like peptide 1.

The sulfonylureas glibenclamide, gliclazide and tolbutamide are predominantly renally excreted and so accumulate in renal failure. Their dosage, and indeed the dosage of any sulfonylurea, may need to be reduced as CKD progresses. Only approximately 10% of the meglitinides, repaglinide and nateglinide, is renally excreted and so they may be suitable alternative agents. The thiazolidenediones, rosiglitazone and pioglitazone are predominantly metabolized in the liver, but their use in ESRD may be limited by fluid retention. Insulin is also excreted by the kidney and so a reduced dosage, and perhaps a switch to shorter-acting preparations may be required.

The DPP-4 inhibitor, sitagliptin, is predominantly renally excreted and so a reduction in dose may be needed; vildagliptin is probably safe as this compound is not renally excreted. The GLP-1 analog, exenatide, is renally excreted and contraindicated in ESRD, while liraglutide probably is safe, as it is not excreted through the kidney.

### Anemia

Anemia is common in people with diabetes and CKD stage 3 or poorer [162]. Investigation may be needed to exclude a non-renal cause. Anemic patients have a higher mortality, higher rates of hospital admission with heart failure and poorer quality of life. Oral iron should be given to replete iron stores, but parenteral iron may be necessary. The level of hemoglobin at which to commence erythropoietin replacement, and the target treatment level, is unclear.

### When to refer to nephrology

Patients who begin dialysis as an emergency do less well than those in whom treatment is planned. Referral to nephrology

**Table 37.7** When to refer to nephrology.

eGFR <45 mL/min/1.73 m <sup>2</sup> or serum creatinine 150–200 μmol/L
Diagnosis unclear
Blood pressure uncontrolled
eGFR falls by >5 mL/min/1.73 m <sup>2</sup>
Nephrotic syndrome
Hb <10.0 g/dL and other causes of anemia have been excluded
Abnormalities in bone chemistry

should be made when serum creatinine is in the range 150–200 μmol/L or eGFR <45 mL/min/1.73 m<sup>2</sup>. This allows structured physical and psychologic preparation for RRT. Earlier referral may be necessary in particular circumstances (Table 37.7). Early referral also allows specialist management of renal bone disease and anemia. The need for RRT should be discussed with all patients, and those who wish it should have access. Patients without significant co-morbidities will usually be offered transplantation. In the work-up for transplantation, full cardiovascular assessment is essential, with exercise testing, (stress)-echocardiography and angiography as indicated. Coronary angioplasty or bypass surgery may be required before transplantation.

### Organization of care

A retrospective audit of a joint diabetes–renal clinic showed improved systolic BP, diastolic BP and cholesterol compared to at presentation to the joint clinic [163]. Analysis of a subset of patients showed that the rate of decline of GFR fell from 1.09 mL/min/month in the first year to 0.39 mL/min/month in the third year. Thus, joint diabetes–renal clinics may be useful.

### Pregnancy in women with diabetes and chronic kidney disease

Recent studies have confirmed the poor pregnancy outcomes in women with diabetic nephropathy (see Chapter 53). Women with T1DM and vascular disease (retinopathy and/or nephropathy and/or pre-existing hypertension) are at increased risk of pre-eclampsia and abnormal fetal growth [164,165]. Women with any evidence of CKD therefore should be counseled about their increased risks. Inhibitors of the RAS should be stopped before trying to conceive. The incidence of congenital malformations is increased in babies exposed to ACE inhibitors in the first trimester, and there is an increased risk of fetopathy with exposure in the second and third trimesters [166]. Alternative therapies known to be safe in pregnancy, such as methyldopa, labetalol and nifedipine, should be substituted. Strict glucose and BP control may improve pregnancy outcome for mother and baby

[167]. In an uncontrolled prospective study of 117 pregnant women with T1DM, methyldopa was given to maintain BP <135/85 mmHg and proteinuria <300 mg/24 hours. Gestational age was longer and birth weight higher than in previous studies.

## Diabetic Peripheral Neuropathy

**Dan Ziegler**

Institute for Clinical Diabetology, German Diabetes Center at the Heinrich Heine University, Leibniz Center for Diabetes Research; Department of Metabolic Diseases, University Hospital, Düsseldorf, Germany

### Keypoints

- Approximately one in three people with diabetes is affected by distal symmetric polyneuropathy (DPN), which represents a major health problem as it may present with excruciating neuropathic pain and is responsible for substantial morbidity, increased mortality and impaired quality of life.
- Neuropathic pain exerts a substantial impact on quality of life, particularly by causing considerable interference with sleep, daily activities and enjoyment of life.
- Treatment is based on four cornerstones: (1) intensive diabetes therapy and multifactorial risk intervention; (2) treatment based on pathogenetic mechanisms; (3) symptomatic treatment; and (4) avoidance of risk factors and complications.
- Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy. From the clinical point of view, it is important to note that, based on these pathogenetic mechanisms, therapeutic approaches could be derived, some of which are currently being evaluated in clinical trials.
- Management of chronic painful DPN remains a challenge for the physician and should consider the following practical rules: the appropriate and effective drug has to be tried and identified in each patient by carefully titrating the dosage based on efficacy and side effects; lack of efficacy should be judged only after 2–4 weeks of treatment using an adequate dosage. Analgesic combination therapy may be useful, and potential drug interactions have to be considered given the frequent polypharmacy in people with diabetes.
- Epidemiologic data indicate that not only increased alcohol consumption but also the traditional cardiovascular risk factors such as visceral obesity, hypertension, hyperlipidemia and smoking have a role in the development and progression of diabetic neuropathy and hence need to be prevented or treated.

### Classification and epidemiology

Diabetic neuropathy has been defined as a demonstrable disorder, either clinically evident or subclinical, that occurs in the setting of diabetes without other causes for peripheral neuropathy. It includes manifestations in the somatic and/or autonomic parts of the peripheral nervous system [1] which are being classified along clinical criteria; however, because of the variety of the clinical syndromes with possible overlaps there is no universally accepted classification. The most widely used classification of diabetic neuropathy proposed by Thomas [2] has subsequently been modified [3]. This proposal differentiates between rapidly reversible, persistent symmetric polyneuropathies and focal or multifocal neuropathies (Table 38.1). Diabetic distal symmetrical sensory or sensorimotor polyneuropathy (DPN) represents the most relevant clinical manifestation affecting approximately 30% of community-based people with diabetes [4]. There is emerging evidence to suggest that intermediate hyperglycemia is associated

with an increased risk of DPN. In the general population living in the region of Augsburg, Southern Germany, the prevalence of DPN was 28.0% in subjects with diabetes, 13.0% in those with impaired glucose tolerance (IGT), 11.3% in those with impaired fasting glucose (IFG) and 7.4% in those with normal glucose tolerance (NGT) [5]. The incidence of DPN is approximately 2% per year.

The most important etiologic factors that have been associated with DPN are poor glycemic control, visceral obesity, diabetes duration, height, hypertension, age, smoking, hypoinsulinemia and dyslipidemia [4]. The clinical impact of DPN is illustrated in Figure 38.1. DPN is related to both lower extremity impairments such as diminished position sense and functional limitations such as walking ability [6]. There is accumulating evidence suggesting that not only surrogate markers of microangiopathy such as albuminuria, but also those used for DPN such as nerve conduction velocity and vibration perception threshold (VPT) may predict mortality in people with diabetes [7,8]. Elevated VPT also predicts the development of neuropathic foot ulceration, one of the most common causes for hospital admission and lower limb amputations among patients with diabetes [9].

Pain is a subjective symptom of major clinical importance as it is often this complaint that motivates patients to seek health

**Table 38.1** Classification of diabetic neuropathies. Adapted from Sima *et al.* [3].

<b>1 Rapidly reversible</b>
Hyperglycemic neuropathy
<b>2 Persistent symmetric polyneuropathies</b>
Distal somatic sensory/motor polyneuropathies involving predominantly large fibers
Autonomic neuropathies
Small-fiber neuropathies
<b>3 Focal/multifocal neuropathies</b>
Cranial neuropathies

care. Pain associated with diabetic neuropathy exerts a substantial impact on quality of life, particularly by causing considerable interference in sleep and enjoyment of life [10]; however, in one UK survey, only 65% of patients with diabetes received treatment for their neuropathic pain, although 96% had reported the pain to their physician [11]. Pain treatment consisted of antidepressants in 43.5% of cases, anticonvulsants in 17.4%, opiates in 39% and alternative treatments in 30%. While 77% of the patients reported persistent pain over 5 years, 23% were pain-free over at least 1 year [11]. Thus, neuropathic pain persists in the majority of patients with diabetes over periods of several years.

Chronic painful DPN is present in up to 26% of patients with diabetes [11–14]. As well as the high prevalence of painful neuropathy among people with diabetes and intermediate hyperglycemia described previously, subjects with macrovascular disease appear to be particularly prone to neuropathic pain [14]. Among survivors of myocardial infarction (MI) from the Augsburg MI Registry, the prevalence of neuropathic pain was 21.0% in the people with diabetes, 14.8% in those with IGT, 5.7% in those with IFG and 3.7% in those with NGT [15]. The most important risk factors of DPN and neuropathic pain in these surveys were age, obesity and low physical activity, while the predominant comorbidity was peripheral arterial disease, highlighting the paramount role of cardiovascular risk factors and diseases in DPN.

## Clinical manifestations

### Distal symmetric polyneuropathy

The term “hyperglycemic neuropathy” has been used to describe sensory symptoms in people with poorly controlled diabetes that are rapidly reversible following institution of near-normoglycemia [2]; however, the most frequent form is DPN, commonly associated with autonomic involvement. Its onset is insidious and, in the absence of intervention, the course is chronic

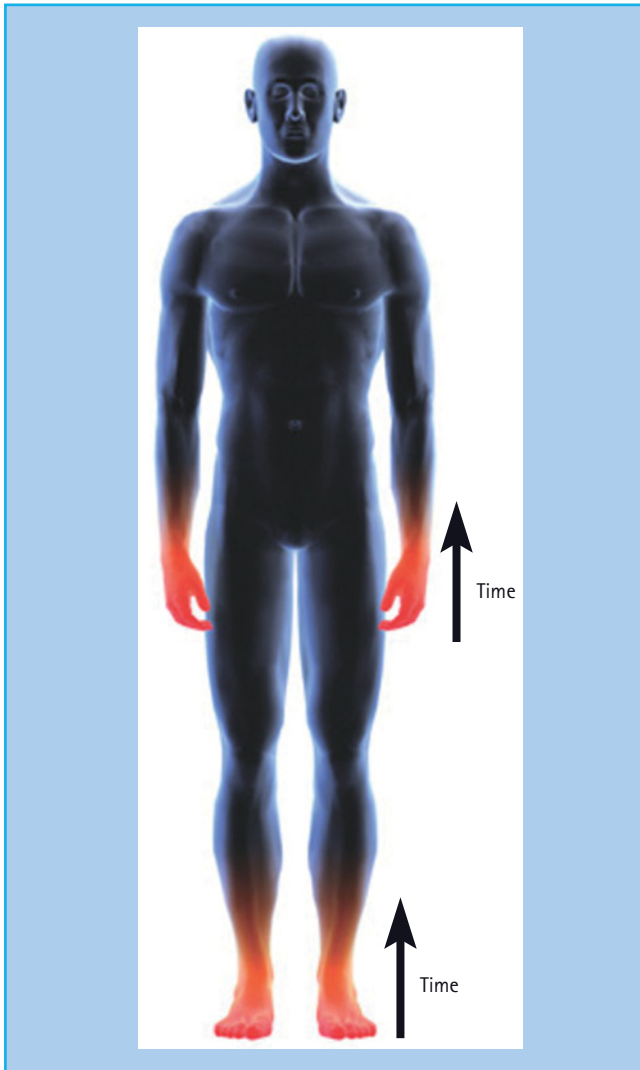

**Figure 38.1** Clinical impact of diabetic distal symmetric polyneuropathy (DPN).

and progressive. It seems that the longer axons to the lower limbs are more vulnerable to the nerve lesions induced by diabetes (length-related distribution). This notion is supported by the correlation found between the presence of DPN and height. DPN typically develops as a “dying-back” neuropathy, affecting the most distal extremities (toes) first. The neuropathic process then extends proximally up the limbs and later it may also affect the anterior abdominal wall and then spread laterally around the trunk. Occasionally, the upper limbs are involved with the fingertips being affected first (“glove and stocking” distribution; Figure 38.2).

Variants including painful small-fiber or pseudosyringomyelic syndromes and an atactic syndrome (diabetic pseudotabes) have been described. Small-fiber unmyelinated (C) and thinly myelinated (Aδ) fibers as well as large-fiber myelinated (Aα, Aβ) neurons are typically involved. It is as yet uncertain whether the various fiber type damage develops following a regular sequence, with small fibers being affected first, followed by larger fibers, or whether the small-fiber or large-fiber involvement reflects either side of a continuous spectrum of fiber damage. Nevertheless, there is evidence suggesting that small-fiber neuropathy may occur early, often presenting with pain and hyperalgesia before sensory deficits or nerve conduction slowing can be detected [2]. The reduction or loss of small fiber-mediated sensation results in loss of pain sensation (heat pain, pinprick) and temperature perception to cold (Aδ) and warm (C) stimuli. Large-fiber involvement leads to nerve conduction slowing and reduction or loss of touch, pressure, two-point discrimination and vibration sensation which may lead to sensory ataxia (atactic gait) in severe cases. A typical example for the distribution of sensory deficits is shown in Figure 38.3. Sensory fiber involvement causes “positive” sensory symptoms such as paresthesia, dysesthesia and pain, as well as “negative” symptoms such as reduced sensation.

Persistent or episodic pain that typically worsens at night and improves during walking is localized predominantly in the feet. The pain is often described as a deep-seated aching but there may

**Figure 38.2** The typical “glove and stocking” distribution of diabetic distal symmetric sensory or sensorimotor polyneuropathy (DPN).

be superimposed lancinating stabs or it may have a burning thermal quality. In a clinical survey including 105 patients with painful DPN, the following locations of pain were most frequent: 96% feet, 69% balls of feet, 67% toes, 54% dorsum of foot, 39% hands, 37% plantum of foot, 37% calves and 32% heels. The pain was most often described by the patients as “burning/hot,” “electric,” “sharp,” “achy” and “tingling” and was worse at night time and when tired or stressed [10]. The average pain intensity was moderate, approximately 5.75/10 on a 0–10 scale, with the “least” and “most” pain 3.6 and 6.9/10, respectively. Allodynia (pain from a stimulus that does not normally cause pain; e.g. stroking) may occur. The symptoms may be accompanied by sensory loss, but patients with severe pain may have few clinical signs. Pain may persist over several years [16] causing considerable disability and impaired quality of life in some patients [10], whereas it remits partially or completely in others [17,18], despite further deterioration in small-fiber function [18]. Pain remission tends

**Figure 38.3** A typical example for the distribution of sensory deficits (dots: reduced thermal sensation; lines: reduced pain sensation; crossed lines: reduced touch sensation) in a patient with distal symmetric sensory or sensorimotor polyneuropathy (DPN).

to be associated with sudden metabolic change, short duration of pain or diabetes, preceding weight loss and less severe sensory loss [17,18].

Compared with the sensory deficits, motor involvement is usually less prominent and restricted to the distal lower limbs resulting in muscle atrophy and weakness at the toes and foot. Ankle reflexes are frequently reduced or absent. At the foot level, the loss of the protective sensation (painless feet), motor dysfunction and reduced sweat production, resulting in dry and chapped skin and which is caused by autonomic involvement, increase the risk of callus and foot ulcers. Thus, the neuropathic patient has a high-risk of developing severe and potentially life-threatening foot complications such as ulceration, osteoarthropathy (Charcot foot) and osteomyelitis as well as medial arterial calcification and neuropathic edema. Because DPN is the major contributory factor for diabetic foot ulcers, and the lower limb amputation rates in subjects with diabetes are 15 times higher than in the

non-diabetic population, early detection of DPN by screening is of paramount importance [9]. This is even more imperative because many patients with DPN are asymptomatic or have only mild symptoms. In view of these causation pathways, the majority of amputations should be potentially preventable if appropriate screening and preventative measures were adopted.

### **Acute painful neuropathy**

Acute painful neuropathy has been described as a separate clinical entity [19]. It is encountered infrequently in patients with type 1 (T1DM) and type 2 diabetes mellitus (T2DM) and presents with continuous burning pain particularly in the soles (“like walking on burning sand”) with nocturnal exacerbation. A characteristic feature is a cutaneous contact discomfort to clothes and sheets which can be objectified as hypersensitivity to tactile (allodynia) and painful stimuli (hyperalgesia). Motor function is preserved, and sensory loss may be only slight, being greater for thermal than for vibration sensation. The onset is associated with and preceded by precipitous and severe weight loss. Depression and impotence are constant features. The weight loss has been shown to respond to adequate glycemic control and the severe manifestations subsided within 10 months in all cases. No recurrences were observed after follow-up periods of up to 6 years [19]. The syndrome of acute painful neuropathy seems to be equivalent to diabetic cachexia as described by Ellenberg [20]. It has also been described in girls with anorexia nervosa and diabetes in association with weight loss [21].

The term “insulin neuritis” was used by Caravati [22] to describe a case with precipitation of acute painful neuropathy several weeks following the institution of insulin treatment. In a recent series, painful symptoms gradually improved in all patients, allowing discontinuation of analgesic therapy within 3–8 months. Thus, careful correction of glucose levels should be considered in patients with long-standing uncontrolled diabetes [23]. Sural nerve biopsy shows signs of chronic neuropathy with prominent regenerative activity [24] as well as epineurial arteriovenous shunting and a fine network of vessels, resembling the new vessels of the retina which may lead to a steal effect rendering the endoneurium ischemic [25]. This may happen in analogy to the transient deterioration of a pre-existing retinopathy following rapid improvement in glycemic control.

### **Focal and multifocal neuropathies**

Most of the focal and multifocal neuropathies tend to occur in long-term patients with diabetes of middle age or older. The outlook for most of them is for recovery, either partial or complete, and for eventual resolution of the pain that frequently accompanies them [26]. With this in mind, physicians should always maintain an optimistic outlook in dealing with patients with these afflictions.

### **Cranial neuropathy**

Palsies of the third cranial nerve (diabetic ophthalmoplegia) are painful in about 50% of cases. The onset is usually abrupt. The

pain is felt behind and above the eye and at times precedes the ptosis and diplopia (with pupillary dysfunction in 14–18% of the cases) by several days. Oculomotor findings reach their nadir within a day or at most a few days, persist for several weeks and then begin gradually to improve. Full resolution is the rule and generally takes place within 3–5 months. The fourth, sixth and seventh cranial nerves are next in frequency [26].

### **Mononeuropathy of the limbs**

Focal lesions affecting the limb nerves, most commonly the ulnar, median, radial and peroneal may be painful, particularly if of acute onset, as may entrapment neuropathies, such as the carpal tunnel syndrome which is associated with painful paresthesia [26].

### **Diabetic truncal neuropathy**

Mononeuropathy of the trunk (thoracoabdominal neuropathy or radiculopathy) presents with an abrupt onset with pain or dysesthesia being the heralding feature, sometimes accompanied by cutaneous sensory impairment or hyperesthesia. Pain has been described as deep, aching or boring, but also the descriptors of jabbing, burning, sensitive skin or tearing have been used. The neuropathy is almost always unilateral or predominantly so. As a result, the pain felt in the chest or the abdomen may be confused with pain of pulmonary, cardiac or gastrointestinal origin. Sometimes, it may have a radicular or girdling quality, half encircling the trunk in a root-like distribution. Pain may be felt in one or several dermatomal distributions and, almost universally, it is worst at night. Rarely, abdominal muscle herniation may occur, predominantly in middle-aged men, involving 3–5 adjacent nerve roots between T6 and T12 (Figure 38.4). The time from first symptom to the peak of the pain syndrome is often just a few days, although occasionally spread of the pain to adjacent dermatomes may continue for weeks or even months. Weight loss of 15–40 pounds (7–18 kg) occurs in >50% of the cases. The course of truncal neuropathy is favorable, and pain subsides within months to a maximum of 1.5–2 years [26].

### **Diabetic amyotrophy**

Asymmetric or symmetric proximal muscle weakness and muscle wasting (iliopsoas, obturator and adductor muscles) are easily recognized clinically in the syndrome of lower limb proximal motor neuropathy (synonyms: Bruns–Garland syndrome, diabetic amyotrophy, proximal diabetic neuropathy, diabetic lumbosacral plexopathy, ischemic mononeuropathy multiplex, femoral–sciatic neuropathy, femoral neuropathy). Pronounced bilateral atrophy and paresis of the quadriceps muscle is shown in Figure 38.5. Pain is nearly universal in this syndrome. Characteristically, it is deep, aching, constant and severe, invariably worse at night and may have a burning raw quality. It is usually not frankly dysesthetic or cutaneous. Frequently, pain is first experienced in the lower back or buttock on the affected side or may be felt as extending from hip to knee. Although severe and tenacious, the pain of proximal motor neuropathy has a good

**Figure 38.4** Diabetic truncal neuropathy (thoracoabdominal neuropathy or radiculopathy) leading to herniation of the oblique abdominal muscle.

prognosis. Concurrent distal sensory polyneuropathy is frequently present. Weight loss is also a frequently associated feature and may be as much as 35–40 pounds (16–18 kg). The weight is generally regained during the recovery phase [27,28].

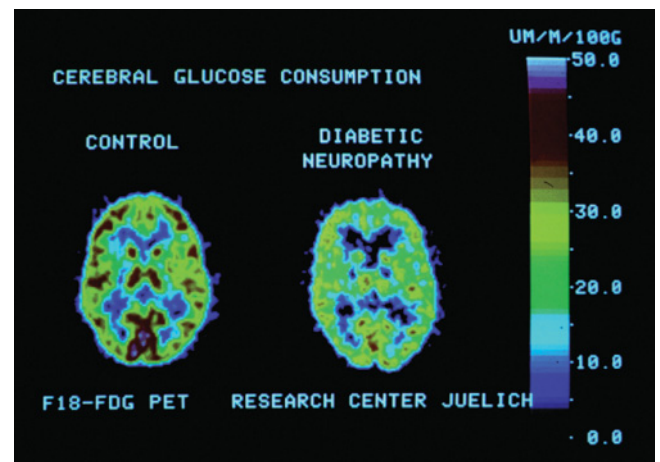

### Central nervous system dysfunction

Relatively little attention has been directed toward impairment of the central nervous system (CNS) in patients with DPN. Previous autopsy studies in people with diabetes have demonstrated diffuse degenerative lesions in the CNS, including demyelination and loss of axon cylinders in the posterior columns [29,30], degeneration of cortical neurons [31] and abnormalities in the midbrain and cerebellum [31,32] which have been described as diabetic myelopathy [30] and diabetic encephalopathy [32].

Studies that evaluated CNS function in people with diabetes using evoked potentials in response to stimulation of peripheral nerves, event-related potentials and neuropsychologic tests have yielded variable results as to the existence of spinal or supraspinal (central) conduction deficits or cognitive dysfunction; however, the author has shown that the degree of dysfunction along the somatosensory afferent pathways in patients with T1DM depends on the stage of peripheral neuropathy, is not related to the duration of diabetes or glycemic control and can be characterized by an alteration of the cortical sensory complex and peripheral rather than spinal or supraspinal conduction deficits [33]. Magnetic resonance imaging (MRI) showed an increased frequency of subcortical and brainstem lesions in patients with T1DM with DPN [34]. Moreover, patients with DPN showed a

**Figure 38.5** Diabetic amyotrophy (proximal neuropathy): pronounced bilateral atrophy and paresis of the quadriceps muscle.

**Figure 38.6** Positron emission tomography (PET) and [ $^{18}\text{F}$ ]-2-deoxy-2-fluoro-D-glucose (FDG) showing reduced cerebral glucose metabolism in a patient with T1DM with polyneuropathy compared to a healthy subject.

smaller cross-sectional chord area at C4/5 and T3/4 [35]. Using positron emission tomography (PET) and [ $^{18}\text{F}$ ]-2-deoxy-2-fluoro-D-glucose (FDG), we have demonstrated reduced cerebral glucose metabolism in patients with T1DM with DPN as compared with newly diagnosed people with diabetes and healthy subjects (Figure 38.6) [36]. Spectroscopic measurement of brain metabolites such as N-acetyl aspartate (NAA) in the thalamus revealed a lower NAA:creatinine ratio, suggesting thalamic neuro-

nal dysfunction in DPN [37]. Thus, there is accumulating evidence suggesting that neuropathic involvement at central and spinal levels is a feature of DPN, but it is not clear whether these are primary or secondary events.

---

## Pathogenetic mechanisms

Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy [38–40]. Most data have been generated in the diabetic rat model on the basis of which two approaches have been chosen to contribute to the clarification of the pathogenesis of diabetic neuropathy. First, it has been attempted to characterize the pathophysiologic, pathobiochemical and structural abnormalities that result in experimental diabetic neuropathy. Secondly, specific therapeutic interventions have been employed to prevent the development of these alterations, to halt their progression or to induce their regression despite concomitant hyperglycemia. At present, the following six pathogenetic mechanisms are being discussed which, in contrast to previous years, are no longer regarded as separate hypotheses, but as a complex interplay with multiple interactions between metabolic and vascular factors (see Chapter 35):

- Increased flux through the polyol pathway that leads to accumulation of sorbitol and fructose, *myo*-inositol depletion and reduction in Na<sup>+</sup>-K<sup>+</sup>-ATPase activity.
- Disturbances in n-6 essential fatty acid and prostaglandin metabolism which result in alterations of nerve membrane structure and microvascular and hemorrhheologic abnormalities.
- Endoneural microvascular deficits with subsequent ischemia and hypoxia, generation of reactive oxygen species (oxidative stress), activation of the redox-sensitive transcription factor nuclear factor κB (NFκB), and increased activity of protein kinase C (PKC).
- Deficits in neurotrophism leading to reduced expression and depletion of neurotrophic factors such as nerve growth factor (NGF), neurotrophin-3, and insulin-like growth factor I (IGF-I) and alterations in axonal transport.
- Accumulation of non-enzymatic advanced glycation end-products on nerve and/or vessel proteins.
- Immunologic processes with autoantibodies to vagal nerve, sympathetic ganglia and adrenal medulla as well as inflammatory changes.

From the clinical point of view it is important to note that, based on these pathogenetic mechanisms, therapeutic approaches could be derived, some of which have been evaluated in randomized clinical trials.

---

## Diagnostic assessment

As a result of the increasing recognition of diabetic neuropathy as a major contributor to morbidity and the recent burst of clinical trials in this field, several consensus conferences have been

convened to overcome the current problems that arise from the lack of agreement about the definition and diagnostic assessment of neuropathy. The Consensus Development Conference on Standardized Measures in Diabetic Neuropathy [41] recommended the following five measures to be employed in the diagnosis of diabetic neuropathy:

- 1 Clinical measures;
- 2 Morphologic and biochemical analyses;
- 3 Electrodiagnostic assessment;
- 4 Quantitative sensory testing; and
- 5 Autonomic nervous system testing.

### Clinical measures

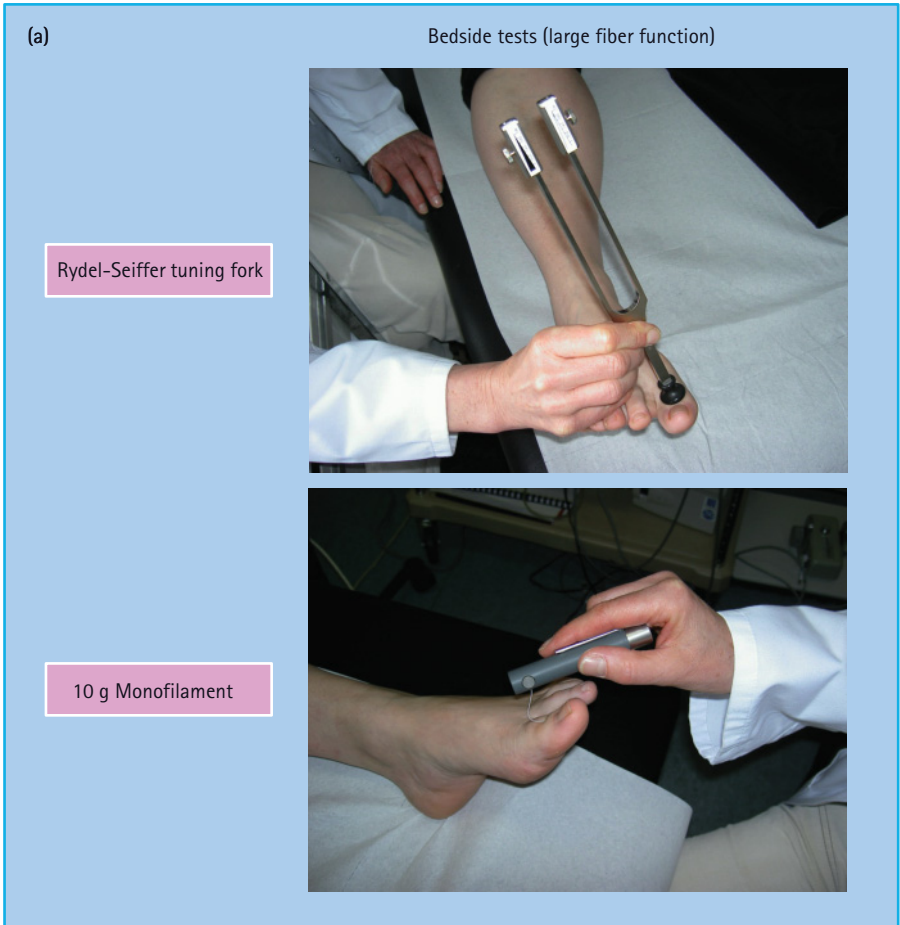

Clinical measures include:

- 1 General medical history and neurologic history;
- 2 Neurologic examination consisting of:
  - Sensory (pain, light touch, vibration, position);
  - Motor (graded as normal = 0, weak = 1–4 [25–100%]);
  - Reflexes (present or absent); and
  - Autonomic (bedside tests including heart rate variation during deep breathing and postural blood pressure response) examination.

The basic neurologic assessment comprises the general medical and neurologic history, inspection of the feet and neurologic examination of sensation using simple semi-quantitative bedside instruments such as the 10g Semmes–Weinstein monofilament (Figure 38.7a), e.g. the Neuropen (touch) [42], NeuroQuick (Figure 38.7b) [43] or Tiptherm (temperature) [44], calibrated Rydel–Seiffer tuning fork (vibration) (Figure 38.7a), pinprick (pain) and tendon reflexes (knee and ankle). In addition, assessment of joint-position and motor power may be indicated. The normal range for the tuning fork on the dorsal distal joint of the great toe is ≥5/8 scale units in persons ≤20–40 years of age, ≥4.5/8 in those aged 41–60 years, ≥4/8 in individuals aged 61–71 years and ≥3/8 scale units in those aged 72–82 years [45]. An indicator test for the detection of sudomotor dysfunction is the Neuropad which assesses plantar sweat production by means of a color change from blue to pink. The patch contains the complex salt anhydrous cobalt-II-chloride. In the presence of water, this salt absorbs water molecules, normally changing its color from blue to pink. If the patch remains completely or partially blue within 10 minutes, the result is considered abnormal (Figure 38.7b) [46].

Clinical assessment should be standardized using validated scores for both the severity of symptoms and the degree of neuropathic deficits such as the Michigan Neuropathy Screening Instrument [47], Neuropathy Symptom Score for neuropathic symptoms and Neuropathy Disability Score for neuropathic deficits (impairments) [48] which appear to be sufficiently reproducible. The neurologic history and examination should be performed once a year. Minimum criteria for the clinical diagnosis of neuropathy according to the Neuropathy Symptom Score and Neuropathy Disability Score are:

- Moderate signs with or without symptoms; or
- Mild signs with moderate symptoms.

**Figure 38.7** (a) Bedside tests for assessment of large fiber function. (b) Bedside tests for assessment of small fiber function.

This means that the exclusive presence of neuropathic symptoms without deficits is not sufficient to diagnose DPN. Therefore, early stages of DPN or a painful small-fiber neuropathy without or with minimal deficits can only be verified using more sophisticated tests such as thermal thresholds or skin biopsy.

The intensity (severity) of neuropathic pain and its course should be assessed using an 11-point numerical rating scale (Likert scale) or a visual analog scale. Various screening tools (with or without limited bedside testing) have been developed to identify neuropathic pain such as the PainDetect, LANSS, NPQ, DN-4, ID-Pain). These questionnaires use verbal descriptors and pain qualities as a basis for distinguishing neuropathic pain from other types of chronic pain such as nociceptive pain [49].

The following findings should alert the physician to consider causes for DPN other than diabetes and referral for a detailed neurologic work-up:

- Pronounced asymmetry of the neurologic deficits;

- Predominant motor deficits, mononeuropathy, cranial nerve involvement;
- Rapid development or progression of the neuropathic impairments;
- Progression of the neuropathy despite optimal glycemic control;
- Symptoms predominantly in the upper limbs;
- Family history of non-diabetic neuropathy; or
- Diagnosis of DPN cannot be ascertained by clinical examination.

The most important differential diagnoses from the general medicine perspective include neuropathies caused by alcohol abuse, uremia, hypothyroidism, vitamin B<sub>12</sub> deficiency, peripheral arterial disease, paraneoplastic syndromes, inflammatory and infectious diseases and neurotoxic drugs.

Clinical measures are used to:

- Establish the presence or absence of neurologic dysfunction in diabetes;

**Figure 38.8** (a) Measurement of motor and sensory nerve conduction velocity.

- Exclude non-neuropathic causes of neurologic dysfunction;
- Eliminate non-diabetic causes of neuropathy;
- Distinguish and classify the different forms of diabetic neuropathy; and
- Monitor progression and provide a clinical correlate of outcome in trials.

The limitations to clinical measures include:

- Lack of sensitivity to change once they become abnormal; and
- Limited reliability and reproducibility.

Positive symptoms may reflect different pathophysiology than deficits (i.e. pain or paresthesia may be related to the degree of compensatory regeneration rather than to the degree of nerve fiber damage). Hence, it has been suggested that symptom or pain scores should not be used to evaluate overall presence or progression of diabetic neuropathy but only to assess pain severity [41].

### Electrodiagnostic measures

Electrophysiologic techniques have the advantage of being the most objective, sensitive, specific and reproducible methods that are available in many neurophysiologic laboratories worldwide (Figure 38.8).

Electrodiagnostic measures have also limitations in as much as they:

- Measure only function in the largest fastest conducting myelinated fibers;
- Have relatively low specificity in detecting diabetic neuropathy;
- Show relatively high intra-individual variability for certain variables (amplitudes);
- Are vulnerable to external factors such as electrode locations or limb temperature; and
- Provide only indirect information about symptoms and deficits [41].

**Figure 38.8** (b) Quantitative sensory testing.

### Quantitative sensory testing

Quantitative sensory testing (QST) is the “determination of the absolute sensory threshold, defined as the minimal energy reliably detected for a particular modality.” The Peripheral Nerve Society has recommended that detection thresholds of touch-pressure, vibration (Figure 38.8b), coolness, warmth (Figure 38.8b), heat pain, cold pain and mechanical pain be used to characterize cutaneous sensation [50].

The procedures that are being used for QST include:

- The method of limits (continuous increase or decrease in intensity to appearance or disappearance threshold);
- Threshold tracking (combination of appearance or disappearance threshold);
- Titration method (graded steps to appearance and disappearance threshold); and
- Two-alternative forced-choice method (pairs of stimulus and null-stimulus phases) [50].

The advantages of QST techniques are that they:

- Are highly sensitive, relatively simple, non-invasive and non-aversive;
- Afford precise control over stimulus intensity and testing algorithms;
- Contribute to differentiation of the relative deficit in small vs large fibers; and
- Are particularly valuable in screening large populations or in longitudinal trials.

The limitations to QST procedures include that they:

- Constitute psychophysical methods vulnerable to the effects of alertness, mood, concentration, ambient noise, etc.;
- Show a relatively high intra-individual variability;
- Have not been adequately standardized; and
- May be time-consuming (forced-choice methods), which may lead to a decline in concentration or boredom in the person tested and thereby result in diagnostic errors [41].

The method of limits has been criticized, because it may be associated with a response delay caused by reaction time which may vary between subjects, but it has been demonstrated that this approach yields a degree of sensitivity and reliability that is similar to the forced-choice techniques. The reproducibility of the QST indices is less favorable than that of nerve conduction but still in an acceptable range.

### Morphologic assessment

#### Sural nerve biopsy

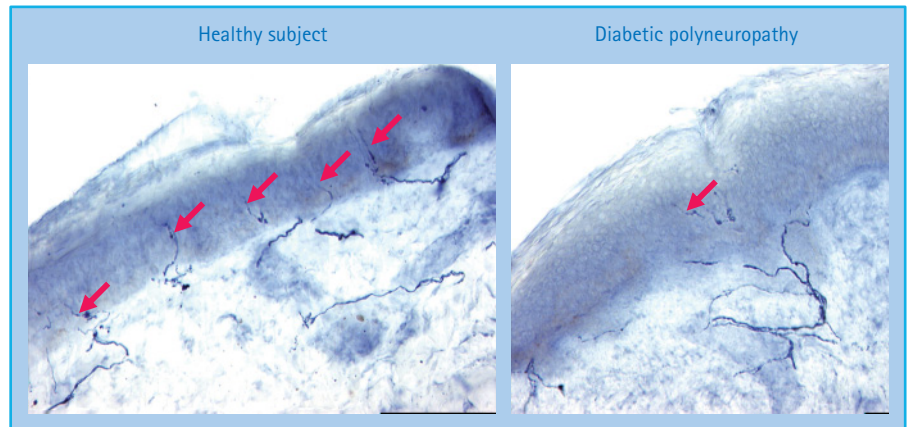

Sural nerve biopsy does not represent a routine method in the diagnosis of diabetic neuropathy. It may be used to establish the diagnosis when the etiology of the neuropathy is in doubt (Figure 38.9). The limitations to this technique are that the information from the biopsy is of no direct benefit to the patient and that the procedure is associated with a certain morbidity and may result in complications [41].

#### Skin biopsy

Skin biopsy has become a widely used tool to investigate small caliber sensory nerves including somatic unmyelinated intra-epidermal nerve fibers (IENF), dermal myelinated nerve fibers and autonomic nerve fibers in peripheral neuropathies and other conditions (Figure 38.10). Different techniques for tissue processing and nerve fiber evaluation have been used. A task force of the European Federation of Neurological Societies recently developed guidelines on the use of skin biopsy in the diagnosis of peripheral neuropathies [51]. For diagnostic purposes in peripheral neuropathies, the guideline recommends performing a 3-mm punch skin biopsy at the distal leg and quantifying the linear density of IENF in at least three 50- $\mu$ m thick sections per biopsy, fixed in 2% periodate-lysine-paraformaldehyde (PLP) or Zamboni solution, by bright-field immunohistochemistry or immunofluorescence with anti-protein gene product 9.5 anti-

**Figure 38.9** Normal sural nerve pathology (left panel) compared to mild (mid panel) and severe (right panel) axonal loss in mild and severe diabetic polyneuropathy (DPN). **Figure 38.10** Loss of intra-epidermal nerve fibers (IENF) in skin biopsy from the lateral lower leg in a patient with diabetic polyneuropathy compared to a healthy subject (red arrows indicate IENF). Bright-field immunohistochemistry with antipeptide gene product 9.5 antibody (PGP 9.5).

bodies (level A recommendation). Quantification of IENF density closely correlated with warm and heat pain threshold, and appeared more sensitive than sensory nerve conduction study and sural nerve biopsy in diagnosing small-fiber sensory neuropathy. Diagnostic efficiency and predictive values of this technique were very high (level A recommendation). Longitudinal studies of IENF density and regeneration rate are warranted to correlate neuropathologic changes with progression of neuropathy and to assess the potential usefulness of skin biopsy as an outcome measure in peripheral neuropathy trials (level B recommendation). In conclusion, punch skin biopsy is a safe and reliable technique (level A recommendation).

## Treatment

### Role of intensive diabetes therapy in treatment and prevention of diabetic neuropathy

Several long-term prospective studies that assessed the effects of intensive diabetes therapy on the prevention and progression of chronic diabetic complications have been published. The large randomized trials such as the Diabetes Control and Complications Trial (DCCT) and UK Prospective Diabetes Study (UKPDS) were not designed to evaluate the effects of intensive diabetes therapy on DPN, but rather to study the influence of such treatment on the development and progression of the chronic diabetic complications [52,53]. Thus, only a minority of the patients enrolled in these studies had symptomatic DPN at entry.

Studies in patients with T1DM show that intensive diabetes therapy retards but does not completely prevent the development of DPN. In the Epidemiology of Diabetes Interventions and Complications (EDIC) study, the benefits of 6.5 years of intensive therapy on neuropathy status extended for at least 8 years beyond the end of the DCCT despite equal HbA<sub>1c</sub> levels (hyperglycemic memory), similar to the findings described for diabetic retinopathy and nephropathy [54]. In patients with T1DM with most advanced stages of peripheral neuropathy, the progression of nerve conduction deficits is halted after 3–4 years of normoglycemia following pancreatic transplantation, but no effect is seen in autonomic neuropathy. Although observational studies sug-

gested a glycemic threshold for the development and progression of the long-term complications in T1DM, the DCCT data do not support such an assumption. Thus, attempts to achieve optimal glycemic control should not aim at a certain HbA<sub>1c</sub> threshold within the diabetic range but follow the goal of achieving normal glycemia as early as possible in as many patients with T1DM as is safely possible. In general, intensive diabetes therapy is associated with a moderately increased risk of weight gain and hypoglycemia.

In contrast, in patients with T2DM, who represent the vast majority of people with diabetes, the results were largely negative. The UKPDS showed a lower rate of impaired VPT (VPT > 25V) after 15 years for intensive vs conventional therapy (31 vs 52%), but the only additional time point at which VPT reached a significant difference between intensive and conventional therapy was the 9-year follow-up, whereas the rates after 3, 6 and 12 years did not differ between the groups. Likewise, the rates of absent knee and ankle reflexes as well as the heart rate responses to deep breathing did not differ between the groups [53]. In the ADVANCE study, which included 11 140 patients with T2DM randomly assigned to either standard glucose control or intensive glucose control, the relative risk reduction (95% confidence interval [CI]) for new or worsening neuropathy for intensive vs. standard glucose control after a median of 5 years of follow-up was 4% (–10% to 2%), without a significant difference between the groups [55]. Likewise, in the Veterans Affairs Diabetes Trial (VADT) [56] study including 1791 military veterans (mean age 60.4 years) who had a suboptimal response to therapy for T2DM, after a median follow-up of 5.6 years, no differences between the two groups on intensive or standard glucose control were observed for DPN or microvascular complications.

In the Steno 2 study, intensified multifactorial risk intervention including intensive diabetes treatment, angiotensin-converting enzyme (ACE) inhibitors, antioxidants, statins, aspirin and smoking cessation in patients with microalbuminuria did not have an effect on the progression of DPN after 3.8 years but on other microvascular complications such as diabetic nephropathy and retinopathy were beneficially affected. A positive effect of this approach was seen on autonomic neuropathy (increase in heart rate variability) only. After 7.8 (range 6.9–8.8) years, the same

results were reported with a relative risk of 1.09 (95% CI 0.54–2.22) for the development or progression of DPN ( $P = 0.66$ ) and 0.37 (95% CI 0.18–0.79) for autonomic neuropathy ( $P = 0.002$ ) and again at 13.3 years, after the patients were subsequently followed observationally for a mean of 5.5 years. Autonomic neuropathy progressed in 39 patients in the intensive therapy group and in 52 patients in the conventional therapy group (relative risk 0.53; 95% CI 0.34–0.81;  $P = 0.004$ ), and peripheral neuropathy progressed in 44 and 46 patients in the two groups, respectively (relative risk 0.97; 95% CI 0.62–1.51;  $P = 0.89$ ) [57]. Thus, there is no evidence that intensive diabetes therapy or a target-driven intensified intervention aimed at multiple risk factors favorably influence the development or progression of DPN in patients with T2DM.

### Treatment based on pathogenetic concepts

Recent experimental studies suggest a multifactorial pathogenesis of diabetic neuropathy. From the clinical point of view it is important to note that, based on the various pathogenetic mechanisms, several therapeutic approaches could be developed, some of which have been evaluated in randomized clinical trials including the aldose reductase inhibitors (alrestatin, sorbinil, ponalrestat, tolrestat, epalrestat, zopolrestat, zenarestat, fidarestat, ranirestat), the antioxidant  $\alpha$ -lipoic acid (thioctic acid), essential fatty acid ( $\gamma$ -linolenic acid), ACE inhibitors (trandolapril), prostacyclin ( $\text{PGI}_2$ ) analogs (iloprost, beraprost), prostaglandin derivatives ( $\text{PGE}_1$ ,  $\alpha\text{CD}$ ), NGF,  $\text{PKC}\beta$  inhibitor (ruboxistaurin), C-peptide, vascular endothelial growth factor and benfotiamine (vitamin  $\text{B}_1$  derivative) [58]. These drugs have been designed to influence the underlying neuropathic process in a favorable manner, rather than for symptomatic pain treatment. Because, in the foreseeable future, normoglycemia will not be achievable in the majority of people with diabetes, the advantage of the aforementioned treatment approaches is that they may exert their effects despite prevailing hyperglycemia. Experimental studies of low-dose combined drug treatment suggest enhanced drug efficacy mediated by facilitatory interactions between drugs. Although considerable improvement in the quality of controlled trials has recently been achieved, no major breakthrough in slowing the progression of diabetic neuropathy in the long run has been achieved with drugs used on the basis of present pathogenetic concepts. Some of the newer drugs have shown promising results in phase II trials which require confirmation from large phase III trials. It is conceivable that drugs interfering with the pathogenesis of diabetic neuropathy may be most effective in terms of prevention, rather than intervention.

Only  $\alpha$ -lipoic acid and benfotiamine are licensed for clinical use to treat symptomatic DPN in several countries, while epalrestat is marketed in Japan and India. The available evidence to support the use of benfotiamine in DPN is weak [59,60]. In contrast, according to a meta-analysis comprising 1258 patients, infusions of  $\alpha$ -lipoic acid (600 mg/day IV) ameliorated neuropathic symptoms and deficits after 3 weeks [61]. Moreover, the SYDNEY 2 trial suggests that treatment for 5 weeks using 600 mg

$\alpha$ -lipoic acid orally four times daily reduces the chief symptoms of DPN including pain, paresthesias and numbness to a clinically meaningful degree [62]. In a multicenter randomized double-masked parallel-group clinical trial (NATHAN 1), 460 patients with stage 1 or stage 2a DPN were randomly assigned to oral treatment with 600 mg  $\alpha$ -lipoic acid four times daily ( $n = 233$ ) or placebo ( $n = 227$ ) for 4 years. After 4 years, some neuropathic deficits and symptoms, but not nerve conduction velocity, were improved, and the drug was well tolerated throughout the trial [63]. Clinical and post-marketing surveillance studies have revealed a highly favorable safety profile [64].

### Pharmacologic treatment of painful neuropathy

Painful symptoms in DPN constitute a considerable management problem. The efficacy of a single therapeutic agent is not the rule, and simple analgesics are usually inadequate to control the pain. There is agreement that patients should be offered the available therapies in a stepwise fashion [65–68]. Effective pain treatment considers a favorable balance between pain relief and side effects without implying a maximum effect. The following general considerations in the pharmacotherapy of neuropathic pain require attention:

- The appropriate and effective drug has to be tried and identified in each patient by carefully titrating the dosage based on efficacy and side effects.
- Lack of efficacy should be judged only after 2–4 weeks of treatment using an adequate dose.
- Because the evidence from clinical trials suggests only a maximum response of  $\approx 50\%$  for any monotherapy, analgesic combinations may be useful.
- Potential drug interactions have to be considered given the frequent use of polypharmacy in people with diabetes.

A rational treatment algorithm including the various causal and symptomatic options is summarized in Table 38.2. Certain antidepressants (tricyclic drugs, duloxetine) and anticonvulsants (pregabalin, gabapentin) are considered as first-line treatments, while opioids are recommended as second-line options [66]. The advantages and disadvantages of the various drugs and drug classes used for treatment of painful diabetic neuropathy under consideration of the various co-morbidities and complications associated with diabetes are summarized in Table 38.3. Prior to any decision regarding appropriate treatment, the diagnosis of the underlying neuropathic manifestation allowing the estimation of its natural history should be established. In contrast to the agents that have been derived from the pathogenetic mechanisms of diabetic neuropathy, those used for symptomatic therapy were designed to modulate the pain, without favorably influencing the underlying neuropathy.

The relative benefit of an active treatment over placebo treatment in clinical trials is usually expressed as the relative risk, the relative risk reduction or the odds ratio; however, to estimate the extent of a therapeutic effect (i.e. pain relief) that can be translated into clinical practice, it is useful to apply a simple measure that serves the physician to select the appropriate treatment for

**Table 38.2** Treatment options for painful diabetic neuropathy.

Approach	Compound/measure	Dose per day	Remarks	NNT
Optimal diabetes control	Lifestyle modification, OAD, insulin	Individual adaptation	Aim: HbA <sub>1c</sub> ≤6.5% (48 mmol/mol)	–
Pathogenetically oriented treatment	α-Lipoic acid (thioctic acid) <sup>‡</sup>	600 mg IV infusion 1200–1800 mg orally	Duration: 3 weeks Favorable safety profile	6.3* 2.8–4.2*
Symptomatic treatment	First line TCA			
	Amitriptyline	(10–)25–150 mg	NNMH: 15	2.1
	Desipramine	(10–)25–150 mg	NNMH: 24	2.2/3.2
	Imipramine	(10–)25–150 mg	CRR	1.3/2.4/3.0
	Clomipramine	(10–)25–150 mg	NNMH: 8.7	2.1
	Nortriptyline	(10–)25–150 mg	plus fluphenazine	1.2 <sup>†</sup>
	SNRI			
	Duloxetine <sup>§</sup>	60–120 mg	NNT with 120 mg, 60 mg	5.3, 4.9
	Anticonvulsants-calcium channel modulators (α2-δ ligands)			
	Gabapentin	900–3600 mg	High dose	3.8/4.0
Pregabalin <sup>§</sup>	300–600 mg	NNT with 600 mg, 300 mg	5.9, 4.2	
Second line weak opioids				
Tramadol	50–400 mg	NNMH: 7.8	3.1/4.3	
Local treatment				
Capsaicin (0.025%) cream	q.i.d. topically	Max. duration: 6–8 weeks	5.7	
Pain resistant to standard pharmacotherapy	Strong opioids			
	Oxycodone		Add-on treatment	2.6
	ESCS		Invasive, specialist required	

CRR, concentration–response relationship; ESCS, electrical spinal cord stimulation; NNMH, number needed for major harm; NNT, number needed to treat; ns: not significant; OAD, oral antidiabetic drugs; TCA, tricyclic antidepressants; TENS, transcutaneous electrical nerve stimulation; SNRI, selective serotonin norepinephrine reuptake inhibitors.

\* ≥50% symptom relief after 3 and 5 weeks.

<sup>‡</sup> Available only in some countries.

<sup>†</sup> Combined with fluphenazine.

<sup>§</sup> Licensed in USA and EU.

<sup>†</sup> Dependent on individual agent.

the individual patient. Such a practical measure is the number needed to treat (NNT; i.e. the number of patients that need to be treated with a particular therapy to observe a clinically relevant effect or adverse event in one patient). This measure is expressed as the reciprocal of the absolute risk reduction (i.e. the difference between the proportion of events in the control group [ $P_c$ ] and the proportion of events in the intervention group [ $P_i$ ]:  $NNT = 1/[P_c - P_i]$ ). The 95% CI of NNT can be obtained from the reciprocal value of the 95% CI for the absolute risk reduction. The NNT and number needed to harm (NNH) for the individual agents used in the treatment of painful diabetic neuropathy are given in Table 38.2. Some authors have cautioned that summary NNT estimates may have limited clinical relevance, because of problems of heterogeneity. The most that can be extracted from systematic reviews published to date is the identity of drugs that have demonstrated efficacy for specific types of neuropathic pain, and the strength of such evidence [69].

### Tricyclic antidepressants

Psychotropic agents, among which tricyclic antidepressants (TCAs) have been evaluated most extensively, constitute an important component in the treatment of chronic pain syndromes for more than 30 years. Putative mechanisms of pain relief by antidepressants include the inhibition of norepinephrine and/or serotonin reuptake at synapses of central descending pain control systems and the antagonism of the *N*-methyl-D-aspartate receptor that mediates hyperalgesia and allodynia. Imipramine, amitriptyline and clomipramine induce a balanced reuptake inhibition of both norepinephrine and serotonin, while desipramine is a relatively selective norepinephrine inhibitor. The NNT (CI) for a  $\geq 50\%$  pain relief by TCAs is 2.4 (2.0–3.0) [65]. The NNH is 2.8 for minor adverse events and 19 for major adverse events (Table 38.2). Thus, among 100 patients with diabetes and neuropathic pain who are treated with antidepressants, 30 will experience pain relief by  $>50\%$ , 30 will have mild adverse events and five will discontinue treatment because of severe adverse events. The mean NNT for drugs with balanced reuptake inhibition is 2.2, while it is 3.6 for the noradrenergic agents [65].

The most frequent adverse events of TCAs include tiredness and dry mouth. The starting dose should be 25 mg (10 mg in frail patients) and taken as a single night time dose 1 hour before sleep. It should be increased by 25 mg at weekly intervals until pain relief is achieved or adverse events occur. The maximum dose is usually 150 mg/day.

The notion that the character of the neuropathic pain is predictive of response, so that burning pain should be treated with antidepressants and shooting pain with anticonvulsants, is obviously unfounded because both pain qualities respond to TCAs. Most evidence of efficacy of antidepressants comes from studies that have been conducted over only several weeks, but many patients continue to achieve pain relief for months to years, although this is not true for everybody. TCAs should be used with caution in patients with orthostatic hypotension and are contraindicated in patients with unstable angina, recent (<6 months)

MI, heart failure, history of ventricular arrhythmias, significant conduction system disease and long QT syndrome. Several authors consider TCAs to be the drug treatment of choice for neuropathic pain [65,70], but their use is limited by relative high rates of adverse events and several contraindications. Thus, there is a need for agents that exert efficacy equal to or better than that achieved with TCAs but with a more favorable side effect profile.

### Selective serotonin reuptake inhibitors (SSRI)

Because of the relative high rates of adverse effects and several contraindications of TCA, it has been reasoned that patients who do not tolerate them because of adverse events could alternatively be treated with selective serotonin reuptake inhibitors (SSRI). SSRIs specifically inhibit presynaptic reuptake of serotonin, but not norepinephrine, and unlike the tricyclics they lack the post-synaptic receptor blocking effects and quinidine-like membrane stabilization. Only weak or no effects on neuropathic pain were observed after treatment with fluoxetine, paroxetine, citalopram and escitalopram [65,71]. Because of these limited efficacy data, SSRIs have not been licensed for the treatment of neuropathic pain.

### Serotonin noradrenaline reuptake inhibitors (SNRI)

Because SSRI have been found to be less effective than TCAs, recent interest has focused on antidepressants with dual selective inhibition of serotonin and noradrenaline such as duloxetine and venlafaxine. The efficacy and safety of duloxetine was evaluated in three controlled studies using a dose of 60 and 120 mg/day over 12 weeks [72]. In all three studies, the average 24-hour pain intensity was significantly reduced with both doses compared with placebo treatment, the difference between active and placebo being achieving statistical significance after 1 week. The response rates defined as  $\geq 50\%$  pain reduction were 48.2% (120 mg/day), 47.2% (60 mg/day) and 27.9% (placebo), giving a NNT of 4.9 (95% CI 3.6–7.6) for 120 mg/day and 5.3 (3.8–8.3) for 60 mg/day. Pain severity, but not variables related to diabetes or neuropathy, predicts the effects of duloxetine in diabetic peripheral neuropathic pain. Patients with higher pain intensity tend to respond better than those with lower pain levels [73]. The most frequent side effects of duloxetine (60/120 mg/day) include nausea (16.7/27.4%), somnolence (20.2/28.3%), dizziness (9.6/23%), constipation 14.9/10.6%), dry mouth (7.1/15%) and reduced appetite (2.6/12.4%). These adverse events are usually mild to moderate and transient. To minimize them, the starting dose should be 30 mg/day for 4–5 days. In contrast to TCAs and some anticonvulsants, duloxetine does not cause weight gain, but a small increase in fasting blood glucose may occur [74].

In a 6-week trial comprising 244 patients, the analgesic response rates were 56%, 39% and 34% in patients given 150–225 mg venlafaxine, 75 mg venlafaxine and placebo, respectively. Because patients with depression were excluded, the effect of venlafaxin (150–225 mg) was attributed to an analgesic, rather than antidepressant, effect. The most common adverse events were tiredness

and nausea [75]. Duloxetine, but not venlafaxine, has been licensed for the treatment of painful diabetic neuropathy.

### **Anticonvulsants**

#### ***Calcium channel modulators ( $\alpha$ 2- $\delta$ ligands)***

Gabapentin is an anticonvulsant structurally related to  $\gamma$ -aminobutyric acid (GABA), a neurotransmitter that has a role in pain transmission and modulation. The exact mechanisms of action of this drug in neuropathic pain are not fully elucidated. Among others, they involve an interaction with the system L-amino acid transporter and high affinity binding to the  $\alpha$ 2- $\delta$  subunit of voltage-activated calcium channels. In an 8-week multicenter dose-escalation trial including 165 patients with painful diabetic neuropathy, 60% of the patients on gabapentin (3600 mg/day achieved in 67%) had at least moderate pain relief compared to 33% on placebo. Dizziness and somnolence were the most frequent adverse events in about 23% of the patients each [76]. Pregabalin is a more specific  $\alpha$ 2- $\delta$  ligand with a sixfold higher binding affinity than gabapentin. The efficacy and safety of pregabalin was reported in a pooled analysis of 6 studies over 5–11 weeks in 1346 patients with painful diabetic neuropathy. The response rates defined as  $\geq 50\%$  pain reduction were 46% (600 mg/day), 39% (300 mg/day), 27% (150 mg/day) and 22% (placebo), giving a NNT of 4.2, 5.9 and 20.0 [33]. The most frequent side effects for 150–600 mg/day are dizziness (22.0%), somnolence (12.1%), peripheral edema (10.0%), headache (7.2%) and weight gain (5.4%) [77]. The evidence supporting a favorable effect in painful diabetic neuropathy is more solid and dose titration is considerably easier for pregabalin than gabapentin.

#### ***Sodium channel blockers***

Although carbamazepine has been widely used for treating neuropathic pain, it cannot be recommended in painful diabetic neuropathy as there are very limited data. Its successor drug, oxcarbazepine [78,79] as well as other sodium channel blockers such as valproate, mexiletine, topiramate [80] and lamotrigine [81] showed only marginal efficacy and have not been licensed for the treatment of painful diabetic neuropathy.

A single IV infusion of lidocaine (5 mg/kg body weight over 30 minutes during continuous ECG monitoring) resulted in a significant pain relief after 1 and 8 days in a controlled study including 15 patients with chronic painful diabetic neuropathy [82]. Potential adverse systemic effects associated with IV lidocaine have led to the development of a newer and potentially safer agent, the topical lidocaine patch 5% (Lidoderm), a targeted peripheral analgesic. In patients with post-herpetic neuralgia, the lidocaine patch 5% has demonstrated relief of pain and tactile allodynia with a minimal risk of systemic adverse effects or drug–drug interactions [83]. Studies in patients with DPN are underway.

#### ***Lacosamide***

Lacosamide is a novel anticonvulsant that selectively enhances the slow inactivation of voltage dependent sodium channels but,

in contrast to the sodium channel blockers, does not influence the fast sodium channel inactivation. Its second putative mechanism is an interaction with a neuronal cytosolic protein, the collapsin response mediator protein 2 which has an important role in nerve sprouting and excitotoxicity. Lacosamide has been evaluated in several studies in painful diabetic neuropathy [84], but the drug has not been approved by the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) for painful diabetic neuropathy; further clinical trials may follow.

#### ***Topical capsaicin***

Capsaicin (trans-8-methyl-N-vanillyl-6-nonenamide) is an alkaloid and the most pungent ingredient in the red pepper. It depletes tissues of substance P and reduces neurogenic plasma extravasation, the flare response and chemically induced pain. Substance P is present in afferent neurones innervating skin, mainly in polymodal nociceptors, and is considered the primary neurotransmitter of painful stimuli from the periphery to the central nervous system. Several studies have demonstrated significant pain reduction and improvement in quality of life in patients with painful diabetic neuropathy after 8 weeks of treatment with capsaicin cream (0.075%) [85]. It has been criticized that a double-blind design is not feasible for topical capsaicin because of the transient local hyperalgesia (usually mild burning sensation  $>50\%$  of the cases), it may produce as a typical adverse event. Treatment should be restricted to a maximum of 8 weeks, as during this period no adverse effects on sensory function (brought about by the mechanism of action) were noted in patients with diabetes.

#### ***Opioids***

Tramadol acts directly via opioid receptors and indirectly via monoaminergic receptor systems. Because the development of tolerance and dependence during long-term tramadol treatment is uncommon and its abuse liability appears to be low, it is an alternative to strong opioids in neuropathic pain. In painful diabetic neuropathy, tramadol (up to 400 mg/day orally, mean dose: 210 mg/day orally) has been studied in a 6-week multicenter trial including 131 patients [86]. Pain relief was 44% on tramadol vs 12% on placebo. The most frequent adverse events were nausea and constipation. The NNH of 7.8 for drop-outs because of adverse events was relatively low, indicating significant toxicity. In a 4-week study including patients with painful neuropathy of different origins, one-third of which being diabetes, tramadol significantly relieved pain (NNT 4.3 [2.4–20]) and mechanical allodynia. One conceivable mechanism for the favorable effect of tramadol could be a hyperpolarization of post-synaptic neurons via post-synaptic opioid receptors. Alternatively, the reduction in central hyperexcitability by tramadol could be from a monoaminergic or a combined opioid and monoaminergic effect.

Most severe pain requires administration of strong opioids such as oxycodone. Although there are few data available on combination treatment, combinations of different substance

classes have to be used in patients with pain resistant to monotherapy. Several add-on trials have demonstrated significant pain relief and improvement in quality of life following treatment with controlled-release oxycodone, a pure  $\mu$ -agonist in patients with painful DPN whose pain was not adequately controlled on standard treatment with antidepressants and anticonvulsants [87–89]. As expected, adverse events were frequent and typical of opioid-related side effects. A cross-over study examined the maximum tolerable dose of a combination treatment of gabapentin and morphine compared to monotherapy of each drug. The maximum tolerable dose was significantly lower and efficacy was better during combination therapy than with monotherapy, suggesting an additive interaction between the two drugs [90]. The results of these studies suggest that opioids should be included among the therapeutic options for painful DPN, provided that careful selection of patients unresponsive to standard treatments, regular monitoring, appropriate dose titration and management of possible opioid-specific problems (analgesic misuse or addiction, tolerance, opioid-induced hyperalgesia) are ensured. Recent recommendations have emphasized the need for clinical skills in risk assessment and management as a prerequisite to safe and effective opioid prescribing [66]. Treatment of painful DPN with opioid agonists should generally be reserved for patients who have failed to respond to or cannot tolerate the first-line medications.

Although several novel analgesic drugs have recently been introduced into clinical practice, the pharmacologic treatment of chronic painful diabetic neuropathy remains a challenge for the physician. Individual tolerability remains a major aspect in any treatment decision. Little information is available from controlled trials on long-term analgesic efficacy, head-to-head comparisons of individual analgesics, and only a few studies have used drug combinations. Combination drug use or the addition of a new drug to a therapeutic regimen may lead to increased efficacy. In future, drug combinations may include those drugs aimed at symptomatic pain relief and quality of life with those aimed at improvement or slowing of the progression of the underlying neuropathic process.

### Non-pharmacologic treatment of painful neuropathy

Because there is no entirely satisfactory pharmacotherapy of painful diabetic neuropathy, non-pharmacologic treatment options should always be considered. As for the pharmacologic treatment, considerable efforts must also be made to develop effective non-pharmacologic approaches. A recent systematic review assessed the evidence from rigorous clinical trials and meta-analyses of complementary and alternative therapies for treating neuropathic and neuralgic pain. Data on the following complementary and alternative medicine treatments were identified: acupuncture, electrostimulation, herbal medicine, magnets, dietary supplements, imagery and spiritual healing. The conclusion was that the evidence is not fully convincing for most complementary and alternative medicine modalities in relieving neuropathic or neuralgic pain. The evidence can

be classified as encouraging and warrants further study for cannabis extract, magnets, carnitine and electrostimulation [91].

### Psychologic support

A psychologic component to pain should not be underestimated. Hence, an explanation to the patient that even severe pain may remit, particularly in poorly controlled patients with acute painful neuropathy or in those painful symptoms precipitated by intensive insulin treatment. Thus, the emphatic approach addressing the concerns and anxieties of patients with neuropathic pain is essential for their successful management [92].

### Physical measures

The temperature of the painful neuropathic foot may be increased by arteriovenous shunting. Cold water immersion may reduce shunt flow and relieve pain. Allodynia may be relieved by wearing silk pyjamas or the use of a bed cradle. Patients who describe painful symptoms on walking likened to walking on pebbles may benefit from the use of comfortable footwear [92].

### Acupuncture

In a 10-week uncontrolled study in patients with diabetes on standard pain therapy, 77% showed significant pain relief after up to six courses of traditional Chinese acupuncture without any side effects. During a follow-up period of 18–52 weeks, 67% were able to stop or significantly reduce their medications and only 24% required further acupuncture treatment [93]. Controlled studies using placebo needles should be performed to confirm these findings.

### Electrical stimulation

#### *Transcutaneous electrical nerve stimulation*

Transcutaneous electrical nerve stimulation (TENS) influences neuronal afferent transmission and conduction velocity, increases the nociceptive flexion reflex threshold and changes the somatosensory evoked potentials. In a 4-week study of TENS applied to the lower limbs, each for 30 minutes daily, pain relief was noted in 83% of patients compared to 38% of a sham-treated group. In patients who only marginally responded to amitriptyline, pain reduction was significantly greater following TENS given for 12 weeks than with sham treatment. Thus, TENS may be used as an adjunctive modality combined with pharmacotherapy to augment pain relief [94].

#### *Mid-frequency external muscle stimulation*

One randomized controlled study showed a better effect of mid-frequency external muscle stimulation than TENS on neuropathic symptoms after 1 week [95], but longer-term controlled studies are not available.

#### *Frequency-modulated electromagnetic nerve stimulation*

Frequency-modulated electromagnetic nerve stimulation applied during 10 sessions over 3 weeks resulted in a significant pain

reduction compared to placebo stimulation [96]. A larger-scale multicenter study is currently ongoing.

### **Electrical spinal cord stimulation**

It is generally agreed that electrical spinal cord stimulation (ESCS) is effective in neurogenic forms of pain. Experiments indicate that electrical stimulation is followed by a decrease in the excitatory amino acids glutamate and aspartate in the dorsal horn. This effect is mediated by a GABAergic mechanism. In diabetic painful neuropathy that was unresponsive to drug treatment, ESCS with electrodes implanted between T9 and T11 resulted in a pain relief >50% in 8 out of 10 patients. In addition, exercise tolerance was significantly improved. Complications of ESCS included superficial wound infection in two patients, lead migration requiring reinsertion in two patients, and “late failure” after 4 months in a patient who had initial pain relief [97]. This invasive treatment option should be reserved for patients who do not respond to drug treatment.

### **Monochromatic infrared energy**

Monochromatic infrared energy has been shown to reduce neuropathic symptoms and signs in patients with diabetes in uncontrolled studies. By contrast, two controlled studies showed that monochromatic infrared energy was no more effective than placebo in increasing sensation in patients with DPN [98,99], emphasizing the need for controlled studies in this area to allow an evidence-based treatment decision.

### **Surgical decompression**

Surgical decompression at the site of anatomic narrowing has been promoted as an alternative treatment for patients with symptomatic DPN. A systematic review of the literature revealed only Class IV studies concerning the utility of this therapeutic approach. Given the current evidence available, this treatment alternative should be considered unproven (Level U). Prospective randomized controlled trials with standard definitions and outcome measures are necessary to determine the value of this therapeutic intervention [100,101].

# 8    Macrovascular Complications in Diabetes

# 39

## The Pathogenesis of Macrovascular Complications Including Atherosclerosis in Diabetes

**Riccardo Candido<sup>1,2</sup>, Mark E. Cooper<sup>1</sup> & Karin A.M. Jandeleit-Dahm<sup>1</sup>**

<sup>1</sup>Baker IDI Heart and Diabetes Institute, Danielle Alberti JDRF Center for Diabetes Complications, Melbourne, Australia

<sup>2</sup>Diabetic Center, A.S.S. 1 Triestina, Trieste, Italy

### Keypoints

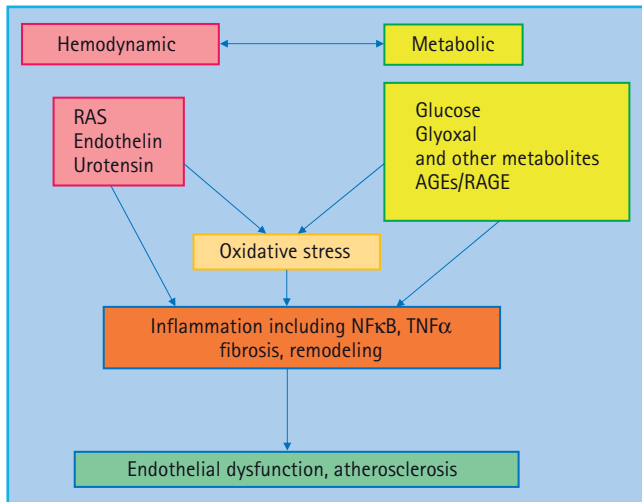

- Diabetes accounts for 75–90% of excess coronary artery disease risk seen in people with diabetes and enhances the effects of other cardiovascular risk factors.
- A range of hemodynamic and metabolic factors contribute to macrovascular disease in diabetes.
- The link between glucose control and cardiovascular disease (CVD) is not as strong as that seen with microvascular complications of diabetes.
- There is clear *in vitro* and *in vivo* evidence that glucose exerts direct and indirect toxic effects on the vasculature.
- Glycemic memory describes the deferred long-term injurious effects of prior glycemic status; early glycemic control appears to be important to reduce vascular complications in subsequent decades.
- Specific insulin resistance pathways appear to contribute to atherogenesis in diabetes.
- The accumulation of advanced glycation end-products (AGEs) exerts pro-inflammatory and pro-fibrotic effects on the vasculature via receptor independent and receptor dependent effects. The AGE receptor (RAGE) is pivotally involved in the pathogenesis of diabetes accelerated atherosclerosis.
- The components of the classic renin angiotensin system (RAS) and in particular more recently discovered components such as angiotensin converting enzyme 2 appear to contribute to macrovascular disease in diabetes. Inhibitors of the RAS have consistently demonstrated reduced endothelial dysfunction and atherosclerosis in animal models via suppression of inflammation, fibrosis and oxidative stress. There is also strong clinical evidence for vasculoprotection by RAS blockade.
- Other vasoactive components such as endothelin and urotensin II are also likely to contribute to macrovascular complications in diabetes and interact with the RAS. Furthermore, the role of novel tumor necrosis factor (TNF) related ligands, such as TNF-related apoptosis inducing ligand and osteoprotegerin, and the complement system in atherosclerosis are currently under evaluation.
- Treatments that reduce oxidative stress and inhibit inflammation such as peroxisome proliferator activated receptor agonists have been shown to be anti-atherosclerotic in experimental studies with some evidence, albeit not uniform, also having been obtained in clinical studies.
- A multifactorial approach treating conventional cardiovascular risk factors as well as diabetes specific risk factors is currently viewed as the optimal strategy to reduce the burden of CVD in diabetes.

### Epidemiology of diabetic macrovascular complications

Macrovascular complications develop in patients with type 1 (T1DM) [1–3] and type 2 diabetes mellitus (T2DM) [4–6]. This is of a particular concern as the increasing prevalence of diabetes now also affects adolescents and younger adults, thus promoting the earlier development of long-term cardiovascular complications. Even after adjusting for concomitant risk factors such as

hypertension and hyperlipidemia there remains an excess risk for cardiovascular disease (CVD) in people with diabetes [7,8]. Indeed, diabetes itself accounts for 75–90% of the excess coronary artery disease (CAD) risk and enhances the effects of other cardiovascular risk factors. Death from stroke and myocardial infarction (MI) are the leading causes of mortality in T1DM and T2DM [2,9].

A range of hemodynamic and metabolic factors have been considered responsible for the development and progression of macrovascular disease in diabetes (Figure 39.1) [10]. In terms of hemodynamic factors, in particular the hormonal cascade known as the renin angiotensin system (RAS) has been shown to have a pivotal role in diabetes-associated atherosclerosis; however, other vasoactive hormone systems such as the endothelin (ET)

**Figure 39.1** Hemodynamic and metabolic mediators contribute to the pathogenesis of diabetic vascular complications. Hemodynamic factors include the renin angiotensin system (RAS), and other vasoactive factors. Metabolic factors include glucose and glucose metabolites such as the formation of advanced glycation end-products (AGEs). Both pathways interact with each other and lead to oxidative stress and inflammation, thus promoting endothelial dysfunction and atherosclerosis. NFκB, nuclear transcription factor κB; TNF-α, tumor necrosis factor α.

[11] and urotensin systems [12,13] have also been implicated in diabetic macrovascular disease. More recently, a role for novel factors such as tumor necrosis factor (TNF) related apoptosis inducing ligand (TRAIL) [14] and the complement system has also been suggested [15].

### Pathogenesis of diabetic macrovascular disease

Atherosclerosis is initiated by the adhesion of monocytes to the vascular wall, particularly to endothelial cells, followed by transmigration of monocytes into the subendothelial space [16]. Monocytes differentiate into macrophages which, via uptake of lipids, transform into foam cells and accumulate in the vascular wall. The early atherosclerotic process results in the formation of fatty streak lesions which over time develop into more advanced lesions, characterized by infiltration with vascular smooth muscle cells (VSMC), formation of a necrotic core and further lipid accumulation [16]. In humans, these lesions can demonstrate features of instability and plaque rupture including intraplaque hemorrhages as well as heightened thrombogenicity.

### Role of hyperglycemia

A pivotal role for glycaemic control and duration of diabetes exposure has been well established for microvascular complications in the UK Prospective Diabetes Study (UKPDS) study [4,17], although the data are not as convincing for macrovascular disease. The importance of glycaemic control for macrovascular injury has

only recently been extensively investigated in a series of studies that were reported over the last 12 months. It has been suggested that HbA<sub>1c</sub> acts as an independent and continuous risk factor for macrovascular disease [18–21]; however, this link is not as strong as has been identified with respect to microvascular complications. For an increase in HbA<sub>1c</sub> from 5.5% (37 mmol/mol) to 9.5% (80 mmol/mol) there is a 10-fold increase in microvascular disease endpoints, whereas the risk for macrovascular disease endpoints increases only twofold.

### Clinical trials and hyperglycemia

Recently, clinical trials such as the Action to Control Cardiovascular Risk in Diabetes trial (ACCORD) [22], Action in Diabetes and Vascular disease: PreterAx and DiamicroN-MR Controlled Evaluation (ADVANCE) trial [23] and the Veterans Affairs Diabetes Trial (VADT) [24], which explored tight glycaemic control in patients with T2DM with established CVD, have investigated the association between tight glycaemic control and cardiovascular endpoints. As observed in the initial reports of the Diabetes Control and Complications Trial (DCCT) in patients with T1DM and in the UKPDS trial in patients with T2DM, tight blood glucose control had little effect on macrovascular outcomes. This was further emphasized by the recent studies including the ADVANCE study [23] and ACCORD trial [22]. Both studies failed to demonstrate significant cardiovascular benefits, with the ACCORD study suggesting possibly deleterious cardiovascular outcomes in association with tight glucose control.

One possible explanation for the lack of a positive effect of tight glycaemic control on cardiovascular outcomes may be the short duration of these trials (less than 5 years). Indeed, as best seen with respect to the longer follow-up of the Steno-2 study [25] and a recent long-term follow-up of the UKPDS [26], the benefits of prior intensified cardiovascular risk management including aggressive glucose control may not appear for up to 10 years after initiation of the studies. Thus, in view of the relative lack of an impact on CVD with intensive glucose control, other risk factor modification strategies need to be emphasized.

### Direct and indirect glycototoxicity

Hyperglycemia is thought to have direct and indirect toxic effect on vascular cells. It has been suggested that increased glucose levels enter the polyol pathway at an increased flux rate leading to heightened formation of diacylglycerol. In addition, increased flux of glucose into the hexosamine pathway may contribute to glucose mediated vascular injury in diabetes. To investigate specifically hyperglycemia mediated atherosclerosis, aldose reductase, transgenic mice have been investigated [27]. These mice demonstrated increased glucose delivery via the polyol pathway and also showed early atherosclerosis, but did not develop advanced vascular lesions.

### In vitro studies

Studies in cell culture experiments have obtained clear evidence that hyperglycemia induces a range of pro-atherogenic effects.

Glucose directly activates monocytes–macrophages *in vitro* initiating increased expression of cytokines such as interleukin 1 $\beta$  (IL-1 $\beta$ ) and IL-6 [28]. Furthermore, this leads to protein kinase C (PKC) and nuclear factor  $\kappa$ B (NF $\kappa$ B) activation resulting in increased production of reactive oxygen species (ROS). Auto-oxidation of glucose can also lead to the formation of ROS and can mediate low density lipoprotein (LDL) oxidation. Scavenger receptors on activated macrophages can mediate the uptake of modified lipids such as the pro-atherogenic oxidized LDL. The formation of advanced glycation end-products (AGEs) in the hyperglycemic milieu can lead to the formation of modified albumin which inhibits scavenger receptor class B type 1 mediated efflux of cholesterol to high density lipoprotein (HDL). Therefore, prolonged hyperglycemia can indirectly lead to a range of secondary changes including changes in lipid profile, cellular lipid accumulation and foam cell formation as well as AGE mediated modification of proteins leading to altered cellular structure and function.

### Animal models

The study of atherosclerosis in diabetes has long been hampered by the lack of an appropriate animal model. Our group and others have developed a murine model of diabetes associated macrovascular disease, the apoE knockout (KO) mouse rendered diabetic by multiple low doses of streptozotocin injections. This model is currently considered by the National Institutes of Health/Juvenile Diabetes Research Foundation (NIH/JDRF) co-sponsored Animal Models for Diabetes Complications Consortium (AMDCC) to be an appropriate model to study macrovascular disease in diabetes [29].

To address the separate roles of hyperglycemia and dyslipidemia in diabetes-associated atherosclerosis, mice deficient in the LDL receptor were bred with transgenic mice expressing a viral protein under control of the insulin promoter [30]. When infected with the virus, T cells mediate destruction of pancreatic  $\beta$ -cells that express the viral protein, thus closely mimicking the autoimmune response in human T1DM. In these animals, atherosclerosis development was accelerated even on a normal diet suggesting that hyperglycemia was driving atherosclerosis in these mice [30,31]. When animals were placed on a high fat diet, a further acceleration of atherosclerosis occurred suggesting that glucose and lipids may act through synergistic mechanisms to accelerate atherosclerosis. Furthermore, plaque disruption and intraplaque hemorrhages, features of plaque instability and potential plaque rupture were observed in this model [30].

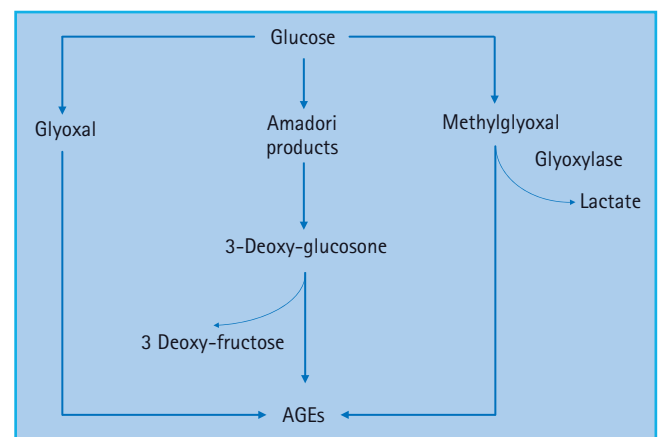

### Metabolic memory

The concept of “glycemic memory” describes the deferred effects of prior glycemic status on the subsequent development of diabetic complications. Episodes of poor glycemic control during the earlier stages of diabetes can precipitate or accelerate the development of complications later in the course of diabetes even when glycemic control is subsequently improved. Two studies have provided evidence for such a metabolic imprint, the DCCT/EDIC

trial in T1DM [2] and the UKPDS in T2DM [26]. Both studies have shown that poor glycemic control was associated with an increased subsequent burden of complications. Another study in patients with T2DM, the VADT study, compared intensive with standard glucose control (6.9 vs. 8.4%, 52 vs 68 mmol/mol), but did not demonstrate significant cardiovascular protection after patients had been exposed to hyperglycemia for long periods of time (12–15 years) [24]. Therefore, it appears that early glycemic control is crucial for a long-term beneficial outcome on diabetic complications.

The concept of “metabolic memory” raises two important issues. First, hyperglycemia may expose patients to the harmful effects of hyperglycemia years before T2DM is diagnosed. Indeed, 25% of patients show complications at the time of diagnosis of T2DM. Therefore, it has been postulated that early diagnosis and strict glycemic control may be pivotal to reduce the induction of this metabolic memory with subsequent development of long-term diabetic vascular complications. Secondly, glycemic oscillations including peaks and troughs are not reflected in the HbA<sub>1c</sub> levels [32,33] but may have a key role in mediating growth factor and cytokine expression as well as inducing chromatin remodeling [34].

There are many cellular and molecular processes that may contribute to the mechanisms underlying metabolic memory with most of those relating to glycototoxicity. These pathways include the formation of AGEs, glycation of DNA, increased flux of glucose metabolism, leading to increased oxidative damage, overproduction of PKC- $\beta$  as well as mitochondrial stress. Recently, it has been shown that transient hyperglycemia induces long-lasting activation of epigenetic changes in the promoter region of the NF $\kappa$ B subunit p65 in aortic endothelial cells both *in vitro* and *in vivo*. These hyperglycemia induced epigenetic changes and increased p65 expression were prevented by reducing mitochondrial superoxide production or superoxide induced generation of  $\alpha$ -oxoaldehydes such as methylglyoxal (Figure 39.2) [34]. These studies suggest that transient hyperglycemia

**Figure 39.2** The formation of advanced glycation end-products (AGEs) can involve early glucose metabolites such as glyoxal and methylglyoxal, highly reactive dicarbonyls and key precursors of AGEs.

causes persistent atherogenic effects during subsequent normoglycemia by inducing long-lasting changes in chromatin remodeling. Specifically, hyperglycemia results in recruitment of the histone methyl transferase Set7 with increased H3K4 mono-methylation of the proximal promoter region of the NFκB subunit p65 gene leading to increased expression of pro-atherogenic pathways including monocyte chemotactic protein 1 (MCP-1) and vascular cell adhesion molecule 1 (VCAM-1) [34]. Subsequent studies in mice, which were initially diabetic but returned spontaneously to normoglycemia, have also demonstrated persistent upregulation of pro-inflammatory genes such as p65 and MCP-1 as a result of prior hyperglycemia. Furthermore, more detailed epigenetic studies revealed that changes in histone modifications as a result of prior hyperglycemia also included changes in H3K9 methylation of the p65 promoter as well as effects on various histone methyl transferases and interestingly also demethylases such as LSD-1 [35].

### Insulin resistance

Insulin resistance occurs in T2DM and in patients with impaired glucose tolerance, and has been associated with increased cardiovascular risk [36–38]. There is now increasing evidence that insulin resistance promotes atherogenesis as an independent risk factor [39–41]. Furthermore, insulin resistance is often associated with a pro-atherogenic lipid profile that includes a high very low-density lipoprotein (VLDL) component, a low HDL and small dense LDL.

*In vitro* studies have shown that insulin exerts both pro-atherogenic and anti-atherogenic effects [42,43]. This has led to the hypothesis of pathway specific insulin resistance (Figure 39.3). It has been suggested that insulin resistance towards glucose transport also affects resistance to the antiproliferative effects of insulin, whereas the signaling pathways leading to cellular proliferation remain intact (Figure 39.3). Insulin signaling via phosphatidylinositol 3 kinase (PI3K) has been associated with antiproliferative and antithrombotic effects with decreased adhesion molecule expression such as MCP-1, VCAM-

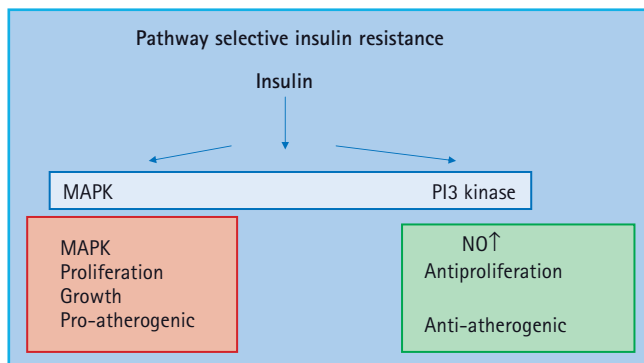

1 and intercellular adhesion molecule 1 (ICAM-1). Furthermore, nitric oxide (NO) production is mediated via the PI3K signal transduction pathway and therefore is impaired in insulin resistance. NO has been shown to reduce LDL oxidation and proliferation of VSMC. In contrast, effects on VSMC proliferation and migration are mediated via the Ras/Raf/MEKK/MAPK signal transduction pathway which is further stimulated in the context of hyperinsulinemia, thus suggesting that pathway specific insulin resistance contributes to the pro-atherogenic effects of insulin. More recently, it has been shown that IL-6 decreases insulin stimulated NO production from endothelial cells via decreased activity of insulin signaling mediated by enhanced TNF-α production [44]. Paradoxically, IL-6 increases insulin stimulated glucose uptake into skeletal muscle and adipose tissue via enhanced insulin signaling, yet IL-6 and insulin have not been linked to increased TNF-α expression in skeletal muscle [44].

### Formation of AGE

AGE formation originates from early glycation products, the Schiff bases, which form the more stable Amadori products such as 1-amino-1-deoxyfructose derivatives. The Amadori products undergo further enzymatic modifications resulting in a number of reactive intermediates such as 3-deoxyglucosone and methylglyoxal (Figure 39.2). Methylglyoxal reacts with amino, sulfhydryl and guanidine functional groups in proteins causing the browning, denaturation and redox active di-amine cross-linking between lysine residues of the target amino acids. Methylglyoxal also generates hydroimidazolones, N-E-(carboxyethyl) lysine, a homolog of carboxymethyl lysine (CML) and methylglyoxal lysine dimer [45,46]. The AGE-based cross-links are resistant to enzymatic degradation and therefore very stable [47]. The rate of AGE formation is dependent on multiple factors including the ambient concentrations of various sugars including glucose, the extent of oxidative stress and the duration of exposure to these various stimuli [48,49].

### Direct effects of vascular AGE accumulation

There is evidence from experimental studies that AGEs directly influence endothelial function [50] as well as enhancing the evolution of macrovascular disease [51,52]. AGEs mediate their effects both directly and via receptor-mediated mechanisms. AGE accumulation in the vascular wall is associated with changes in the structural integrity of proteins, disturbance of their cellular function and degradation of these proteins [28]. AGEs accumulate on many proteins including collagen, albumin and apolipoproteins. Furthermore, the cross-linking of AGEs with matrix molecules can disrupt matrix–matrix and matrix–cell interactions. It has been shown that AGE cross-linking to collagens decreases vascular elasticity and reduces vascular compliance resulting in increased vascular stiffness [53,54]. In addition, AGEs are also able to quench NO [50,55] and generate ROS by stimulating nicotinic acid adenine dinucleotide phosphate (NADPH) oxidase activity [56].

**Figure 39.3** Pathway selective insulin resistance leading to endothelial dysfunction and atherosclerosis. MAPK, mitogen activated protein kinase; NO, nitric oxide; PI3 kinase, phosphatidylinositol 3 kinase.

### AGE binding proteins

The receptor-mediated effects of AGEs occur via binding to proteins such as RAGE [57], AGE-R1 (p60), AGE-R2 (p90) and AGE-R3 (galectin-3), the ezrin-radixin-moesin (ERM) family of proteins [58] macrophage scavenger receptor ScR-11 and CD-36 [59]. The exact roles of AGE-R1, AGE-R2 and AGE-R3 have not been fully elucidated. Finally, the interaction between AGEs and several macrophage scavenger receptors, such as CD36 [59], has been postulated to also promote atherosclerosis with studies using CD36-knockout mice supporting the view that CD36 promotes atherosclerosis [60].

### Receptor for AGEs, RAGE

RAGE is a multiligand signal transduction receptor of the immunoglobulin superfamily of cell surface molecules that acts as a pattern recognition receptor [57]. In addition to binding ligands actively participating in inflammation and immune responses, RAGE serves as an endothelial adhesion receptor for leukocyte integrins and promotes leukocyte recruitment and extravasation of infiltrating cells. Of direct relevance to diabetic macrovascular complications, RAGE is found on endothelial cells and monocytes-macrophages [52,61,62], with RAGE having been implicated in inflammatory lesions in many disorders [63].

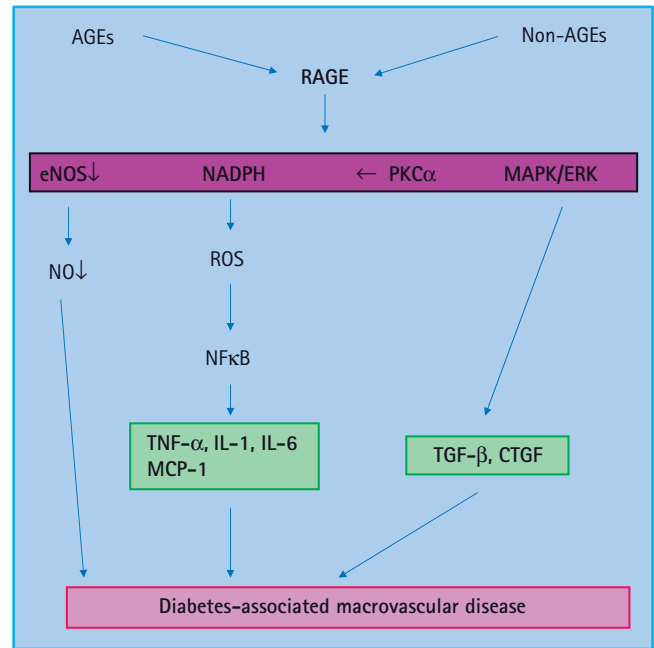

### Downstream effects of RAGE activation

Engagement of RAGE leads to activation of the pro-inflammatory transcription factor NF $\kappa$ B (Figure 39.4) [64]. AGE binding to RAGE activates various signaling pathways, including NADPH oxidase [56], MAPKs, p21<sup>ras</sup> [65], extracellular signal-regulated kinases (ERKs) [66] and PKC causing activation and translocation of NF $\kappa$ B [64]. Furthermore, expression of RAGE itself can be induced by NF $\kappa$ B [67]. RAGE expression within tissues is markedly enhanced in response to metabolic disturbances such as diabetes, dyslipidemia, uremia and aging, possibly because of accumulation of AGEs in these conditions [61,63]. In plaques from diabetic apoE KO mice, upregulation of connective tissue growth factor (CTGF) has been demonstrated that appears to be AGE dependent [51] and may be mediated via RAGE. Intracellular accumulation of AGEs may also promote phenotypic conversion of VSMCs into foam cells within atherosclerotic plaques [68].

### Studies reducing vascular AGE accumulation

A variety of pharmacologic interventions have been used to reduce the accumulation of AGEs via decreasing the total AGE load or via chemical modification of existing AGEs into inactive forms [69,70]. Aminoguanidine is a potent inhibitor of the formation of AGEs, scavenges reactive dicarbonyl AGE precursors [69,70] and decreases oxidative damage to mitochondrial proteins [71]. In experimental and clinical diabetes, aminoguanidine treatment has been shown to reduce microvascular [72] and more recently macrovascular complications in a model of accelerated atherosclerosis, the diabetic apoE KO mouse [51].

Another potential agent which inhibits AGE accumulation is ALT-711 or alagebrium [73]. Based initially on a range of *in vitro*

**Figure 39.4** Activation of AGE receptor (RAGE) contributes to diabetes associated macrovascular disease via increased production of reactive oxygen species (ROS), decrease in nitric oxide (NO) availability, activation of the nuclear transcription factor  $\kappa$ B (NF $\kappa$ B) and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) as well as activation of profibrotic growth factors such as transforming growth factor  $\beta$  (TGF- $\beta$ ) and connective tissue growth factor (CTGF) associated with vascular remodeling. eNOS, endothelial nitric oxide synthase; ERK, extracellular signal-regulated kinase; MAPK, mitogen activated protein kinase; MCP, monocyte chemoattractant protein; NADPH, nicotinamide adenine dinucleotide phosphate; PKC, protein kinase C.

studies, this thiazolium compound and its original prototype, phenylthiazolium bromide [74], have been shown to cleave preformed AGEs and thus one of the postulated mechanisms of ALT-711 is as an AGE cross-link breaker [73].

The removal of established cross-links in diabetic rats with ALT-711 has been shown to be associated with reversal of the diabetes-induced increase in large artery stiffness, increased collagen solubility and reduced vascular and cardiac AGE accumulation [54,75–77]. In addition, alagebrium prevents the progression of nephropathy [78,79] possibly via direct inhibition of PKC- $\alpha$  phosphorylation [80], thus reducing renal expression of vascular endothelial growth factor (VEGF). Treatment with ALT 711 in diabetic apoE KO mice was associated with a significant reduction in atherosclerosis [51]. This anti-atherosclerotic effect was associated with reduced vascular AGE accumulation and RAGE expression. Alagebrium treatment was also associated with less inflammation and reduced expression of pro-fibrotic growth factors, in particular CTGF [81,82]. In the clinical setting, ALT 711 has been shown to reduce pulse pressure and improve vascular compliance in patients with systolic hypertension [54].

### Soluble RAGE

There are three major splice variants of RAGE [83]. First, there is the full-length RAGE receptor; secondly, the N-terminal variant, that does not contain the AGE-binding domain; and, thirdly, a C-terminal splice variant, soluble RAGE (sRAGE), which does not contain the *trans*-membrane and effector domains. It remains controversial as to whether the effects of sRAGE are primarily as a decoy to ligands such as AGEs or whether sRAGE acts as a competitive antagonist to the full-length biologically active RAGE [83,84].

### Soluble RAGE and diabetes associated atherosclerosis

Soluble RAGE (sRAGE) has been identified as having therapeutic value in a model of diabetes associated atherosclerosis, the streptozotocin diabetic Apo E KO mouse [85,86]. In the original study, Park *et al.* [85] reported that diabetic apoE KO mice treated with sRAGE showed a dose-dependent suppression of atherosclerosis and reduced plaque complexity. These beneficial effects were independent of effects on glucose or lipid levels. Furthermore, AGE levels in these diabetic mice were suppressed in a dose-dependent manner by sRAGE to levels similar to those seen in non-diabetic animals. Furthermore, the effect of RAGE blockade with sRAGE was investigated in established atherosclerosis [86]. Administration of sRAGE decreased the expression of RAGE, as well as reducing the number of infiltrating inflammatory cells and gene expression for transforming growth factor  $\beta$  (TGF- $\beta$ ), fibronectin and type IV collagen in both the aorta and the kidney in association with reduced plaque area. Therefore, it was concluded by these investigators that RAGE activation not only contributes to lesion formation, but also to the progression of atherosclerosis.

Soluble RAGE treatment has also been reported to be effective in reducing vascular complications in other models of atherosclerosis and diabetes. Atherosclerosis in the LDL receptor  $-/-$  mouse made diabetic by streptozotocin injection [87] was significantly attenuated by sRAGE treatment. ApoE KO mice bred onto a *db/db* background, a model of T2DM and deficient leptin receptor signaling, showed increased atherosclerosis which was significantly attenuated by daily sRAGE treatment [88].

To understand better the specific role of RAGE in the genesis of vascular lesions, animals selectively deficient in RAGE/apoE (RAGE  $-/-$ ) have been created [89,90]. These mice completely lack not only tissue bound full-length RAGE, but also soluble RAGE. As had been predicted by the pharmacologic intervention studies directed towards the RAGE ligands and AGEs, RAGE-knockout mice bred onto an apoE  $-/-$  background showed a marked reduction in plaque area in the presence and absence of diabetes [89,90]. More recently, the effect of RAGE deletion on atherosclerosis development has been investigated in streptozotocin diabetic RAGE/apoE KO mice and showed a significant reduction in atherosclerotic plaque area when compared with diabetic apoE KO mice expressing RAGE. These vascular changes seen in the streptozotocin diabetic double RAGE/apoE KO mice were associated with reduced inflammation, less accumulation of

RAGE ligands such as S100/CML, decreased infiltration by macrophages and T lymphocytes and a reduction in expression of pro-fibrotic and pro-inflammatory growth factors and cytokines [90].

These promising results with RAGE antagonism have encouraged the development of RAGE neutralizing compounds for clinical use. The RAGE modulating agent TTP488 is currently being considered in phase II clinical trials in patients with Alzheimer disease and in patients with diabetic nephropathy. Another compound, TP4000, will soon enter phase I clinical trials ([www.Clinicaltrials.gov](http://www.Clinicaltrials.gov) and [www.ttpharma.com](http://www.ttpharma.com)); however, currently, the major focus of antagonizing RAGE does not appear to involve studies addressing CVD in the absence or presence of diabetes.

### Interaction with the renin angiotensin system

Because diabetic complications appear to be multifactorial in origin and involve interactions between hemodynamic pathways such as the RAS and metabolic pathways such as hyperglycemia and the formation of AGEs, there has been increasing investigation of the potential links between these various pathways (Figure 39.1) [91]. There is increasing evidence that AGE accumulation can induce an upregulation of certain components of the RAS, although these studies have been performed predominantly in the renal context [92]. Furthermore, angiotensin-converting enzyme (ACE) inhibition has been reported to confer its end-organ protective effect, partly via a reduction in AGEs and an increase in sRAGE [93]. Therefore, the status of the RAS could represent a key modulator in AGE-induced diseases. More recently, other therapeutic interventions shown to be anti-atherosclerotic have been reported to exert part of their vasculoprotective effect via inhibition of the AGE/RAGE pathway. These include angiotensin II receptor blockers (ARBs), peroxisome proliferator-activated receptor  $\alpha$  (PPAR- $\alpha$ ) and PPAR- $\gamma$  agonists and statins [94–96].

---

## Role of vasoactive hormones in diabetes-related atherosclerosis

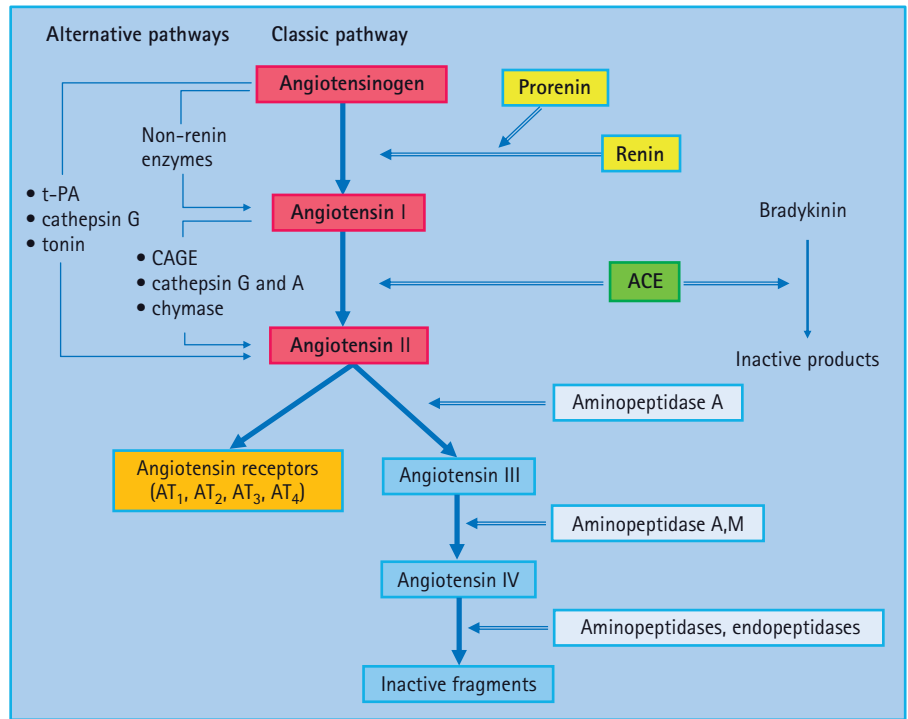

### Classic RAS

Renin was described more than 100 years ago by Tigerstedt & Bergman [97]. Nevertheless, our understanding of the RAS is still not complete and has grown increasingly complex over the last decade. The classic pathway is now very well characterized (Figure 39.5). The generation of angiotensin (AT) I and II is not restricted to the systemic circulation but this production also takes place in vascular and other tissues (Figure 39.5) [98].

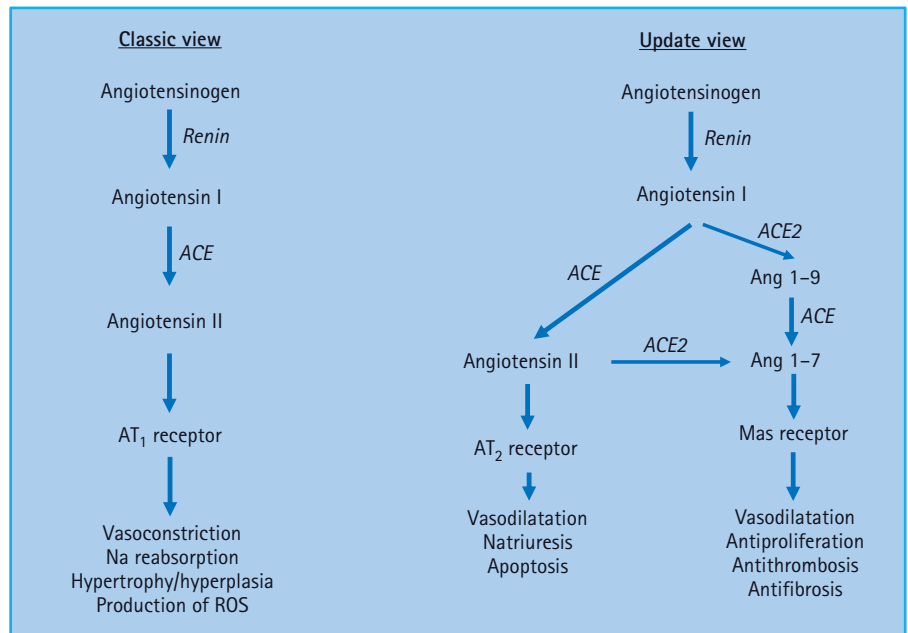

### Novel aspects of the RAS: ACE2

In 2000, a further enzyme associated with the generation of AT peptides was identified – ACE2, a carboxypeptidase with sequence similarity to ACE [99]. ACE2 does not generate AT II but increases the formation of AT 1-7 (Figure 39.6). This heptapeptide causes vasodilatation and has growth inhibitory effects [100]. Further

**Figure 39.5** Overview of the enzymatic cascade of the renin-angiotensin system (RAS): classic and alternative pathways. In the classic pathway, renin cleaves the decapeptide angiotensin I from angiotensinogen. Angiotensin I is then converted to angiotensin II which acts through several receptor subtypes, being AT<sub>1</sub> and AT<sub>2</sub> receptors the more relevant in the vasculature. CAGE, chymostatin-sensitive angiotensin II-generated enzyme; t-PA, tissue plasminogen activator.

**Figure 39.6** New aspects of the renin-angiotensin system (RAS) components and its interactions. The classic RAS illustrates the main pathway for angiotensin II (AT II) generation from angiotensin I (AT I) via ACE, with effects being mediated via AT<sub>1</sub> receptor. The updated view illustrates the new components of the RAS in which ACE2 has a role to degrade AT I to AT 1-9, and AT II to the vasodilator AT 1-7 which acts through the Mas receptor.

research, including into specific inhibitors, is needed to understand the many functions of ACE2 inside and outside the RAS.

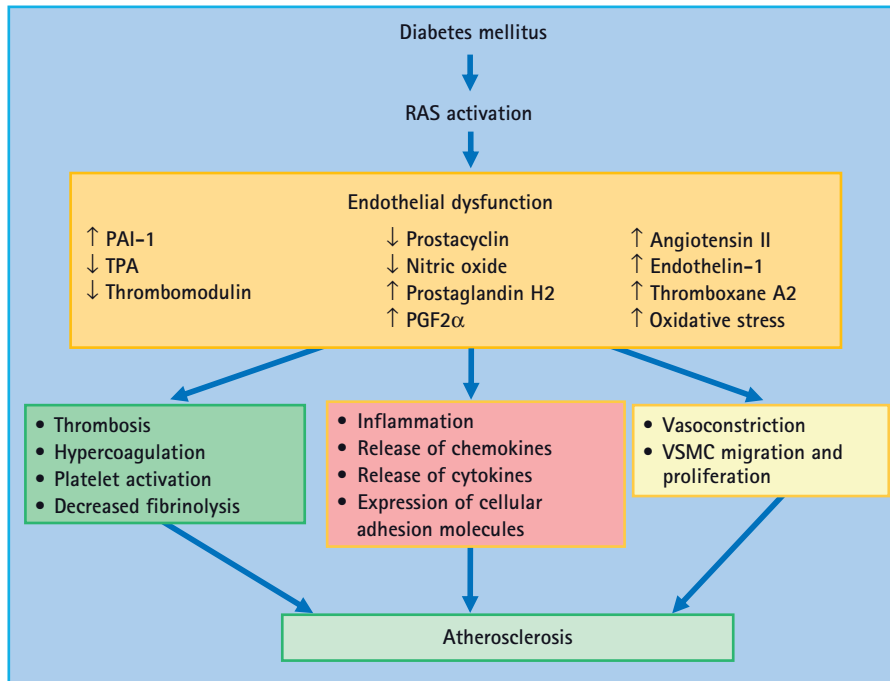

**AT receptors**

The effects of all AT peptides are mediated through specific cell surface receptors (Figures 39.5 and 39.6). The AT<sub>1</sub> receptor mediates most of the effects usually associated with AT II. The

role of the AT<sub>2</sub> receptor subtype remains controversial, but it appears to antagonise certain effects of AT II mediated via the AT<sub>1</sub> receptor [101].

**Role of the RAS in macrovascular disease**

It is now recognized that local RAS activation has an important role in the pathogenesis of diabetes-induced endothelial

**Figure 39.7** Effects of diabetes-induced renin angiotensin system (RAS) activation on mechanisms associated with endothelial dysfunction and atherosclerosis. In diabetes, activation of RAS induces endothelial dysfunction which is characterized by vasoconstriction, inflammation, cellular growth and thrombosis. By losing its protective properties, dysfunctional endothelium is a major promoter of atherogenesis and, consequently, cardiovascular events. PAI-1, plasminogen activator inhibitor-1; TPA, tissue plasminogen activator; VSMC, vascular smooth muscle cells.

dysfunction and atherosclerosis [102–104]. As a result, there is a strong rationale for blockade of the RAS to prevent cardiovascular events in patients with diabetes. In addition, several recent clinical trials [105–110] have suggested that blockade of the RAS may protect against the development of T2DM in at-risk patients.

### RAS activation and endothelial dysfunction

Endothelial dysfunction has been considered as an imbalance between vasoconstrictors and vasodilators in the vascular tone [111] associated with a decrease in NO activity and increased AT II and endothelin (ET) activity [112]. Endothelial dysfunction is characterized by defective endothelium-dependent vasorelaxation in association with inflammatory cytokine-induced increased interactions with blood leukocytes, in which adhesion molecules such as VCAM-1 and chemo-attractants such as MCP-1 are essential [113]. Endothelial dysfunction is strongly associated with atherosclerosis (Figure 39.7) [114,115].

Crucial to the pathogenesis of diabetes-induced endothelial dysfunction in the early stages, in the absence of structural changes of the vessel wall, is the activation of the RAS. Although measurements of components of the RAS in plasma have, in general, suggested suppression of this system in diabetes, there is increasing evidence for activation of the local cardiovascular RAS in the diabetic context [116,117]. It has been demonstrated that there is an increase in ACE expression and activity, in AT II expression, and in AT<sub>1</sub> receptor expression in the aortic wall of diabetic apoE KO mice suggesting a key role for RAS activation in the pathogenesis of diabetes associated endothelial dysfunction [102,118].

### RAS and regenerative endothelial cell repair

A role for the RAS has also been demonstrated in affecting the number of regenerative endothelial progenitor cells in patients with diabetes. An increased concentration of circulating endothelial progenitor cells, which are believed to maintain the integrity of the vascular endothelium, has been associated with a favorable cardiovascular outcome in patients with CAD [119]. A study in patients with T2DM [120] suggested that treatment with an ARB (olmesartan) increases the number of regenerative endothelial progenitor cells, which could contribute to the beneficial cardiovascular effects seen with AT<sub>1</sub> receptor blockade.

### Role of AT 1-7 and ACE2 in endothelial dysfunction

It has been hypothesized that disruption of the ACE–ACE2 balance may result in abnormal blood pressure, with increased ACE2 expression protecting against hypertension, and ACE2 deficiency causing hypertension (Figure 39.6) [121]. As reported above, it is well established that AT II produces endothelial dysfunction through different pathways, such as increasing oxidative stress and exerting proliferative and pro-thrombotic activities [122]. Recently, it has been observed that AT 1-7, which is generated by the enzyme ACE2, promotes the release of NO and prostaglandins [123,124] and potentiates bradykinin effects in different experimental models [124,125]. In addition, AT 1-7 inhibits growth of VSMC [126], platelet aggregation and thrombosis [127], inflammation, fibrosis [128] and oxidative stress [129] which in turn might lead to restoration of endothelial function. It appears that AT 1-7 can antagonize AT II effects, not only by the stimulation of other vasodilators but also through AT<sub>1</sub> receptor inhibition. In this regard, Kostenis *et al.* [130] reported

that the Mas receptor, which is increasingly considered to be the major receptor conferring the biologic effects of AT 1-7, seems to act as a physiologic antagonist of AT<sub>1</sub> receptor and thus counteracting many of the actions of AT II at the endothelial level.

### RAS activation and atherosclerosis

Clinical and experimental evidence clearly indicates that activation of the RAS is central to almost all these pro-atherosclerotic pathways (Figure 39.7) [103,131]. Diet *et al.* [104] observed increased ACE protein accumulation within the atherosclerotic plaque in human coronary arteries suggesting that ACE may contribute to an increased production of local AT II which may participate in the pathophysiology of artery disease. In addition, there is evidence that AT II and the AT<sub>1</sub> receptor are overexpressed in atherosclerotic plaques [102,132,133]. Indeed, blockade of the RAS with an ACE inhibitor or an AT<sub>1</sub> receptor antagonist prevents atherosclerosis by mechanisms involving inhibition of pro-inflammatory molecules such as VCAM-1 and MCP-1 and pro-sclerotic and pro-proliferative cytokines such as CTGF and platelet derived growth factor. These observations confirm a key role for RAS activation in the development and progression of atherosclerosis.

Production of pro-inflammatory cytokines, such as IL-1 $\beta$ , TNF- $\alpha$  and IL-6, have a major role in the pathogenesis of atherosclerosis [134]. IL-6, ACE and AT<sub>1</sub> receptors have been detected in stable and unstable atherosclerotic plaques [132,135]. AT II stimulates the redox sensitive nuclear transcription factor, NF $\kappa$ B, which could serve as a unifying signaling system for inflammatory stimuli in atherogenesis through enhanced expression of adhesion molecules ICAM-1 and VCAM-1, E-selectin, MCP-1 and IL-8. Several clinical and experimental studies have demonstrated that both ACE inhibitors and AT<sub>1</sub> receptor blockers decrease the expression of several adhesion molecules, thus confirming that the chronic inflammatory response associated with atherosclerosis appears to be modulated by AT II at every level and can be targeted therapeutically by RAS inhibition [103,116,136].

Moreover, the sustained pro-inflammatory state seems to play an important part in the transformation of a stable atherosclerotic plaque into a vulnerable plaque prone to rupture. Plaque rupture has been connected with activation of matrix metalloproteinases in the fibrous cap of the atherosclerotic lesion [137], and there is evidence that AT II is implicated in matrix metalloproteinase activation, both through a direct action and through induction of pro-inflammatory cytokines such as IL-6.

### ACE2 and diabetes accelerated atherosclerosis

Although studies on the expression and activity of ACE2 in atherosclerosis are limited, there is increasing evidence that such more recently identified components of the RAS may be involved in the development and progression of atherosclerosis. Recently, Zulli *et al.* [138] have shown very high expression of ACE2 in endothelial cells, macrophages and  $\alpha$ -smooth muscle cells within atherosclerotic plaques in a rabbit model of atherosclerosis. It is

not clear whether this increase in ACE2 is in response to injury in an attempt to protect the vessel by increasing levels of AT 1-7.

In the human context, there is evidence for a significant activation of the cardiac RAS after coronary artery occlusion, and it is well known that RAS blockade reduces remodeling and improves survival in humans after an MI. In recent studies [139], cardiac ACE2 expression and activity are also increased with experimental MI. All these observations suggest that an imbalance in the RAS activity has a central role in the pathogenesis of atherosclerosis. Nevertheless, as yet, it is unknown if deficiency of ACE2 contributes to the accelerated atherosclerotic disease process seen in diabetes.

### RAS and oxidative stress

There is increasing evidence that the local production of ROS has a pivotal role in atherosclerosis, specifically in the diabetic milieu. Increased vascular superoxide production in aortas from diabetic atherosclerotic apoE KO mice has been demonstrated [94]. These changes were mediated by increased NAD(P)H oxidase (Nox) activity in the aorta with increased expression of various Nox subunits including p47phox, gp91phox and rac-1 [94]. Evidence of increased local vascular ROS generation in diabetes is further supported by the demonstration of increased nitrotyrosine staining in these diabetic plaques. Indeed, interventions that reduce vascular superoxide production such as PPAR- $\alpha$  and PPAR- $\gamma$  agonists have been associated with reduced plaque formation, further emphasizing the link between vascular oxidative stress and atherosclerosis [94,140]. Furthermore, the deletion of antioxidant enzymes such as glutathione peroxidase, specifically the Gpx1 isoform in the vascular wall, results in an increase in plaque area particularly in the diabetic context via increases in inflammatory mediators including adhesion molecules and chemokines [141]. More recently, it has been shown that treatment of GPx1 deficient mice with the Gpx1 analog, ebselen, reduced oxidative stress variables and atherosclerosis in diabetic GPx1/apoE KO mice [142]. Furthermore, in the Gpx1/apo E double KO mice, there was associated upregulation of RAGE further linking vascular RAGE expression to increased oxidative stress and accelerated atherosclerosis in settings such as diabetes [141].

### Therapeutic implications

#### RAS blockade and endothelial dysfunction

As a result of previous observations, RAS blockade has emerged as an obvious and attractive therapeutic target. Early evidence for a clinical beneficial effect of inhibition of this system on impaired endothelial function was derived from the Trial on Reversing Endothelial Dysfunction (TREND) [143] which showed that ACE inhibition improves endothelial function in subjects with coronary artery disease. Moreover, O'Driscoll *et al.* [144] observed that ACE inhibition with enalapril improved both basal and stimulated NO-dependent endothelial function in normotensive patients with T2DM.

Data are also available for the role of ARBs in improving endothelial function such as the AT<sub>1</sub> receptor antagonist, losartan

[145,146]. Furthermore, in patients with T1DM treated with the ACE inhibitor ramipril or the ARB losartan for 3 weeks [147] improved endothelial dysfunction potentially mediated by increased bradykinin levels with ACE inhibition or increased levels of AT 1-7 levels.

### RAS inhibition and cardiovascular protection

There is accumulative evidence that pharmacologic therapy that interrupts the RAS may afford special benefits in reducing CVD in people with diabetes [109,148,149]. In a *post hoc* subgroup analysis of the Captopril Prevention Project (CAPP) study, the patients with diabetes treated with captopril fared significantly better compared with those treated with conventional therapy (beta-blockers and diuretics) in terms of primary endpoint as well as for MI, all cardiac events and total mortality [148]. These relative beneficial effects of ACE inhibitor therapy were particularly striking in those at highest risk, specifically those with the highest median fasting glucose or those with more elevated blood pressure (BP). This is in contrast to the UKPDS [150], in which there was comparable CVD benefits for patients with T2DM who were randomized to captopril or atenolol, perhaps reflecting a lower CVD risk in the newly diagnosed patients with diabetes studied in the UKPDS.

In a sub-study of the Hypertensive Old People in Edinburgh (HOPE) study, the MICRO-HOPE [151], of the relative risk reduction in the 3577 patients who had diabetes and one other CVD risk factor, there was a risk reduction of 25% for combined CVD events, 37% for CVD mortality, 22% for MI and 33% for stroke. In the Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET) study, the incidence of CVD events was less in hypertensive patients with T2DM treated with fosinopril than the amlodipine-treated group [152]. The European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease (EUROPA) [153] has shown that ACE inhibition reduced cardiovascular mortality and morbidity in patients with established CAD without left ventricular dysfunction. The data from these trials were pooled with those of the Quinapril Ischemic Event Trial (QUIET) [154] study in a meta-analysis that included a total of 31 555 patients [155]. This analysis showed that, compared with placebo, ACE inhibitor therapy produced a significant 14% reduction in all-cause mortality and MI, a 23% reduction in stroke and a 7% statistically significant reduction in revascularization procedures. Recently, the ADVANCE study [23] has shown that the administration of the ACE inhibitor perindopril and the diuretic indapamide in high-risk patients with T2DM induced a reduction in macrovascular outcome when compared with placebo.

Recent reports of trials with ARBs indicate that these agents have CVD protection effects in patients with T2DM similar to those observed with ACE inhibitors. In the Losartan Intervention For Endpoint reduction in hypertension (LIFE) study [109], treatment with losartan in patients with T2DM and left ventricular hypertrophy (LVH) resulted in a significant reduction in death from CVD and in particular all cause mortality. An analysis from

the large Reduction of Endpoints in NIDDM with Angiotensin II Antagonist Losartan (RENAAL) study has shown that treatment with losartan in patients with T2DM, nephropathy and LVH reduced the cardiovascular risk to levels similar to those observed in patients without LVH [156]. Recently, the Ongoing Telmisartan Alone and in combination with Ramipril Global Endpoint Trial (ONTARGET) has shown that the ARB telmisartan provides a benefit similar to that of a proven ACE inhibitor such as ramipril in high risk patients with CVD or subjects with diabetes who have end-organ damage. This is a population similar to that examined previously in the HOPE study [157]. Furthermore, in the ONTARGET study the combination of ramipril with telmisartan, despite the further lowering of BP, did not reduce the risk of cardiovascular events, compared with an ACE inhibitor alone, but was associated with additional adverse effects including hypotension and renal dysfunction. Thus, an ACE inhibitor, or possibly an ARB, is an initial antihypertensive agent of choice in patients with diabetes because these agents have been shown to have the capacity to prevent or retard the development of diabetic macrovascular complications, thus significantly reducing cardiovascular mortality and morbidity.

---

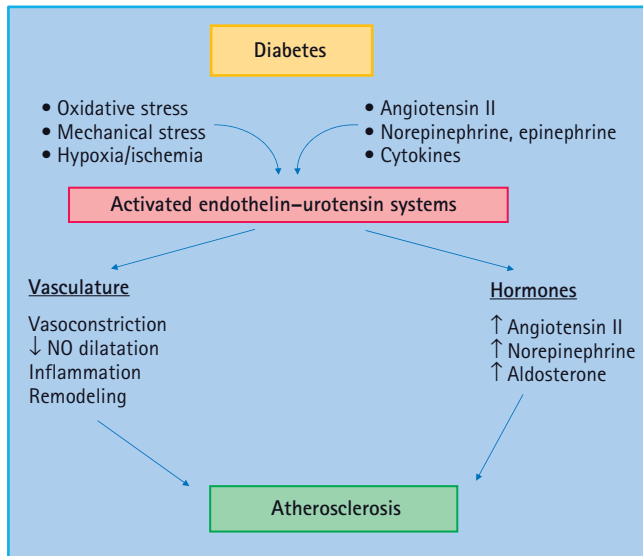

## The endothelin system

Endothelin (ET) was first discovered in 1988 by Yanagisawa *et al.* [158] and is one of the most potent vasoconstrictors known. There are three distinct ET genes that encode different mature ET sequences, designated ET-1, ET-2 and ET-3. Big ET-1 is converted into mature 21 amino acid ET-1 by ET-converting enzyme. ET-1 is predominantly present in endothelial cells. In 1990, the ET<sub>A</sub> and ET<sub>B</sub> receptor subtypes [159], were cloned. ET<sub>A</sub> receptors are found in VSMCs and mediate vasoconstriction and cell proliferation (Figure 39.8). ET<sub>B</sub> receptors are found in endothelial cells (ET<sub>B1</sub>) where they mediate vasodilation via the release of NO and on smooth muscle cells, where they may elicit vessel contraction and cell proliferation (Figure 39.8).

### Role of ET in diabetic macrovascular complications

Plasma concentrations of ET-1 are increased in patients with T2DM complicated with atherosclerosis, compared with patients without diabetes with atherosclerosis and healthy subjects [160]. Kalogeropoulou *et al.* [161] demonstrated increased ET-1 levels in subjects with diabetes and carotid atherosclerosis. ET stimulates the production and release of inflammatory cytokines from monocytes [162] and enhances the uptake of LDL cholesterol by these cells, promoting a phenotypic change into foam cells [163]. Cytokines released from monocytes–macrophages, in turn, stimulate ET-1 production, providing positive feedback for further cytokine production [164].

In several animal models, both ET<sub>A</sub> receptor-selective and non-selective ET<sub>A</sub>/ET<sub>B</sub> receptor blockade have been shown to inhibit the development of atherosclerotic lesions suggesting that elevated vascular ET-1 tissue levels promote endothelial dysfunction

**Figure 39.8** Proposed mechanisms of the endothelin and urotensin systems on atherosclerosis in diabetes. In diabetes, activation of the endothelin system induces vasoconstriction, vascular smooth muscle cells proliferation, wall thickening, inflammation and tissue remodeling thus leading to the development and progression of atherosclerosis.

and vascular structural alterations *via* the activation of  $ET_A$  receptors [163,165]. Treatment with an  $ET_A$  receptor antagonist decreased atherosclerotic lesion area in the aorta in apoE KO mice [11]. Similar results have been reported with a non-selective  $ET_A/ET_B$  receptor blocker in rabbits. The role of the  $ET_B$  receptor in atherosclerosis remains controversial at this stage although it has been shown to have anti-atherosclerotic effects via stimulation of NO production [166].

Finally, some of the beneficial effects of ACE-inhibitors in term of cardiovascular protection may be at least in part mediated by ET inhibition. Captopril inhibits the release of ET from cultured human endothelial cells and decreases 24-h urinary ET-1 excretion [167,168]. Furthermore,  $ET_A$  receptor antagonism appears to be beneficial in the treatment of diabetic nephropathy, but there are currently no data to support a protective effect on macrovascular disease in people with diabetes.

## Urotensin II

Several recent reports have revealed the powerful vasocontractile effect of urotensin II (UT II) consistent with a potential importance of this peptide in cardiovascular physiology and diseases (Figure 39.8) [169]. A specific UT II receptor was identified in 1999 [170]. Elevated circulating concentrations of UT II have been detected in patients with various CVD states including heart failure, hypertension [171], carotid atherosclerosis, pre-eclampsia and eclampsia, renal dysfunction and diabetes mellitus [172]. In addition, upregulation of the UT receptor system has been

found in patients with congestive heart failure and pulmonary hypertension [173].

### Role of urotensin II in atherosclerosis

Expression of UT II is upregulated in endothelial, myointimal and medial smooth muscle cells of atherosclerotic human coronary arteries. Boussette *et al.* [12] have demonstrated that UT II expression is increased in both atherosclerotic carotid arteries and aortas. It has been shown that the plasma UT II level is correlated positively with carotid atherosclerosis in patients with essential hypertension [174]. In apoE KO mice, UT expression was significantly higher than in wild-type control mice [175]. Chronic infusion of UT II enhances atherosclerotic lesion in the aorta of apoE KO mice by increasing ROS production and acyl-CoA-cholesterol acyl-transferase 1 expression. UT II expression in endothelial cells and VSMCs is increased following balloon injury in rat carotid arteries [176]. Furthermore, treatment with a UT II receptor blocker was associated with a 60% reduction in intima lesion development.

UT II is linked to the activation of the redox-sensitive enzyme NADPH oxidase in the vascular wall and increased expression of inflammatory cytokines (Figure 39.8). In human peripheral blood mononuclear cells, inflammatory stimuli including IL-1 $\beta$  and TNF- $\alpha$  strongly enhance UT receptor mRNA and protein expression [177]. Of direct relevance to atherosclerosis, UT II has been shown, predominantly in *in vitro* studies to enhance LDL cholesterol and ROS production via NADPH oxidase and to promote monocyte recruitment.

## TNF-related apoptosis inducing ligand and osteoprotegerin

Tumor necrosis factor (TNF) related apoptosis inducing ligand (TRAIL) is a member of the TNF ligand family [178]. Both the membrane-bound and soluble forms of TRAIL rapidly induce apoptosis in multiple transformed cell lines and tumor cells, but not in normal cells [178,179].

Osteoprotegerin (OPG) is a member of TNF-receptor superfamily [180], which is produced by a variety of tissues including the cardiovascular system. OPG has two known TNF family ligands: receptor activator of NF $\kappa$ B ligand (RANKL) [181] and TRAIL [182]. Increasing experimental evidence suggests that both TRAIL and OPG are involved in vascular pathophysiology.

Recently, the potential role of soluble recombinant (sr) TRAIL in the pathogenesis and/or treatment of diabetes-induced atherosclerosis has been investigated *in vivo*, in streptozotocin-diabetic apoE KO mice [183]. Repeated intraperitoneal injections of srTRAIL significantly attenuated plaque development and contributed to stabilize atherosclerotic lesions by selectively decreasing the number of infiltrating macrophages and increasing the VSMCs within the atherosclerotic plaques [183]. The potential clinical relevance of these results is corroborated by two studies in patients with acute coronary syndrome, revealing significantly

lower sTRAIL serum levels in these subjects when compared to patients with stable angina or normal coronary arteries [184,185].

OPG-deficient mice demonstrated calcifications of the aorta and renal arteries [186], suggesting that OPG might have a role in protecting from vascular calcification. Interestingly, a study in elderly women found a significant correlation between elevated OPG serum levels and cardiovascular mortality [187]. The potential links between OPG and vascular disease in humans have been further supported by the detection of a single nucleotide polymorphism in the promoter region of the human gene for OPG related to vascular morphology and function [188]. Several independent studies have reported elevated serum and/or plasma OPG levels in people with diabetes, and in particular in people with diabetes and vascular complications [189]. Although some authors have proposed that the increase in OPG levels may represent a defence mechanism against other factors that promote vascular pathologies, other studies support a pro-atherosclerotic role for OPG in the vasculature [190].

### Complement activation

The complement system consists of approximately 30 proteins that provide an important component of the innate immune system. The complement system is activated through three different pathways: the classic, the alternative and the mannose-binding lectin (MBL) complement pathway, respectively. These three pathways merge and stimulate the formation of a C3 convertase (Figure 39.9).

Recently, an increasing amount of evidence indicates that the complement system activation may have a role in the development of diabetic macrovascular complications [15], in particular

the MBL pathway as the initiating pathway of complement activation in patients with diabetes [15]. Patients with T1DM with nephropathy and CVD have significantly higher circulating levels of MBL than normoalbuminuric patients [191]. Furthermore, there is evidence that MBL levels may have prognostic relevance in people with diabetes. Several observations have suggested that MBL may be involved in the pathogenesis of microvascular and macrovascular complications in T1DM and that determination of MBL status might be useful to identify patients at increased risk of developing these complications [191,192]. High levels of MBL early in the course of T1DM are significantly associated with later development of persistent microalbuminuria and macroalbuminuria [193]. In addition, in patients with T2DM, measurement of MBL has been shown to provide prognostic information on mortality and development of microalbuminuria [194]. The mechanism responsible for this potential activation of the complement system in patients with diabetes is still unknown. It has been hypothesized that hyperglycemia in people with diabetes may activate the complement system via mitochondrial ROS production or enhanced RAGE activation.

Clinical studies using pexelizumab, an inhibitor of C5, have recently demonstrated a significant reduction in mortality following acute MI as well as reducing the incidence of death or MI in patients after coronary artery bypass graft surgery [195]. Further studies are needed to determine in particular if manipulation of the complement system may represent a promising target in the treatment and prevention of diabetes associated macrovascular disease.

### Interventions to reduce diabetes associated macrovascular complications

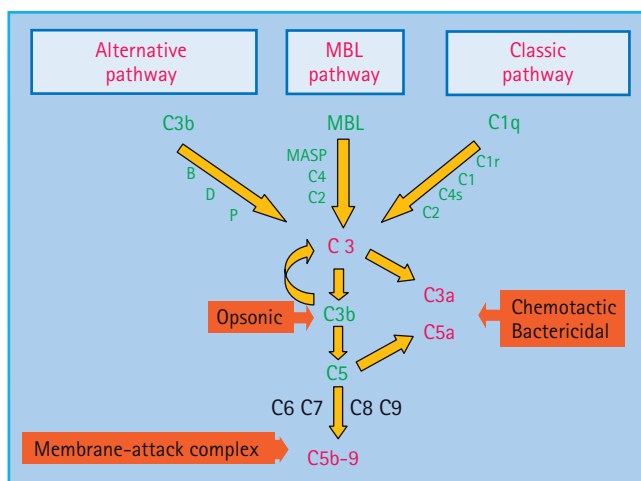

A range of interventions has been proposed to reduce the macrovascular complications of diabetes including lifestyle modification, weight reduction, dietary changes and regular exercise.

#### Glucose control

Optimal glucose control is pivotal for the prevention and treatment of microvascular complications of diabetes; however, based on the recent clinical trials [22,23], the evidence for beneficial effects on macrovascular outcomes is less clear. Nevertheless, it has been suggested to aim for a HbA<sub>1c</sub> <7% (53 mmol/mol), but to be more cautious in patients with underlying and pre-existing CVD.

#### Hypertension

Epidemiologic studies have shown that the risk for cardiovascular events and mortality starts at BP values as low as 115/75 mmHg for the general population and doubles for every increase in 20 mmHg systolic and 10 mmHg diastolic (see Chapter 40). The question of what systolic or diastolic BP level should be targeted has not been completely answered by currently available outcome trials. Based on studies such as the Hypertension Optimal Treatment (HOT) study [196], UKPDS [197] and the Appropriate Blood Pressure Control in type 2 Diabetes (ABCD) trial [198], a

**Figure 39.9** Schematic presentation of the complement system. The complement cascade is activated by either of the three pathways: the classic, the mannose-binding lectin (MBL) pathway, or the alternative pathway. Activation leads to formation of the membrane-attack complex as well as formation of opsonic, chemotactic and bactericidal factors.

maximum systolic BP of 130–135 mmHg should be the goal for people with diabetes.

The more recently completed ADVANCE trial [23] evaluated the effect of a fixed dose of perindopril and indapamide on macrovascular and microvascular outcomes in subjects with T2DM. The treatment group showed a mean reduction in systolic and diastolic BP of 5.6 and 2.2 mmHg respectively, which was associated with a 18% reduction in cardiovascular deaths and a 14% reduction in coronary events in comparison to the control group. No lower limit for BP reduction appears to exist at which benefits related to cardiovascular outcomes are not observed with a similar pattern recently reported for renal disease [199]. The ACCORD trial is currently testing the effects of lowering BP below 140/90 mmHg on cardiovascular outcomes. Specifically, it will evaluate if a BP reduction to 120 mmHg systolic will further reduce the cardiovascular event rate.

### Choice of antihypertensive treatment

Experimental studies have clearly demonstrated a reduction in atherosclerosis with RAS inhibitors with a possible superiority of ACE inhibitors compared to ARBs in T2DM; however, in the human setting, there are no conclusive studies as yet to show clear superiority of one class of antihypertensive drugs over another. The majority of the beneficial effects on cardiovascular events appear to be related to the antihypertensive actions of these agents. The ONTARGET study was the first study to evaluate the effect of combined RAS blockade in comparison to full-dose ramipril and telmisartan alone [200]. There was no superiority of the ACE inhibitor versus the ARB in terms of cardiovascular events, and dual blockade did not confer greater cardiovascular protection and indeed was associated with more adverse events; however, only 30% of all subjects enrolled in this study had diabetes, and no specific subgroup analysis has been reported so far. Therefore, this study cannot conclusively answer the question of superiority of different blockers of the RAS and combination RAS-blockade on microvascular and macrovascular outcomes in diabetes.

### Dyslipidemia

The lipid profile is usually altered in the diabetic milieu and further altered in the context of liver or renal disease. Dyslipidemia further accelerates atherosclerosis development and progression (see Chapter 40). At any given level of cholesterol, a person with diabetes has a two- to threefold increased cardiovascular risk than a person without diabetes.

Current guidelines based on numerous studies particularly with statins (Heart Protective Study [HPS] [201], the Collaborative Atorvastatin Diabetes Study [CARDS] [202]) suggest to reduce LDL levels below 2.5 mmol/L with some more recent evidence suggesting enhanced benefits if LDL is lowered <2 mmol/L, triglycerides <1 mmol/L and HDL > 1 mmol/L according to pre-existing CVD and risk [203].

### Hypercoagulability

Diabetes is associated with pro-thrombotic changes and enhanced coagulability, thus increasing cardiovascular risk [204,205].

Although not studied in detail, agents such as aspirin may be useful in people with diabetes, with increasing evidence that higher doses of these agents are often required in people with diabetes to confer cardiovascular benefits. Other drugs to consider in diabetes are clopidogrel as well as the use of drugs such as abciximab [206], which has been reported to be particularly effective in people with diabetes.

### Novel therapies

Several approaches have been used to intervene in diabetes-associated complications including aldose reductase inhibitors, PKC isoform inhibitors, in particular PKC  $\beta$ , but most of the evidence for a potential role for these agents has been obtained in the context of microvascular complications. Furthermore, inhibitors of glucose induced ROS formation, such as benfotiamine, have been investigated in clinical trials with variable results. AGE inhibitors and RAGE antagonism have also been employed, mainly in the context of diabetic nephropathy. The cross-link breaker, alagebrium, has shown to reduce arterial stiffness in hypertensive patients and to improve left ventricular function. Direct antagonists of RAGE and human chimeric sRAGE are also currently being investigated in early clinical trials, however, not as yet with respect to macrovascular disease.

The role of PPAR- $\alpha$  and PPAR- $\gamma$  agonists have also been investigated with modest or no effects on cardiovascular outcomes [207–209]. The dual PPAR- $\alpha/\gamma$  agonists such as muraglitazar do not appear to be likely to be introduced as a result of adverse side effects and the possibility of adverse cardiovascular events [210].

### Multifactorial approaches

The Steno-2 study, using a multifactorial approach addressing lipids, BP and hyperglycemia, demonstrated significant improvements on cardiovascular outcomes [25]. Thus, a synergistic multifactorial approach addressing glycemic control in the context of additional strategies to reduce concomitant cardiovascular risk factors remains the best approach to be currently considered. Furthermore, strategies directed towards a reduction in activation of vasoactive systems such as the RAS, the ET and UT systems, the AGE/RAGE axis, novel proteins such as TRAIL and the complement system as well as oxidative stress and inflammation may additional promising approaches to prevent and minimize macrovascular disease in diabetes.

### Hypertension

*Peter M. Nilsson*

#### Keypoints

- Hypertension is up to twice as common in people with diabetes as in the general population, affecting 10–30% of people with type 1 diabetes mellitus (T1DM) and 60–80% of those with type 2 diabetes (T2DM).
- Hypertension is associated with insulin resistance and other features of the metabolic syndrome. Insulin resistance could raise blood pressure (BP) by loss of insulin's normal vasodilator activity or through effects of the accompanying hyperinsulinemia.
- BP rises during the early microalbuminuric phase of diabetic nephropathy, especially in young patients with T1DM.
- Hypertension worsens both macrovascular and microvascular complications in diabetes. The effects of BP on the risk of fatal coronary heart disease are 2–5 times greater than in people without diabetes. The risks of nephropathy and end-stage renal failure are also increased 2–3 times by hypertension.
- All people with diabetes should be carefully screened for hypertension and evidence of hypertensive tissue damage at diagnosis and at least annually thereafter. Treatment is required for values that consistently exceed 130–140/80–85 mmHg – lower than the World Health Organization/International Society of Hypertension thresholds defined for hypertension in the general population. The blood lipid profile should also be checked.
- The treatment of hypertension begins with lifestyle management, including reduced dietary fat and salt intakes, weight loss for obese patients, smoking cessation and increased regular physical activity. These measures can lower BP by up to 11/8 mmHg.
- First-line antihypertensive drugs suitable for use in patients with diabetes are diuretics, such as low dose bendroflumethiazide (bendrofluazide); or cardioselective beta-blockers, calcium-channel antagonists (CCAs), angiotensin-converting enzyme (ACE) inhibitors and angiotensin II type 1 (AT1) receptor blockers (ARBs). Subjects of African descent tend to have low renin hypertension, and may not respond to beta-blockers or ACE inhibitors. Drugs can be selected for their beneficial effects on coexistent problems, e.g. angina or arrhythmia (beta-blockers, CCAs), heart failure (ACE inhibitors, certain beta-blockers), previous myocardial infarction (ACE inhibitors, beta-blockers) or nephropathy (ACE inhibitors, ARBs).
- Over two-thirds of people with diabetes need combinations of two or more antihypertensive drugs to control hypertension. Effective combinations include beta-blocker plus CCAs; ACE inhibitor/ARB plus diuretic (non-potassium-sparing); and CCA plus ACE inhibitor/ARB.

## Introduction

Hypertension often accompanies diabetes mellitus, both type 1 (T1DM) and type 2 (T2DM). The association between the two conditions has long been recognized. In 1923, the Swedish physician Eskil Kylin described a syndrome of diabetes, hypertension and hyperuricemia [1], which are now regarded as aspects of the broader “metabolic syndrome” that has been linked to insulin resistance (IR) [2,3]. The relationship between diabetes and hypertension is complex. Both are common and so are likely to be associated by chance, but in some instances, they may have a common cause; moreover, hypertension can develop as a consequence of diabetic nephropathy, while some drugs used to treat hypertension can induce diabetes in susceptible subjects.

Hypertension is important because, like diabetes, it is a major cardiovascular risk factor and one that synergizes with the deleterious effects of diabetes. It is also a risk factor for microvascular complications: nephropathy and retinopathy. The management of hypertension in diabetes has been widely debated, and there is still a need to agree on treatment targets and strategies. During the last decade, several well-constructed trials have added considerably to the evidence base [4–8], demonstrating convincingly the benefits of lowering blood pressure (BP), but also highlighting how difficult this can be to achieve in practice.

## Size of the problem

Hypertension is widely defined according to the World Health Organization/International Society of Hypertension (WHO/ISH) criteria (Table 40.1). People with diabetes are still at risk of macrovascular and microvascular complications at BP levels below these thresholds, and the treatment target range is therefore lower (130–140/80–85 mmHg).

Overall, hypertension (according to the WHO criteria) is up to twice as common in people with diabetes as in the general population [9]. In white Europeans, 10–30% of subjects with T1DM and 60–80% of those with newly diagnosed T2DM are hypertensive [10]. There are racial and ethnic differences in the prevalence of hypertension, which presumably are at least partly genetically determined: for example, hypertension (and macrovascular disease) is less frequent among the Pima Indians and Mexican-Americans [11]. Impaired glucose tolerance (IGT) is also associated with hypertension (20–40% of cases), perhaps reflecting the common origins of these aspects of the metabolic syndrome [12].

There is evidence that the true prevalence of hypertension is increasing in the diabetic population (especially T2DM) after allowing for the greater number of cases identified through improved screening and the lowering of thresholds for treatment of BP [13]. The causes probably include the rising prevalence of obesity and longer survival of older people with diabetes.

**Table 40.1** Criteria for hypertension and related tissue damage, defined by the World Health Organization (WHO) and the International Society for Hypertension, 1999 [33].

Category	Systolic (mmHg)	Diastolic (mmHg)
<b>WHO criteria for the general population*</b>		
Optimal	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Grade 1 hypertension (mild)	140–159	90–99
Subgroup: borderline	140–149	90–94
Grade 2 hypertension (moderate)	160–179	100–109
Grade 3 hypertension (severe)	≥180	≥110
Isolated systolic hypertension	≥140	<90
Subgroup: borderline	140–149	<90
<b>Hypertension-related tissue damage (WHO criteria)</b>		
Grade I: none		
Grade II: subclinical damage (e.g. retinopathy, proteinuria)		
Grade III: clinical damage (e.g. heart failure, ischemia)		
<b>Degree of proteinuria</b>		
Microalbuminuria: 30–300 mg/24 hours (20–200 mg/min)		
Macroalbuminuria: >300 mg/24 hours (>300 mg/min)		

\* Desirable blood pressure limits in the diabetic population are suggested in Figure 40.6.

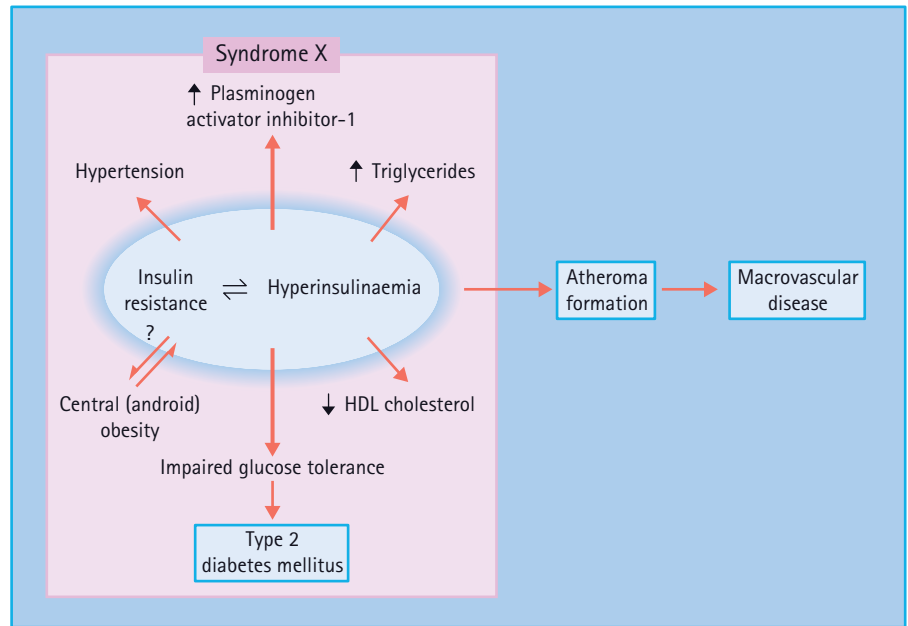

## Causes of hypertension in diabetes

Associations between hypertension and diabetes are listed in Table 40.2. Essential hypertension and isolated systolic hypertension are both common in the non-diabetic population (especially in the elderly). It is estimated that essential hypertension accounts for about 10% of cases in people with diabetes. Other important causes are the hypertension that coexists with IR, obesity and IGT in the metabolic syndrome, and hypertension secondary to diabetic nephropathy, as discussed in detail below.

### Hypertension in the metabolic syndrome

This syndrome consists of IR, IGT (including T2DM), a characteristic dyslipidemia – hypertriglyceridemia, low high-density lipoprotein (HDL) cholesterol, and raised low density lipoprotein (LDL), with an excess of small dense LDL particles – truncal obesity, procoagulant changes (raised plasminogen activator inhibitor 1 and fibrinogen levels) and hyperuricemia [2,14,15]. As these abnormalities are all risk factors for atherogenesis, the syndrome is completed by a marked tendency to vascular aging leading to macrovascular disease, especially coronary heart disease (CHD) and stroke (Figure 40.1). As discussed in Chapter 11, IR has been proposed by Reaven [2], DeFronzo and Ferrannini [14] and others [15] to be a fundamental cause of hypertension and cardiovascular disease (CVD) as well as T2DM. IR is partly genetically determined, and acquired factors such as obesity,

**Figure 40.2** Hypertension is associated with insulin resistance. Insulin sensitivity, measured as the metabolic clearance rate (MCR) of glucose during an insulin clamp study, is inversely related to the mean 24-hour systolic and ambulatory blood pressure. Reproduced from Pinkney *et al.* [17], with permission from the Editor.

physical inactivity and perhaps malnutrition *in utero* and during early infancy may also contribute [16]. In support of the latter, family studies have revealed a correlation between the BP of the mother and her offspring that appears to be non-hereditary in origin; early growth retardation is suggested to program abnormal development of the vasculature as well as the tissues that regulate glucose homeostasis.

IR is closely associated with high BP in both humans and animals. Experimental induction of IR (e.g. feeding rats with fructose) is accompanied by a rise in BP. More persuasively, an inverse relationship has been demonstrated in humans between BP and insulin sensitivity [17] (Figure 40.2). Various mechanisms have been proposed to explain how IR and/or the hyperinsulinemia that accompanies it could increase BP (Figure 40.3). First, there is some evidence that insulin is an endothelium-dependent vasodilator, releasing nitric oxide (NO) from the endothelium, which relaxes vascular smooth muscle [18,19]; blunting of this

**Figure 40.3** Possible mechanisms of hypertension in conditions of insulin resistance. NO, nitric oxide.

effect, caused by insensitivity to the action of insulin on the endothelium as well as on metabolically important tissues, could contribute to the increased peripheral resistance that is the hallmark of hypertension in obesity and T2DM. Impaired endothelium-mediated vasodilatation is associated with IR states and may have a key role in the initiation and progression of atherosclerosis [20].

By contrast, insulin also has several actions that tend to raise BP, and there is some evidence that these are accentuated in IR states, presumably because sensitivity is preserved to the effects of the raised insulin levels. Insulin acts on the distal renal tubule to retain  $\text{Na}^+$  ions and water [20,21], an effect that still operates in IR subjects [22], and so could contribute to the rise in total body  $\text{Na}^+$  content that occurs in obesity and T2DM [23]. Insulin also stimulates the cell membrane  $\text{Na}^+-\text{K}^+$  ATPase, which would raise intracellular  $\text{Na}^+$  concentrations in vascular smooth muscle and, by increasing systolic  $\text{Ca}^{2+}$  levels, would enhance contractility and increase peripheral resistance [22,23]. Through its effects on the

CNS, insulin may stimulate the sympathetic outflow. Theoretically, this could also increase BP, although direct evidence in humans is lacking [22,24]. Finally, insulin may stimulate the proliferation of vascular smooth muscle cells, which could lead to medial hypertrophy and increased peripheral resistance [22,25].

### Hypertension and diabetic nephropathy

This association is most obvious in young patients with T1DM, in whom the presence of hypertension is strikingly related to renal damage and even minor degrees of proteinuria. BP begins to rise when the urinary albumin excretion (UAE) enters the microalbuminuric range ( $>30 \text{ mg}/24 \text{ hours}$ ) and is usually over the WHO threshold when UAE reaches the macroalbuminuric stage ( $>300 \text{ mg}/24 \text{ hours}$ ) [26]. The association may be partly genetically determined: subjects with diabetes and microalbuminuria commonly have parents with hypertension and may also inherit overactivity of the cell-membrane  $\text{Na}^+-\text{H}^+$  pump (indicated by increased  $\text{Na}^+-\text{Li}^+$  counter-transport in red blood cells),

which would tend to raise intracellular  $\text{Na}^+$  concentrations and thus increase vascular smooth muscle tone [27].

The basic mechanisms of hypertension include decreased  $\text{Na}^+$  excretion with  $\text{Na}^+$  and water retention. Peripheral resistance is increased, to which raised intracellular  $\text{Na}^+$  will contribute. The role of the renin angiotensin aldosterone system (RAS) is uncertain, as both increased and decreased activity has been reported [28,29]. These discrepancies may be explained by differences in diet, treatment, metabolic control and the type and duration of diabetes.  $\text{Na}^+$  retention and hypertension would be predicted to suppress the RAS, while renin levels may be influenced by other complications of diabetes: renal tubular acidosis type 4 causes hyporeninemic hypoaldosteronism and neuropathy can also lower plasma renin, while renin may be raised in retinopathy and advanced nephropathy. Patients with microalbuminuria who are insulin-resistant appear to be particularly susceptible to hypertension [30].

### Impact of hypertension in diabetes

A large proportion of hypertensive people with diabetes show signs of cardiovascular aging and target-organ damage [10]. Hypertension, as an independent risk factor for atherogenesis, synergizes with the effects of diabetes and significantly increases the development and progression of CHD, cerebrovascular and peripheral vascular disease. Overall, the effects of hypertension on deaths from CHD are increased by 2–5 times in people with diabetes, with the greatest increase occurring at the lowest BP levels (Figure 40.4).

**Figure 40.4** Synergistic effects of diabetes and hypertension on deaths from coronary heart disease (CHD). Data from 342 815 people without diabetes and 5163 people with diabetes aged 35–57 years, free from myocardial infarction at entry. Reproduced with permission from O. Vaccaro, paper presented at the 26th Annual Meeting of the European Diabetes Epidemiology Group, Lund, 1991.

The deleterious effects of hypertension on left ventricular function are also accentuated by the presence of diabetes. These include impaired left ventricular relaxation [31] and increased left ventricular mass [32], the latter being an independent predictor of premature death from CHD.

Hypertension also predisposes to the development of certain microvascular complications, particularly nephropathy and end-stage renal failure (ESRF), for which the risk is increased by 2–3 times (see Chapter 37). Hypertension is also a risk factor for retinopathy, as has been confirmed by the beneficial effects of improved BP control in patients with T2DM, reported by the UK Prospective Diabetes Study (UKPDS) [4].

### Screening for hypertension in diabetes

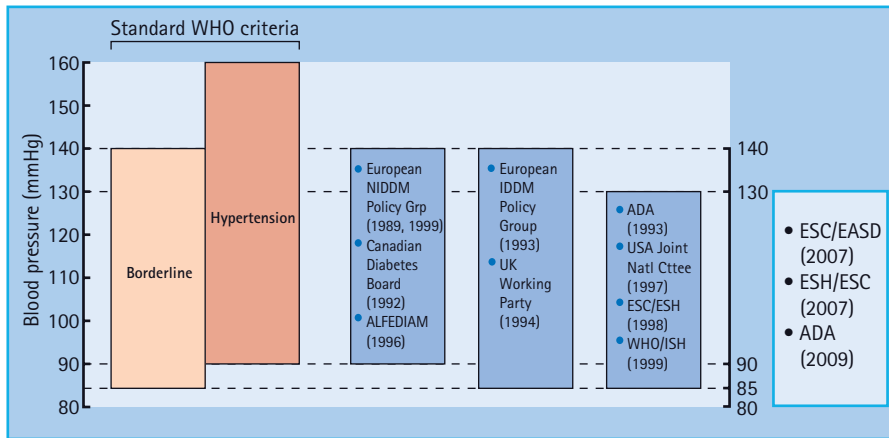

As the two conditions are so commonly associated, people with diabetes must be regularly screened for hypertension and vice versa. Hypertensive patients, especially if obese or receiving treatment with potentially diabetogenic drugs, should be screened for diabetes at diagnosis and during follow-up. Should hyperglycemia be detected, potentially diabetogenic antihypertensive drugs should be reduced or changed to others or used in combinations that do not impair glucose tolerance, and normoglycemia can then often be restored.

All people with diabetes should have their BP checked at diagnosis and at least annually thereafter. This is especially important in those with other cardiovascular risk factors, such as nephropathy (which is associated with a substantial increase in the cardiovascular mortality rate), obesity, dyslipidemia, smoking or poor glycemic control.

### Measurement of blood pressure

BP should be measured with the patient in the supine or sitting position, with an accurate sphygmomanometer and a cuff of appropriate size (i.e. wider for obese subjects with an arm circumference of >32 cm). Systolic and diastolic BP should be recorded, to the nearest 2 mmHg if using a manual sphygmomanometer, from phases I and V (i.e. appearance and final disappearance of the sounds of Korotkoff). Usual precautions should be taken to ensure reliability and avoid “white coat” stress effects which can acutely raise BP. Conditions should be quiet and relaxed, and at least two readings should be taken initially and then repeated at intervals over weeks or months to determine the subject’s typical values and any trend to change. Office BP could be complemented by repeated home BP recordings.

BP should also be checked with the patient in the upright position (1 minute after standing), because there may be a significant postural fall (>20 mmHg systolic) in patients with diabetic autonomic neuropathy, the elderly or those treated with vasodilators or diuretics. Marked postural hypotension, which can coexist with supine hypertension, may indicate the need to change or reduce antihypertensive medication, especially if symptoms are provoked.

**Figure 40.5** Blood pressure treatment targets suggested for subjects with diabetes, compared with the World Health Organization/International Society of Hypertension definition of hypertension and borderline hypertension [34]. ALFEDIAM, Association de langue française pour l'étude du diabète et des maladies métaboliques; ADA, American Diabetes Association; ESC, European Society of Cardiology; EASD, European Association for the Study of Diabetes; ESH, Europe Society of Hypertension.

Ambulatory BP monitoring over 24 hours may be useful in some cases to exclude “white coat” effects, and in patients with early nephropathy who have nearly normal BP during the day, but who may be at risk of hypertensive tissue damage because they fail to show the physiologic BP dip during sleep [33].

### Diagnosis of hypertension in diabetes

The criteria issued in 1999 by WHO and ISH [34] define hypertension as an office BP exceeding 140/90 mmHg (Korotkoff I–V), and borderline hypertension as being below these limits but above 130 mmHg systolic and/or 85 mmHg diastolic (Figure 40.5) [34]. Established hypertension is diagnosed when readings consistently exceed 140/90 mmHg over several weeks, or when the BP is very high (diastolic BP >110 mmHg), or when there are clinical signs of tissue organ damage from long-standing hypertension.

It is clear from numerous epidemiologic studies that the WHO/ISH threshold is too high in people with diabetes because of their additional risk of both macrovascular and microvascular disease, and that there are definite benefits from treating microalbuminuric subjects whose diastolic BP is <90 mmHg [35]. Various other expert bodies have suggested alternative, generally lower target levels (Figure 40.5). A consensus would be to aim for a BP of less than 130–140 mmHg systolic and below 80–85 mmHg diastolic, and to treat any subject whose BP is consistently above one or both of these thresholds.

### Investigation of hypertension in diabetes

Initial investigation of the hypertensive patient with diabetes aims to exclude rare causes of secondary hypertension (Table 40.2), to assess the extent of tissue organ damage caused by hypertension and diabetes (Table 40.1) and to identify other potentially treatable risk factors for vascular disease. The major points in the medical history and examination are shown in Table 40.3.

• *Cardiac function.* A standard 12-lead electrocardiogram may show obvious ischemia, arrhythmia or left ventricular hypertro-

**Figure 40.6** Renal artery stenosis affecting the right kidney, in a patient with diabetes and hypertension. Uptake of the isotope on this side is markedly reduced and delayed.

phy; the latter is more accurately demonstrated by echocardiography, which will also reveal left ventricular dysfunction and decreased ejection fraction. Exercise testing (or stress-echo) testing and 24-hour Holter monitoring may also be appropriate.

• *Renal function.* A fresh urine sample should be tested for microalbuminuria (see Chapter 37) and another examined microscopically for red and white blood cells, casts, and other signs of renal disease. Microscopic hematuria can occasionally occur in patients with T1DM (particularly children) in the apparent absence of significant renal dysfunction, but coexistent renal disease must always be excluded. Serum urea, creatinine and electrolytes should be checked. If the serum creatinine concentration is raised, measurement of the glomerular filtration rate (GFR) should be considered, ideally using a specific clearance method such as chromium ethylenediamine tetra-acetic acid (Cr-EDTA), iohexol or cystatin C. Further specialist investigations that may be needed include an isotope renogram and other tests for renal artery stenosis (Figure 40.6). This complication of renal

Fasting lipids	
<b>Urinary tests</b>	
(Micro-)albuminuria	

arterial atherosclerosis may affect up to 20% of older patients with T2DM and, if bilateral, can lead to severe and sometimes permanent renal impairment if angiotensin-converting enzyme (ACE) inhibitors are given.

• **Lipid profile.** Fasting serum lipid concentrations should be checked. If total cholesterol or triglyceride levels are found to be elevated after repeated measurements, further investigation of lipoprotein subclasses – very low density lipoprotein (VLDL), LDL, HDL, as well as the apo-B:apo-A1 lipoprotein ratio – is recommended. Treatment for hyperlipidemia should be considered if the total cholesterol is >4.5 mmol/L, the LDL cholesterol level is >2.5 mmol/L or the LDL:HDL cholesterol ratio is >4 [36]. This is discussed in more detail in the second half of this chapter.

Other forms of secondary hypertension may be indicated by clinical findings of endocrine or renal disease, significant hypokalemia (plasma potassium <3.5 mmol/L without previous diuretic treatment), failure of hypertension to respond to standard treatment or a sudden decline in GFR after starting treatment with ACE inhibitors (suggestive of renal artery stenosis).

## Management of hypertension in diabetes

Strict BP control is the primary goal of treatment. In recent years, target treatment levels have declined progressively to the current recommendation of a mean office BP less than 130–140/80–85 mmHg, for all patients who can tolerate this without side effects such as orthostatic reactions or compromising arterial circulation in critical vascular beds. Recent observations indicate that subgroups of susceptible patients might exist who will not tolerate a dramatic BP reduction below 130 mmHg systolic BP and so caution should be exercised.

Management begins with lifestyle modification, but few patients respond to this alone, and most will require more than one antihypertensive drug to control BP adequately [4,5].

### Non-pharmacologic treatment

The treatment of hypertension in patients with diabetes must be based on structured lifestyle intervention. This means weight reduction or weight stabilization in the obese, sodium restriction, diet modification and regular physical exercise (moderate intensity, 40–60 minutes, 2–3 times weekly). Dietary intake of saturated fat has been associated with impaired insulin sensitivity and should therefore be reduced [37]. Alcohol should be restricted to 2–3 units/day in men and 2 units/day in women, but omitted altogether if hypertension proves difficult to control.

Smoking causes an acute increase in blood pressure and greater variability overall [38]. Smoking cessation is especially important, as smoking not only accelerates the progression of atherosclerosis and vascular aging, but also impairs insulin sensitivity [39] and worsens albuminuria [40]. Treatment with nicotine supplementation for 4–6 weeks (chewing gum or patches), bupropion or varenicline may be useful.

When adopted in full by the patient, lifestyle modification can be extremely effective. The above measures can lower systolic and diastolic BP by 11 and 8 mmHg, respectively [41] – as much as many antihypertensive drugs – and sometimes enough to obviate the need for drug therapy. Weight reduction in obese patients can similarly reduce BP.

### Antihypertensive drug therapy

Numerous drugs are available to lower BP, but some are better suited than others to the particular needs of subjects with diabetes because of their favorable or neutral effects on glucose metabolism and other factors. Most patients (at least two-thirds) will require combinations of antihypertensive drugs to control BP – an average of around three different drugs in two large studies [4,5]. Accordingly, the clinician must be able to use a wide variety

of antihypertensive drugs and to choose combinations that exploit pharmacologic synergy. Combination therapy usually means that lower dosages of individual drugs can often be used, thus reducing the risk of their adverse effects.

### Diuretics

Diuretics are often effective antihypertensive agents for people with diabetes, in whom the total body sodium load is increased and the extracellular fluid volume expanded [42]; however, diuretics that increase urinary potassium and magnesium losses can worsen hyperglycemia, as insulin secretion is impaired by potassium depletion, and insulin sensitivity in peripheral tissues may also be decreased [43]. The use of high-dose thiazide diuretics – equivalent to  $\geq 5$  mg/day bendroflumethiazide (bendrofluazide) – is reported to increase the risk of hypertensive patients developing diabetes by up to threefold; this does not seem to occur with low dosages (up to 2.5 mg/day bendroflumethiazide) [44]. Potassium depletion is particularly severe with high-dose chlorthalidone (chlorthalidone), less with furosemide (frusemide) and bendroflumethiazide and apparently negligible with indapamide. This mechanism is irrelevant to C-peptide-negative subjects with T1DM who are totally dependent on exogenous insulin. Thiazides may also aggravate dyslipidemia [45], although low dosages probably carry a small risk. Thiazides have also been associated with gout and impotence and are generally avoided in middle-aged men with diabetes and hyperuricemia or erectile dysfunction; nevertheless some evidence suggests that the risk of erectile failure may have been overstated. Diuretics may precipitate hyperosmolar hyperglycemia syndrome and should be avoided or used at the lowest effective dose in patients with a history of this complication.

Diuretics have been shown to prevent CVD successfully in elderly subjects with T2DM and systolic hypertension [46], but one observational study suggested that the use of diuretics increased cardiovascular mortality in hypertensive patients with T2DM who were still hyperglycemic in spite of treatment [47]. Overall, these drugs are effective and safe when used appropriately in patients with diabetes.

Diuretics suitable for use in diabetic hypertension include furosemide, bendroflumethiazide ( $\leq 2.5$  mg/day), hydrochlorothiazide, spironolactone and indapamide. Low dosages should be used, sometimes in combination with potassium supplements or potassium-sparing drugs, such as amiloride. If ineffective, diuretics should be combined with another first-line drug (e.g. an ACE inhibitor or an angiotensin II-receptor antagonist [ARB]), rather than given at increased dosage. Spironolactone is best not combined with an ACE inhibitor, as this increases the risk of hyperkalemia. Furosemide is useful in patients with renal impairment (serum creatinine  $>150$   $\mu\text{mol/L}$ ) or edema.

Serum urea, creatinine and potassium should be checked when starting diuretic therapy and every 6–12 months thereafter, as dangerous disturbances in plasma potassium levels can develop, especially in patients with diabetes and renal impairment.

### $\beta$ -Adrenergic blocking agents

Beta-blockers may significantly lower BP levels in patients with diabetes and hypertension, even though renin release (a major target for these drugs) is commonly reduced in diabetes because of  $\text{Na}^+$  and fluid retention. These drugs are often ineffective in Afro-Caribbean patients, who commonly have low renin hypertension. Other mechanisms of action that reduce BP include reductions in heart rate and cardiac output via interaction with  $\beta_1$ - and  $\beta_2$ -receptors in the myocardium and in the vessel wall.

Like diuretics, beta-receptor blockers may aggravate both hyperglycemia and dyslipidemia [48]. These effects depend on both the dosage and the degree of selectivity of the individual drug. The hyperglycemic effect is attributed to inhibition of  $\beta_2$ -adrenergic-mediated insulin release and decreased insulin action in peripheral tissues; the long-term risks of a person without diabetes developing the disease may be increased by sixfold [49] and even more if given together with thiazides. Some studies suggest that the hazards of both hyperglycemia and hyperlipidemia have been exaggerated and may be both dose-dependent and secondary to weight gain [50]. The metabolic side effects of beta-blockers can be reduced by using low dosages combined with other agents, particularly dihydropyridine calcium channel antagonists (CCAs), or by intensifying non-pharmacologic efforts to decrease weight and improve physical activity.

Beta-blockers have other side effects relevant to diabetes. They may interfere with the counter-regulatory effects of catecholamines released during hypoglycemia, thereby blunting manifestations such as tachycardia and tremor and delaying recovery from hypoglycemia [51]. In clinical practice, however, this rarely presents a serious problem, especially when cardioselective  $\beta_1$ -blockers are used. Beta-blockers may also aggravate impotence, and are generally contraindicated in second- or third-degree atrioventricular (AV) heart block, severe peripheral vascular disease, asthma and chronic airway obstruction. Recent studies have shown that certain beta-blockers such as metoprolol and carvedilol [52,53] can be used favorably in cardiac failure in patients with diabetes, as shown in the Metoprolol CR/XL Randomized Intervention Trial in congestive heart failure (MERIT-HF) study, in which 25% of the patients had diabetes [52].

Atenolol is a commonly used drug, as it is cardioselective and water soluble, which reduces CNS side effects and renders its metabolism and dosage more predictable. It is mostly effective as a single daily dose, which probably encourages compliance. In the UKPDS, its effect was comparable to that of the ACE inhibitor, captopril [54]; however, it should be kept in mind that the stroke preventive effect of atenolol is 16% less than other antihypertensive drugs, based on data from meta-analyses. Metoprolol is an alternative, in moderate dosages. Both non-selective and selective beta-blockers are effective in the secondary prevention of myocardial infarction (MI) after an initial event in patients with diabetes [55]. Metoprolol or carvedilol may be indicated in patients who also have heart failure [52,53], and beta-blockers

in general are useful in patients who also have angina or tachyarrhythmias.

### **Calcium-channel antagonists**

These useful vasodilator agents do not generally worsen metabolic control when used at conventional dosages, although sporadic cases of hyperglycemia have been reported after starting a calcium-channel antagonist (CCA) of the dihydropyridine class [56]. This may be caused by inhibition of insulin secretion (a calcium-dependent process) in susceptible patients, or a compensatory sympathetic nervous activation, which antagonizes both insulin secretion and action, following vasodilatation.

CCAs have a slight negative inotropic effect and are contraindicated in significant cardiac failure; they often cause mild ankle edema, but this is caused by relaxation of the peripheral precapillary sphincters and raised capillary pressure rather than to right ventricular failure. Because of their potent vasodilator properties, these drugs can cause postural hypotension and can aggravate that brought about by autonomic neuropathy. Non-dihydropyridine CCAs (e.g. verapamil) reduce proteinuria in diabetic nephropathy, but this effect is not seen with dihydropyridine derivatives such as nifedipine, amlodipine, felodipine and isradipine [57].

Because of their other cardiac actions, these drugs are particularly indicated in hypertensive patients who also have angina (e.g. sustained-release nifedipine and diltiazem) or supraventricular tachycardia (e.g. verapamil). Their vasodilator properties may also be beneficial in peripheral vascular disease. CCAs are ideally combined with selective  $\beta_1$ -blockers, but the specific combination of verapamil and beta-blockers (especially together with digoxin) must be avoided because of the risk of conduction block and asystole. Overall, CCAs appear less or similarly cardioprotective but better at preventing stroke than either beta-blockers or thiazide diuretics [58,59].

Amlodipine given once daily is an evidence-based and convenient preparation for general use, and felodipine, isradipine and sustained-release nifedipine are suitable alternatives.

### **Angiotensin-converting enzyme inhibitors**

ACE inhibitors may be used in diabetic hypertension, even in cases where the general RAS is not activated as the drugs may interfere with local angiotensin action in specific target tissues. When used alone, however, these agents have a limited hypotensive action in many black patients, who tend to have suppressed RAS activity.

ACE inhibitors have no adverse metabolic effects and may even improve insulin sensitivity [60]; hypoglycemia has rarely been reported [61]. These drugs are particularly beneficial in diabetic nephropathy by reducing albuminuria and possibly delaying progression of renal damage [62]. Their antiproteinuric effect may be caused specifically by relaxation of the efferent arterioles in the glomerulus, which are highly sensitive to vasoconstriction by angiotensin II, thus reducing the intraglomerular hypertension

that is postulated to favor albumin filtration; however, the importance of this mechanism remains controversial [63]. ACE inhibitors are also indicated in cardiac failure, in combination with relatively low dosages of diuretics.

A dry cough is reported by 10–15% of patients treated with ACE inhibitors, because these drugs also interfere with the breakdown of kinins in the bronchial epithelium. Changing to another ACE inhibitor or an ARB may avoid this problem. ACE inhibitors occasionally precipitate acute renal failure, particularly in the elderly and in subjects taking non-steroidal anti-inflammatory drugs (NSAIDs), or who have bilateral renal artery stenosis. Other side effects (rashes, neutropenia, taste disturbance) are unusual with the low dosages currently recommended, but become more prominent in renal failure. Because ACE inhibitors cause potassium retention, they should not generally be taken concurrently with potassium-sparing diuretics (spironolactone and amiloride) or potassium supplements. Serum creatinine and potassium levels should be monitored regularly, especially in patients with renal failure or type 4 renal tubular acidosis, in whom hyperkalemia can rapidly reach dangerous levels.

Ramipril, enalapril, captopril, lisinopril and perindopril are all established ACE inhibitors that are suitable for use in people with diabetes; enalapril, lisinopril, perindopril and ramipril are given once daily for hypertension. The first dose of an ACE inhibitor should be small and taken just before bedtime to minimize postural hypotension, which may be marked in subjects receiving diuretics or on a strict sodium-restricted diet. The same problem may arise in patients with autonomic neuropathy. ACE inhibitors are now recommended in patients with left ventricular dysfunction following MI (see Chapter 41). Ramipril has been shown to prevent cardiovascular morbidity and mortality in high-risk patients with diabetes, with or without pre-existing ischemic heart disease [64].

### **Angiotensin II type 1 receptor blockers**

This promising new class includes losartan, irbesartan, valsartan, candesartan and telmisartan, which act on the AT1 receptor to decrease BP. They are metabolically neutral [65] and, unlike the ACE inhibitors, do not cause cough. They are effective antihypertensive drugs in people with diabetes [66] and have been shown to slow the progression of nephropathy in patients with diabetes and varying degrees of albuminuria (in the RENAAL, IDNT and PRIME-2 studies) [67–69]. Losartan has also been shown (in a subgroup of the LIFE study) to be better than atenolol in reducing both cardiovascular endpoints (by 25%) and total mortality (by 40%) in high-risk patients with T2DM with hypertension and left ventricular hypertrophy [70]. Interestingly, the combination of an ACE inhibitor (lisinopril) with an AT1-antagonist (candesartan) was more effective than either agent alone in lowering BP and UAE in patients with T2DM [71]; however, in the recent ONTARGET study, no extra benefits were recorded for the combination of telmisartan and ramipril on cardiovascular endpoints compared to monotherapy [72].

**Figure 40.7** Treating hypertension slows the progression of diabetic nephropathy. Lowering blood pressure significantly decreased the rate of decline in the glomerular filtration rate (GFR) and urinary albumin excretion. Reproduced from Parving *et al.* [79], with permission.

**α<sub>1</sub>-Adrenoceptor antagonists**

α<sub>1</sub>-Blockers can lower BP effectively and also improve dyslipidemia and insulin sensitivity. Doxazosin is normally well tolerated, especially in combination therapy; side effects include nasal congestion and postural hypotension. Doxazosin has been reported to be inferior to the diuretic chlorthalidone in the prevention of stroke and heart failure [73].

**Treatment strategies**

In general, lifestyle modification should be tried initially for 3 months or so. If moderate hypertension (diastolic BP >100 mmHg, or systolic BP >160 mmHg) or signs of hypertensive tissue damage

are present, then drug therapy should be started at the outset. Initially, monotherapy with one of the first-line drugs suggested above should be used, the choice being influenced by other factors such as coexistence of angina, heart failure or nephropathy. All drug treatment should aim for being evidence-based and cost-effective in the individual patient.

**Hypertension in T1DM**

ACE inhibitors are especially suitable if the patient has albuminuria or more advanced stages of diabetic nephropathy. Diuretics, β<sub>1</sub>-selective blockers and CCAs are equally valid alternatives with regard to BP reduction.

If renal function is moderately impaired (serum creatinine values  $>150\mu\text{mol/L}$ ), thiazide diuretics become less effective, and furosemide or other loop diuretics should be used instead; however, in established ESRF (serum creatinine  $>500\mu\text{mol/L}$ ) furosemide may be toxic, and dialysis must be started. In some patients, hypoglycemia attacks may be masked by use of beta-blockers.

### Hypertension in T2DM

BP control is generally more important than the choice of individual drugs. First-line agents, according to evidence from clinical studies, are ACE inhibitors, ARBs, beta-blockers, low-dose thiazide diuretics (in the elderly), furosemide and CCAs [4–8].

Ramipril has evidence-based support for its use in patients with T2DM because of their high cardiovascular risk [64]. Beta-blockers (in combination with low-dose aspirin) are indicated as secondary prevention for patients who have had a MI, as long as no serious contraindications are present. Low doses of thiazide diuretics are useful in elderly patients with diabetes, as this class of drugs has proven efficacy in preventing stroke and all-cause mortality in elderly hypertensive patients [8].

$\alpha_1$ -Blockers may be used as part of combination therapy, especially in patients with dyslipidemia (high triglycerides and low HDL cholesterol levels) and prostatic hyperplasia. Indapamide is well tolerated and has no metabolic side effects. Spironolactone may also be of value [74], especially for elderly obese female patients with hypertension and hypervolemia with a low renin profile.

### Combination therapy

Combination therapy is needed in most people with diabetes (especially those with T2DM) to achieve satisfactory BP control [4,5]. It is often better to use low dose combinations than to increase dosages of single agents, as side effects are commonly dose-dependent. As already mentioned, potassium-sparing agents (spironolactone and amiloride) should not be combined with an ACE inhibitor, because of the increased risk for hyperkalemia.

Certain combinations of antihypertensive drugs have proved very safe and effective in low to moderate doses, e.g. ACE inhibitor plus diuretic, for example in the ADVANCE study [75]; CCA plus ACE inhibitor, for example in the ACCOMPLISH study [76]; selective  $\beta_1$ -blocker plus CCA; or  $\beta_1$ -blocker plus  $\alpha_1$ -blocker. In some high risk patients a combination treatment could also be considered as initial therapy.

### Special considerations in ethnic groups

Hypertension in diabetes represents a serious medical problem in many ethnic groups, such as African-Americans [77]. In non-white European patients, beta-blockers and ACE inhibitors are often less effective at lowering BP because the RAS is already underactive. Diuretics and CCAs are often drugs to be preferred, particularly in African-Americans [78].

## Outcome of treating hypertension in diabetes

It has long been recognized that effective treatment of hypertension can slow the progression of diabetic nephropathy, lowering UAE and decreasing the rate of fall of the GFR [79] (Figure 40.7).

The assumptions that improved BP control would improve cardiovascular and other prognoses in T2DM have been confirmed by the UKPDS [4]. In this study, tighter BP control (averaging 144/82 mmHg) for over 8 years led to significant improvements in several outcomes, compared with less strict control that averaged 154/87 mmHg (Table 40.4). Interestingly, the most powerful effects were related to microvascular complications (retinopathy and nephropathy), although significant reductions were seen in the risk of stroke (44%) and heart failure (56%). MI and peripheral vascular disease showed non-significant reductions (Table 40.4; Figures 40.8 and 40.9).

Overall, therefore, tight BP control has been proven to provide substantial benefits for hypertensive patients with diabetes. Moreover, this treatment strategy seems to be cost-effective, at least according to the health economics analyses in the UKPDS [80]; however, it must be kept in mind that these benefits will not last if a continuous BP reduction cannot be achieved long-term, as shown by the 10-year follow-up of the UKPDS [81].

## Conclusions

The diagnosis and treatment of hypertension is of great importance for the person with diabetes [34,36,82–84]. The treatment targets are demanding and require considerable effort from both patient and physicians, but the benefits are now undisputed.

New antihypertensive drugs are constantly being introduced but have to prove themselves for both efficacy and tolerability. Even some antidiabetic drugs appear to lower BP as well as blood glucose [85], but safety concerns are important (see Chapter 29).

In the future, the application of cardiovascular genomics may substantially change the approach to treating hypertension in

**Table 40.4** Impact of stricter control of hypertension on diabetic complications, macrovascular disease and diabetes-related deaths in T2DM. Data from the UKPDS [4].

Measure	Relative risk with tight control (mean, 95% confidence intervals)	P value
Diabetes-related deaths	0.76 (0.62–0.92)	0.19
All-cause mortality	0.82 (0.63–1.08)	0.17
Myocardial infarction	0.79 (0.59–1.07)	0.13
Stroke	0.56 (0.35–0.89)	0.013
Peripheral vascular disease	0.51 (0.19–1.37)	0.17
Microvascular disease	0.63 (0.44–0.89)	0.009

**Figure 40.8** Kaplan–Meier curves for the primary outcome and all-cause mortality in the two study groups in the ADVANCE Trial [74]. The combined primary outcome were composites of major macrovascular and microvascular events. Major macrovascular events were cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke. Major microvascular events were new or worsening nephropathy or retinopathy.

diabetes [86], aiming at tailoring treatment according to the genotype of the individual patient.

In addition, further large-scale studies with large numbers of hypertensive patients with T2DM are awaited [87]. In the recent ACCORD-Blood pressure study [88] there was no significant difference in the primary composite outcome of cardiovascular events between patients randomized to achieve a systolic blood pressure goal below 120 mmHg versus below 140 mmHg, even if

a reduction in stroke was noticed (secondary end-point) in the intensive arm. This means that the optimal blood pressure goal for patients with hypertension and T2DM is still not established [89].

Finally, it takes a multifactorial approach to address and to treat all major cardiovascular risk factors, not only BP, to achieve lasting cardiovascular protection, as evidenced by the Steno-2 trial [90].

**Figure 40.9** Treating hypertension improves the prognosis in T2DM. (a) Stricter BP control (mean pressure 144/82 mmHg) significantly reduced the risks of both microvascular complications (*top*) and diabetes-related death (*bottom*), compared with less strict control (mean 154/82 mmHg). (b) The relationship between BP and rates of microvascular disease and MI. Lowering the BP progressively reduced the risk of microvascular complications, but there was no significant effect on MI. The red line represents MI and the yellow line represents microvascular complications. Reproduced from UKPDS [4,91], with permission.

## Dyslipidemia: Diabetes Lipid Therapies

Adie Viljoen<sup>1</sup> and Anthony S. Wierzbicki<sup>2</sup>

### Keypoints

- The greatest long-term risk in diabetes is cardiovascular disease (CVD), with macrovascular disease being the cause of 80% of mortality in people with diabetes.
- Epidemiologic studies have established that glycemic control, nephropathy and lipids are risk factors for CVD in type 1 diabetes.
- Low density lipoprotein (LDL) cholesterol, high density lipoprotein (HDL) cholesterol, smoking and hypertension are the principal risk factors in type 2 diabetes mellitus (T2DM).
- In T2DM, optimized glycemic control has modest effects in reducing CVD endpoints.
- Reduction of LDL cholesterol with statins has consistently shown cardiovascular event reductions >30%.
- The dyslipidemia of T2DM is associated with elevated triglycerides, reduced HDL cholesterol and small dense particles.
- Fibrates, when used as monotherapy, have shown a modest reduction in events in T2DM in the FIELD study.
- Post hoc analysis of the Coronary Drug Project with niacin suggests possible benefits on cardiovascular endpoints.
- Trials now underway will allow the efficacy of combination lipid-lowering therapies in diabetes to be determined.
- Optimal control of all risk factors can reduce cardiovascular events and mortality in diabetes by 50%.

## Introduction

An association between diabetes and heart disease was described more than a century ago. Two decades later, in 1906, it was hypothesized that this association was caused by atherosclerosis. The importance of diabetes as a cardiovascular disease (CVD) risk factor became established following the Framingham Study and this was subsequently confirmed by other landmark studies [1,2]. The magnitude of diabetes as a CVD risk factor is substantial, with the increase in cardiovascular risk being two- to fourfold. Many guidelines regard diabetes as a coronary heart disease (CHD) risk equivalent [3–5]. This concept is based originally on a Finnish cohort [6], which showed comparable risk of CHD outcomes such as myocardial infarction (MI) and CHD death between subjects with type 2 diabetes mellitus (T2DM) for >10 years and subjects with established CHD (Figure 40.10). This was still apparent after adjusting for known risk factors such as age, sex, hypertension, total cholesterol and smoking. The Organization to Assess Strategies for Ischemic Syndromes (OASIS) study showed that patients with diabetes and no previous CVD have the same long-term morbidity and mortality as patients with

established CVD but no diabetes after hospitalization for unstable coronary artery disease (CAD) [7]; however, there is a wide variation in the rate of CHD in diabetes which depends on the population studied, duration of diabetes, as well as existing risk factors [8,9]. This equivalence has not been confirmed by a subsequent study and it also seems less valid in older subjects where those with existing CHD have a greater risk than non-CHD patients with diabetes [9,10]. Most of the literature that reports on CVD risk and diabetes only considers T2DM. Even though people with type 1 diabetes mellitus (T1DM) are clearly at increased risk for CVD [11,12], no study has specifically examined whether subjects with T1DM have a CVD risk that is comparable or higher than those with T2DM. In T1DM there may even be a higher risk of premature CVD. In a cohort of 292 patients with T1DM followed for 20–40 years, the cumulative mortality rate from CAD was 35% by age 55 [11]. As T1DM mostly presents at an earlier age, it remains more difficult to assess and compare this but rates of CVD are increased at all ages [13].

Concomitant CVD risk factors also differ according to the type of diabetes. For example, those with T1DM have a two- to three-fold increase in risk of developing CHD and stroke in later life. This risk is notably increased in those developing diabetic neph-

**Figure 40.10** Equivalence of cardiovascular risk in patients with previous coronary heart disease (CHD) and those with diabetes. MI, myocardial infarction. Reproduced from Haffner *et al.* [6], with permission from Massachusetts Medical Society.

ropathy. Other markers of CVD risk in people with diabetes include diabetic retinopathy, autonomic neuropathy, erectile dysfunction, microalbuminuria and proteinuria [14].

In general, people with diabetes have a two- to fourfold CVD risk compared with the non-diabetic population [15]. Even though guidelines do not recommend formal CVD risk estimation in those with diabetes because of the significant risk these patients already have and the tendency of the Framingham algorithm to underestimate risk in this group, clinicians may still opt to estimate the risk by employing various risk calculators of which the UK Prospective Diabetes Study (UKPDS) is the most used [16]. It should be noted however, that these risk calculators predict risk with variable accuracy [17]. As all methods of CVD risk estimation suffer from distinct limitations, clinical judgment remains necessary to assess risk accurately and select and titrate appropriate treatment [18,19].

## Cardiovascular disease risk factors in diabetes

### Glucose

A risk continuum exists across a broad glucose concentration range which incorporates individuals without diabetes, with the risk of CVD being the lowest when the fasting blood glucose is 4–4.9 mmol/L [20–22]. Despite the well-established association between blood glucose and atherosclerosis, surprisingly few studies have been able to show an improvement in cardiovascular outcome by reduction in blood glucose. In T1DM, the Epidemiology of Diabetes Interventions and Complications (EDIC) study [23] which followed subjects after the completion the Diabetes Control and Complications Trial found that glucose lowering was associated with a long-term benefit with regard to cardiovascular complications that became apparent only years after recruitment. In T2DM, 10-year follow-up data from the UKPDS intensive glucose therapy showed long-term beneficial

**Figure 40.11** Results of the UK Prospective Diabetes Study (UKPDS) at 10 years follow-up. Reproduced from Holman *et al.* [24], with permission from Massachusetts Medical Society.

**Figure 40.12** Effects of improved diabetes control to an HbA<sub>1c</sub> <6.5% (48 mmol/mol) in the ACCORD and ADVANCE studies. CVD, cardiovascular disease; Lo, intensive glycaemic control; Hi, conventional glycaemic control. Data from ACCORD group *N Engl J Med* 2008; **358**:2545 and ADVANCE group *N Engl J Med* 2008; **358**:2560.

effects on macrovascular outcomes [24]; however, unlike the microvascular benefits, risk reductions for MI and death from any cause were observed only with extended post-trial follow-up (Figure 40.11). These results suggested that improved glucose control may result in a larger cardiovascular risk reduction in patients with T1DM than among those with T2DM, which is consistent with the results of one meta-analysis. Furthermore, neither the recent Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation (ADVANCE) [25] nor the Action to Control Cardiovascular Risk in Diabetes (ACCORD) [26] trials, each including in excess of 10 000 participants, could not show a significant beneficial effect on CVD outcome when targeting near-normal glucose levels in T2DM as determined by a HbA<sub>1c</sub> <6.5% (48 mmol/mol) (Figure 40.12). More worrying was the finding in the ACCORD trial that

near-normal glucose control was actually associated with a significantly increased risk of death from any cause and death from cardiovascular causes, the very outcomes the trial was designed to prevent [27]. Several other outcomes trials are underway, which should improve our understanding of the problem of glycemic control and CVD [28].

### Dyslipidemia

Compared with hyperglycemia, targeting dyslipidemia has proven much more effective in preventing the macrovascular complications of diabetes; however, for many years the benefits of intervention on lipoproteins as cardiovascular risk factors in diabetes were uncertain. The principal reason was that people with diabetes were excluded from trials of lipid-lowering therapies. Thus, virtually no data exist from early studies with bile acid sequestrants, fibrates or nicotinic acid.

The reasons for the excess CVD risk in diabetes are numerous and varied and in part relate to the lipid abnormalities seen in diabetes. Enhanced glycation of lipoproteins has direct effects on lipoprotein metabolism as glycated lipoproteins are handled differently by lipoprotein receptors, particularly of the scavenger group, thus promoting atherogenesis [29]. Enhanced glycation also amplifies the effects of oxidative stress on lipoproteins and therefore affects both T1DM and T2DM [30]. The term diabetic dyslipidemia refers to the lipid abnormalities typically seen in persons with T2DM and is synonymous with atherogenic dyslipidemia [31,32]. It is characterized by elevated triglyceride-rich remnant lipoproteins (routinely measured as hypertriglyceridemia), small dense LDL particles and low HDL cholesterol concentrations. Several factors are likely to be responsible for diabetic dyslipidemia: insulin effects on liver apolipoprotein production, downregulation of lipoprotein lipase (LPL) as opposed to hepatic lipase, increased cholesteryl ester transfer protein (CETP) activity, and peripheral actions of insulin on adipose and muscle.

### Low density lipoprotein cholesterol

LDL cholesterol is identified as the primary target of lipid-lowering therapy. Analysis of the UKPDS showed that LDL cholesterol was the strongest risk factor for CHD in this population and HDL cholesterol was the second strongest [33]. Even relatively modern studies discouraged recruitment or restricted entry to patients with hypercholesterolemia and reasonable glycemic control ( $HbA_{1c} < 8\%$  [64 mmol/mol]) as in the Scandinavian Simvastatin Survival Study (4S) [34]. Only recently have studies been performed recruiting large groups of people with T2DM. The 4S trial included only 202 people with diabetes out of 4444 participants. In this small group of subjects, simvastatin therapy was associated with a 55% reduction in major CHD (fatal and non-fatal CHD) ( $P = 0.002$ ) compared with a 32% reduction in major CHD in subjects without diabetes [35]. It was concluded that the absolute benefit of cholesterol lowering in patients with diabetes may be greater than that in patients without diabetes because the patients with diabetes have a higher absolute risk of atherosclerotic events

and CHD. This notion was later confirmed in several other studies that also recruited people with diabetes as a subgroup [36].

A number of studies have been specifically performed with statins in diabetes. Most notable of these were the Collaborative Atorvastatin Diabetes Study (CARDS) [37] and the Heart Protection Study (HPS) [38] where subjects were randomized in a double-blind placebo-controlled fashion to 10 mg/day atorvastatin in CARDS and to 40 mg/day simvastatin in the HPS. This produced, respectively, a 40% and 33% reduction in LDL cholesterol associated with a 37% and 31% reduction in combined cardiovascular endpoints. The HPS is the largest statin study to date and included a subgroup of 5963 patients with diabetes (29% of the total study group) [39]. The CARDS trial only included people with diabetes and more than one additional risk factor (e.g. uncontrolled hypertension and/or microalbuminuria) but without prior overt CVD. The study was terminated 2 years prematurely having shown unexpected early benefit. By contrast, the Atorvastatin Study for Prevention of Coronary Heart Disease Endpoints in Non-Insulin-Dependent Diabetes Mellitus (ASPEN) study of similar design to CARDS and also using atorvastatin showed a non-significant 15% reduction in events [40]. In end-stage diabetes with renal failure, aggressive LDL cholesterol reduction reduced events by a non-significant 8% despite a 41% reduction in LDL cholesterol [41]. Thus, the benefits of statin therapy seem to occur early in disease in diabetes.

Overall, the accumulated evidence therefore supports the efficacy of statin therapy in reducing cardiovascular risk in patients with diabetes. A meta-analysis, which evaluated the efficacy of cholesterol-lowering therapy in 18 686 people with diabetes in 14 randomized trials of statins, reported a 9% proportional reduction in all-cause mortality and a 21% proportional reduction in major vascular events per 1 mmol/L reduction in LDL cholesterol (Figure 40.13) [42].

There are few data on diabetes and other drugs that reduce LDL cholesterol as people with diabetes were excluded from trials of bile acid sequestrants. The cholesterol absorption inhibitor, ezetimibe, works by reducing the upper intestinal cholesterol

**Figure 40.13** Comparison of the effects of reducing low density lipoprotein (LDL) cholesterol on cardiovascular events in patients with and without diabetes. Reproduced from Cholesterol Treatment Trialists Collaborators. *Lancet* 2005; **366**:1267–1278, with permission from Elsevier.

absorption to produce in monotherapy a 20–25% reduction in LDL cholesterol and, in contrast to bile acid sequestrants, it has remarkably little effect on other lipid fractions. People with diabetes were excluded from the Simvastatin Ezetimibe Aortic Stenosis study [43]. More recently, it has received several potential setbacks with respect to surrogate marker measurements as well as pointers of potential detrimental effects [44]. Two ongoing trials, the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT), in which simvastatin plus ezetimibe is compared with simvastatin plus placebo, and the Study of Heart and Renal Protection (SHARP) trial, in which simvastatin plus ezetimibe is compared with placebo, will hopefully provide answers to these questions.

### Low density lipoprotein subfractions

The LDL class comprises a heterogeneous population of particles [45]. LDL is heterogeneous with respect to lipid composition, charge, density, and particle size and shape. The sizes of LDL particles fall between the large triglyceride-enriched very low density lipoprotein (VLDL) particles and the dense and small protein-rich HDL. In addition, these small dense LDL particles may be more atherogenic than would be suspected by their concentration alone, because *in vitro* and cell culture studies suggest they may be more readily oxidized and glycated. Oxidized LDL delivers cholesterol to the atherosclerotic plaque in an unregulated way through uptake by the macrophage and is increased in diabetes [46].

Another aspect is the fatty acid composition of the LDL particle. Linoleic acid is the main polyunsaturated fatty acid in the LDL particle, and this is increased in diabetes. The reason for this may be because of the decreased activity of the insulin sensitive enzyme, 5 $\alpha$ -desaturase. There is a strong correlation between linoleic acid in the LDL particle and propensity of the LDL particle to be oxidized. Uncontrolled diabetes results in increased free radical formation which leads to increased oxidation. The fact that the LDL particles are smaller and denser means that they carry relatively less cholesterol per particle. Estimation of the LDL cholesterol may therefore be misleading as there will be more LDL particles for any cholesterol concentration.

Large numbers of studies, including the Quebec Cardiovascular study [47], have confirmed the association of small dense LDL with CVD which reported that men with small dense LDL particles had an increased risk of CAD compared with men with normal-sized LDL particles, independent of LDL cholesterol, triglyceride and the total cholesterol:HDL cholesterol ratio; however, no prospective studies have specifically examined whether altering particle size profiles results in benefits on cardiovascular events although analysis of the Veterans Affairs High Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) study does suggest some role for this mechanism [48].

Even with effective LDL cholesterol treatment, the residual risk of further cardiovascular events remains high, emphasizing the importance of improving other abnormalities and other CVD risk factors commonly observed in these patients.

### Triglycerides

The reason for the elevated triglycerides in diabetes is complex, however, because of this derangement, it has been suggested that diabetes should not be called mellitus but rather lipidus [49]. Defects in insulin action and hyperglycemia can lead to changes in plasma lipoproteins in patients with diabetes. Alternatively, especially in the case of T2DM, the obesity and insulin-resistant metabolic disarray that are at the root of this form of diabetes could, themselves, lead to lipid abnormalities exclusive of hyperglycemia [32]. This molecular interplay between lipid and carbohydrate metabolism has led to what might be termed a “lipocentric” view of the pathogenesis of insulin resistance and T2DM [50]. As fatty acids have such a central role in insulin sensitivity, obesity and T2DM, it follows that the major disturbance in lipoprotein metabolism in diabetes is found in the triglyceride-rich lipoproteins, stemming from abnormalities in chylomicron synthesis and clearance [51].

Triglycerides (also referred to as triacylglycerol) are formed from a single molecule of glycerol combines with three fatty acids and represent a heterogeneous group of molecules which most frequently are measured collectively, as a “family” of analytes [52]. Elevated serum triglyceride levels are associated with increased risk for atherosclerotic events [53,54]. As high serum triglyceride levels are associated with abnormal lipoprotein metabolism, as well as with other cardiovascular risk factors including obesity, insulin resistance, diabetes and low levels of HDL cholesterol, it becomes more difficult to distinguish between cause and effect and to establish hypertriglyceridemia as an independent cardiovascular risk factor. Some causes of hypertriglyceridemia have no apparent effect on atherosclerotic vascular disease, making it difficult to prove that elevated triglycerides are a risk factor [55]. Nevertheless, several meta-analyses have found that triglycerides are an independent risk factor for CHD [54,56,57].

The two main sources of plasma triglycerides are exogenous (i.e. from dietary fat) carried in chylomicrons and endogenous (from the liver) and carried in VLDL particles. In capillaries within fat and muscle tissue, these lipoproteins and chylomicrons are hydrolyzed by LPL into free fatty acids. LPL is activated by apolipoprotein C-II, cleaving the triglyceride core and releasing free fatty acids, which can be oxidized by muscle for energy or kept in adipose tissue for future use, and inhibited by the action of apolipoprotein C-III [58]. In routine clinical practice, hypertriglyceridemia is the most frequent lipoprotein abnormality found in uncontrolled diabetes. The mechanisms for these include increased production or absorption, or reduced catabolism (mainly because of decreased activity of LPL). Liver apolipoprotein B production (the major protein component of VLDL and LDL) is increased in T2DM. This is indirectly brought about by increased lipolysis which occurs in adipose tissue, a consequence of insulin resistance and/or insulin deficiency. The increased lipolysis results in increased fatty acid release from fat cells with increase in fatty acid transport to the liver. Studies in tissue cultures, animal experiments [59] and humans [60] suggest that fatty acids modulate liver apolipoprotein B secretion.

Microsomal triglyceride transfer protein (MTP) assembles the chylomicron in the intestine and the VLDL particle in the liver. MTP has been shown to be increased in the intestine of subjects with diabetes [61]. Cholesterol absorption also seems to be adversely influenced in subjects with diabetes. The Niemann–Pick C1-like 1 protein, which has a critical role in the absorption of cholesterol, is increased in people with diabetes. The ATP-binding cassette transporters ABC-G5 and ABC-G8 dimerize to form a functional complex necessary for efflux of dietary cholesterol and non-cholesterol sterols from the intestine and liver. These proteins have been shown to be reduced in diabetes in both liver and intestine. LPL is an insulin-dependent enzyme being responsible for the conversion of lipoprotein triglyceride into free fatty acids. It has several other activities relating to lipid and carbohydrate metabolism [62]. Both patients with T1DM and T2DM have reduced LPL activity which is further suppressed by adipose-derived cytokines such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and interleukin 6 (IL-6) [32].

Statins form the mainstay of lipid management based on their efficacy in lowering LDL cholesterol, but their effects on components of the atherogenic dyslipidemia associated with T2DM are more modest, reducing triglycerides at most by 15–30% and raising HDL cholesterol typically by less than 10%. There is no clear consensus on the benefits of directly targeting hypertriglyceridemia [63]. As the interventions usually affect both triglycerides and HDL cholesterol, it also becomes more difficult to distinguish between the individual benefits.

### Fibrates

The “fibrate” class of lipid-lowering drugs is useful for lowering elevated triglyceride or non-HDL cholesterol levels as these agents, which act on peroxisomal proliferator-activated receptor  $\alpha$  (PPAR $\alpha$ ), increase lipoprotein lipase activity, reduce apolipoprotein C-III and may increase HDL cholesterol or decrease fibrinogen [64]. Despite this, clinical trials of these drugs have reported mixed results in general, and most early trials recruited only a few patients with diabetes [65,66].

The VA-HIT study evaluated the potential benefits of gemfibrozil in 2531 men with an acute MI. Patients with relatively low LDL cholesterol (<3.6 mmol/L) and low HDL cholesterol (<1.0 mmol/L) were recruited. A significant reduction in the primary endpoint (fatal and non-fatal MI) of 22% was achieved [67]. One-third of participants had T2DM. These outcomes were achieved despite relatively small changes in HDL cholesterol (8%) and no change in LDL cholesterol (0%). An exploration of the effect of gemfibrozil showed that the principal effect of the fibrate treatment was a 31% reduction in triglycerides which reflects changes in particle sizes, but was not related to event reduction [68]. A subgroup analysis of the subjects with diabetes showed a relative risk reduction of 32% compared to 18% in the non-diabetic group [69], however, the enthusiasm for fibrate use has been considerably dampened by results of the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study [70]. This trial randomized 9795 subjects with T2DM to fenofibrate

**Figure 40.14** Reductions in mortality, coronary heart disease (CHD) and cardiovascular events with fenofibrate therapy in the FIELD study. HDL, high density lipoprotein; LDL, low density lipoprotein; TC, total cholesterol; TG, triglycerides. Reproduced from Keech *et al.* [70], with permission from Elsevier.

(200 mg/day) or placebo who were not on statin treatment at the beginning of the study, and participants in the trial were treated for 5 years. The study reported a non-significant 11% reduction in the primary endpoint of CHD although a significant reduction in total cardiovascular events was achieved with fenofibrate therapy ( $P = 0.035$ ) (Figure 40.14). The study was confounded by asymmetrical statin drop-in with many more patients on placebo arm being initiated on statin therapy during the trial (17%) than those on the fenofibrate arm (8%) [65]. It is therefore difficult to compare fibrate trials as they seem to give heterogeneous results depending on the compound used, and no fibrate trials have shown to reduce all cause mortality. Nevertheless, meta-analyses suggest they may reduce non-fatal MI [71]. It is hoped that the ACCORD trial, which randomized fenofibrate in addition to baseline 20–40 mg simvastatin, can provide more definitive answers.

### Niacin

Nicotinic acid (niacin) is another potential drug to address the combination of hypertriglyceridemia and low HDL cholesterol. Because of its favorable effects on LDL cholesterol, it has been referred to as the “broad-spectrum” lipid drug [72]. Nicotinic acid was the first lipid-lowering agent to show a significant reduction in cardiovascular events, but not in mortality. The Coronary Drug Project randomized 3908 men with previous MI to either nicotinic acid or placebo [73]. Major CHD events, non-fatal MI and cerebrovascular events were reduced, but there was no effect on mortality; however, in the 15-year post-trial follow-up, nearly 9 years after termination of the trial, mortality from all causes was 11% lower in the nicotinic acid group [74]. Several long-term clinical studies with niacin have since demonstrated a reduction in CHD events and mortality when used in combination with other lipid-modifying drugs which include: colestipol (a bile acid sequestrant) [75], fibrate [76] and statins [77]. Unfortunately,

**Figure 40.15** Reduction in coronary heart disease in patients with a fasting plasma glucose >7 mmol/L from a post hoc analysis of the Coronary Drug Project. Reproduced from Canner *et al.* [81], with permission from Excerpta Medica.

niacin has been hampered by its side effects, particularly flushing, although strategies exist to reduce this [78], and by hyperglycemia [79]. No long-term outcome trials with niacin in people with diabetes have been conducted. Furthermore, niacin adversely affects glycemic control. This effect is related to the dose of nicotinic acid. The study of the effect of extended release niacin on diabetic dyslipidemia found that, at week 16, whereas the HbA<sub>1c</sub> did not change significantly in the 1 g group, in the 1.5 g group there was an increase from 7.2% (55 mmol/mol) to 7.5% (58 mmol/mol) [80]. Wider variations are seen in clinical practice [79]. Analysis of data from the Coronary Drug Project showed that regardless of how patients were grouped, niacin appeared as effective in lowering cardiovascular outcomes in patients with hyperglycemia as patients with normoglycemia (Figure 40.15) [81].

Guidelines are conflicting on the use of niacin in diabetes. The current position statement from the American Diabetes Association (ADA) suggests the use of nicotinic acid as an option in treating lipoprotein fractions other than LDL cholesterol [82]. It reports that only modest changes in glucose occur and that these are generally amenable to adjustment of diabetes therapy. A previous statement discouraged its routine use as do the recent National Institute for Health and Clinical Excellence (NICE) guidelines for management of diabetes in England and Wales [83]. Large outcome studies are currently underway. The Atherothrombosis Intervention in Metabolic syndrome with low HDL cholesterol/high triglyceride and Impact on Global Health outcomes (AIM-HIGH) hopes to report in 2011 [84]. The large Oxford-based outcome trial with extended release niacin/laropiprant (an inhibitor of prostaglandin receptor D1 which reduces the flushing), the Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) [85], includes 28 000 patients with cardiovascular disease or at high risk of developing it, including a pre-specified subgroup of 6000 with diabetes, and is scheduled to report in 2013.

### Other triglyceride-reducing agents

Hypoglycemic agents may also have an effect on triglyceride concentrations because of the peripheral actions of insulin on adipose and muscle or via their action on LPL. In poorly controlled T1DM and even ketoacidosis, hypertriglyceridemia and reduced HDL cholesterol is seen to occur, and this is most often corrected with insulin therapy. In T2DM, metformin [86], sulfonylureas [87] and acarbose [88] all show modest reductions in triglycerides which correlate with glycemic control [89,90]. In general, thiazolidinediones have better overall effects on lipids than sulfonylureas or insulin [91], but pioglitazone and rosiglitazone have distinctly different effects on the lipid profile [64,92]. Pioglitazone is associated with a reduction in triglycerides whereas rosiglitazone is associated with increased concentrations. Both medications raised LDL cholesterol, but the increase was significantly greater with rosiglitazone than pioglitazone. Pioglitazone did not significantly change apolipoprotein B levels but did reduce LDL particle concentration. Conversely, rosiglitazone increased both apolipoprotein B and LDL particle concentrations. Both medications increased HDL cholesterol, with pioglitazone having no effect on serum apolipoprotein AI levels while rosiglitazone was associated with a decrease in apolipoprotein AI levels. Differential effects on CVD outcomes in recent meta-analyses have recently been reported. Outcome data for rosiglitazone are awaited. In the Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycaemia in Diabetes (RECORD) trial, a prospective trial in patients with T2DM, no evidence for an increased cardiovascular event rate was found [93]. An outcome trial for pioglitazone, the PROspective pioglitAZone Clinical Trial in macroVascular Events (PROACTIVE) study, which added pioglitazone to the current treatment in patients with T2DM, showed that treatment with pioglitazone was associated with reductions in major atherosclerotic events as defined in the main secondary endpoint [94]. The differential effects on lipid profiles may in part explain the differences these two drugs have on CVD outcomes as reported by recent meta-analyses (Figure 40.16) [95,96].

A number of other existing interventions reduce triglycerides secondary to their action in reducing weight [97]. Orlistat has been shown to prevent progression to diabetes in the XENical in the prevention of diabetes in obese subjects (XENDOS) study [98], and both sibutramine [99] and rimonabant [100,101] (prior to their suspension) showed benefits on lipids in patients with the metabolic syndrome and diabetes. Rimonabant had a non-significant benefit on coronary atherosclerosis as assessed by intravascular ultrasound in line with its lipid effects [102,103].

### High density lipoprotein cholesterol

Analogous to LDL, the HDL class also comprises a heterogeneous population of particles. The inverse relationship between HDL cholesterol levels and atherosclerotic CVD provides the epidemiologic basis for the widely accepted hypothesis that HDL is atheroprotective [104,105]. Experimental studies, which include limited work on humans, have shown that HDL has several

**Figure 40.16** Effects of thiazolidinedione drugs on coronary heart disease (CHD) in trials using rosiglitazone and pioglitazone. CCF, congestive cardiac failure; CVD, cardiovascular disease; MI, myocardial infarction. Reproduced from Singh *et al.* *JAMA* 2007; **298**:1189, with permission from the American Medical Association.

distinct but potentially overlapping atheroprotective functions. These include the well-known reverse cholesterol transport [106] as well as reductions in oxidative stress and innate immune inflammation [107]. More HDL-associated proteins are involved in immune/inflammatory functions than in lipid transport and metabolism, suggesting the fundamental role for HDL in innate immunity [108]. There are several reasons that could account for the decrease in HDL cholesterol in diabetes [32]. CETP-mediated exchange of VLDL triglyceride for HDL cholesteryl esters is accelerated in the presence of hypertriglyceridemia [45]. The clinical laboratory measures the cholesterol component of HDL; substitution of triglyceride for cholesteryl ester in the core of the HDL particle therefore leads to a decrease in this measurement of HDL cholesterol. The triglyceride, but not cholesteryl ester, in HDL is a substrate for plasma lipases, especially hepatic lipase which converts HDL to a smaller particle being more rapidly cleared from the plasma. Precursors of advanced glycation end-products (AGEs) can also impair reverse cholesterol transport by HDL.

As opposed to LDL cholesterol lowering, therapies to intervene in order to raise HDL cholesterol have proven to be “not that simple.” Some HDL therapies may reduce CVD without actually changing HDL cholesterol concentrations [109]. The Intravascular Ultrasound Study (IVUS) of the effects of 5 weekly infusions of a hyperfunctional apolipoprotein A-1 (apoA-1)<sub>Milano</sub> produced significant regression of coronary atherosclerosis after 3 months. In contrast, in the Investigation of Lipid Level Management to Understand Its Impact in Atherosclerotic Events (ILLUMINATE) trial, which investigated the CETP inhibitor, torcetrapib, in 15 000 patients, HDL cholesterol increased by 72% and LDL cholesterol decreased by 25%, although this trial was terminated early as the treatment arm had an increase of major cardiovascular events by 25% and death from cardiovascular causes by 40%, possibly related to the hypertensive properties of this particular molecule [110].

Guidelines vary when it comes to treatment targets for HDL cholesterol, mostly because there is no evidence base for intervention at the moment [111]. The Joint British Societies Guidelines and NICE argue that there is no treatment target for HDL cholesterol as it is only modestly altered, and not independently of changes in other lipid variables in the clinical trials [5,83,112]. Furthermore, there are no drugs available yet that independently alter HDL cholesterol. The American Heart Association and the ADA suggest lowering triglycerides to below 1.7 mmol/L (150 mg/dL) and raising HDL to more than 1.15 mmol/L (40 mg/dL) [3,82,113]. In women, an HDL cholesterol goal of 0.3 mmol/L (10 mg/dL) higher than this should be considered.

### Future drug developments and drug targets

Drugs that target the exogenous and or the endogenous pathways of cholesterol metabolism may prove to be useful in the future [114,115]. These include Niemann–Pick C1-like 1 protein inhibitors, new PPAR agents and MTP inhibitors. Interventions that regulate fatty acid synthesis may also prove to be beneficial. Stearoyl-coenzyme A desaturase 1 catalyzes the synthesis of monounsaturated fatty acids and has emerged as a key regulator of metabolism [116]. Recent studies in human and animal models have highlighted that modulation of stearyl-coenzyme A desaturase 1 activity by dietary intervention or genetic manipulation strongly influences several facets of energy metabolism to affect susceptibility to obesity, insulin resistance, diabetes and hyperlipidemia. HDL mimetic therapies may also prove to be beneficial. Other CETP inhibitors are also still under investigation [117]. Although numerous drug classes have been devised, many, such as torcetrapib, have recently failed in late phase III trials even after showing good initial results on lipids in human and in animal models. Other drugs, such as rimonabant, have shown unfavorable side effect profiles which led to the suspension of marketing in the European Union. Given the importance of atherosclerosis as a cause of morbidity and mortality in diabetes, numerous therapeutic approaches are in development, and all will require systematic evaluation through endpoint clinical trials to validate their effects in animal models or on surrogate markers [103].

### Conclusions

CVD is a very common complication of diabetes. Up to 80% of all people with diabetes will die from macrovascular complications. Lifestyle intervention is both effective and paramount to prevent and treat diabetes and its dyslipidemia. Statins have revolutionized preventive cardiovascular medicine and this has formed the foundation of therapeutic lipid intervention (Figure 40.17). The abnormalities in lipids and lipoproteins represent only one factor among several that are responsible for the increased risk in persons with diabetes (Table 40.5) and therefore multifactorial intervention is required, and this reduces events and mortality by 50% (Figure 40.18) [118,119].

## Congestive Heart Failure

Inga S. Thrainsdottir<sup>1</sup> & Lars Rydén<sup>2</sup>

<sup>1</sup>Department of Cardiology, Landspítali University Hospital, Reykjavik, Iceland

<sup>2</sup>Department of Cardiology, Karolinska University Hospital, Stockholm, Sweden

### Keypoints

- There is a strong link between congestive heart failure (CHF), and diabetes and both conditions are becoming increasingly more common.
- The prevalence of the combination of CHF and diabetes was 0.5% in men and 0.4% in women increasing by age in a recent population-based study. Diabetes was found in 12% of those with CHF compared with only 3% of the controls without CHF.
- Diabetes is a serious prognostic factor for cardiovascular mortality in patients with left ventricular dysfunction caused by ischemic heart disease.
- A 1% (11 mmol/mol) reduction in glycated hemoglobin (HbA<sub>1c</sub>) has been found to reduce CHF by 16%. In this study, the prognosis improved with a decrease in HbA<sub>1c</sub> without any threshold or observed upper limit.
- Available data favor a proportionately similar efficacy of evidence-based CHF therapy in patients with and without diabetes. The impact expressed as number of patients needed to treat to avoid one event is lower among people with diabetes because of their higher absolute risk.
- Further studies have to be conducted before an aggressive glucose normalization can be recommended as a possibility to improve the prognosis in patients with diabetes and CHF.
- Thiazolidinediones can provoke or worsen CHF. These drugs should be used with great caution in patients with diabetes and heart failure.

### Introduction

The concept that there may be a direct relation between diabetes and congestive heart failure (CHF) is not new. In 1954, Lundbaek [1,2] published an article on clinically important complications in patients with diabetes underlining that heart disease was common in patients with diabetes; indeed, it was present in two-thirds of elderly subjects. He was the first to suggest the presence of a diabetes-specific cardiomyopathy. Twenty years later, Rubler *et al.* [3] published supporting data, concluding that myocardial disease seemed to be a complication of the diabetic state and not merely caused by coronary artery disease (CAD). Shortly thereafter, the Framingham study presented epidemiologic evidence for a strong relation between CHF and diabetes. The latter study clearly indicated that the relation between diabetes and CHF was not only caused by traditional risk factors for coronary heart disease (CHD), but also involved other mechanisms [4].

The prevalence of CHF is increasing in Western societies because of an aging population and also because of increased

survival following ischemic heart disease (IHD), and in particular myocardial infarction (MI) [5]. There are many known causes of CHF, including hypertension, CAD, valvular dysfunction, arrhythmias, anemia, renal failure and thyroid dysfunction [5–9]. Risk factors for the development of CHF include increasing age, valvular heart disease and IHD, particularly previous MI, electrocardiographic signs of left ventricular hypertrophy, cardiomegaly detected by chest X-ray, increased heart rate, hypertension and decreased pulmonary vital capacity; diabetes should be added to this list as a strong risk factor. The Framingham study used several of these risk factors to construct a multivariate risk formula to identify high-risk candidates for CHF [10].

Currently, IHD is the leading cause of CHF in industrialized societies with diabetes as a rapidly emerging risk factor for both CHF and IHD [8,11]. Considering the rapidly growing prevalence of diabetes [12], this means that the combination of diabetes and CHF will become increasingly more common in the future. Poor glucose control contributes to the development of CHF as reflected by the relation between an increase in glycated hemoglobin (HbA<sub>1c</sub>) and the risk of developing CHF [13]. In an epidemiologic study of an elderly Italian cohort, 9.5% of the participants had CHF and 14.7% diabetes. Interestingly, the prevalence of diabetes among subjects with CHF was high, almost 30%. The association was strengthened

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

during follow-up, indicating that CHF predicted the appearance of diabetes [14].

In summary, there is a strong link between the existence of CHF and diabetes, and both conditions are becoming increasingly more common. The links between these disorders are complex and not yet fully explored.

## Symptoms and diagnosis

### Diagnosis and definition of congestive heart failure

The state of the art diagnosis of CHF is based on a combination of clinical symptoms combined with characteristic signs of myocardial dysfunction [5]. In clinical practice, CHF is commonly divided into systolic and diastolic myocardial dysfunction, the latter also being known as heart failure with preserved left ventricular function, with systolic dysfunction representing an impaired capacity to eject blood from the left ventricle and diastolic dysfunction an impaired ventricular filling caused by relaxation abnormalities. Echocardiography is the preferred method for documentation of such dysfunction, and left ventricular ejection fraction is the most commonly used expression for impaired systolic dysfunction. Evidence of abnormal left ventricular relaxation, reduced diastolic distensibility or diastolic stiffness are the echocardiographic signs of diastolic dysfunction. Echocardiography, including tissue Doppler imaging (TDI), is useful in detecting myocardial diastolic dysfunction in people with diabetes as well as in the non-diabetic population [15,16]. Plasma concentrations of natriuretic peptides or their precursors are also helpful for diagnosing CHF in patients, including those with diabetes [5,17]. The main clinical classification of the severity of CHF is that presented by the New York Heart Association (Table 41.1). This classification is used for all patients with CHF irrespective if seen in a hospital or outpatient setting and irrespective of etiology.

### Diagnosis and definition of glucose abnormalities

Diabetes and other glucose abnormalities are a group of metabolic disorders characterized by hyperglycemia caused by defects in insulin secretion, insulin action or both. Diabetes is associated with damage, dysfunction and failure of various organs [18]. The metabolic syndrome is an entity that has been defined in various

ways [19,20], combining different cardiovascular risk factors including abnormalities in glucose homeostasis. Further details on the classification and diagnosis of different glucose abnormalities are given elsewhere in this book.

## Epidemiology

### Risk factors for CHF and diabetes

The most important risk factors for cardiovascular disease (CVD) and MI are family history, smoking, abnormal blood lipids, hypertension, diabetes, obesity and socioeconomic factors [21]. Many of the risk factors for CHF are by necessity similar to those for CVD, with IHD and hypertension as leading causes. Other common factors influencing the occurrence of CHF are male gender, smoking, overweight, physical inactivity and valvular heart disease [5]. Type 2 diabetes mellitus (T2DM) as well as poor glucose control observed as high fasting plasma glucose and elevated HbA<sub>1c</sub> are also of considerable importance [22–27].

Risk factors for T2DM are family history, age, overweight or increased waist:hip ratio and a sedentary lifestyle [28,29]. The morbidity is known to increase progressively with the number of existing risk factors [30]. Particular risk factors for CAD in T2DM are lipid perturbations, including small, dense, easily oxidized low density lipoprotein (LDL) particles, low high density lipoprotein (HDL) cholesterol and increased triglycerides. Moreover, poor glucometabolic control observed as high fasting plasma glucose and elevated HbA<sub>1c</sub> contribute [31]. Hypertension is another important factor. The Reykjavík Study showed a strong relation between fasting and post load glucose levels and subsequent risk for hypertension, even after adjustment for age, body mass index (BMI) and weight gain, which is interesting because hypertension is one of the main risk factors for CHF [24,25]. Patients with diabetes and CHF have more IHD, increased systolic blood pressure (BP), lower diastolic BP and a higher HbA<sub>1c</sub> than their counterparts without diabetes [26]. Accordingly, there are many mutual risk factors for CHF and glucose abnormalities.

### Prevalence of CHF and glucose abnormalities

The prevalence of CHF varies somewhat in different studies, partly because of differences in the definition of this disease [5]. The demand that a heart failure diagnosis should be supported by evidence of systolic dysfunction on echocardiography may be difficult to fulfill in epidemiologic studies. Modern echocardiographic techniques did not exist when several of the studies, still serving as important sources of information, were conducted [4,32]. The prevalence of CHF has been estimated to be 0.6–6.2% in Swedish men with an increase by age [32]. This is similar to the overall prevalence of CHF among both genders in the Rotterdam population and in the Reykjavík Study [33,34]. The prevalence of CHF was 1–10% in a British outpatient population [35]. It increases considerably when looking at elderly populations as exemplified by the Italian Campania study, in which the prevalence was 9.5%, once more underlining the impact of age [14].

**Table 41.1** Classification of congestive heart failure (CHF) according to New York Heart Association (NYHA).

NYHA Class I	No limitation of physical activities Patients without symptoms during ordinary activities
NYHA Class II	Slight to mild limitation of physical activity Patients comfortable at rest and mild exertion
NYHA Class III	Marked limitation of activity Patients comfortable only at rest
NYHA Class IV	Confined to complete rest in a bed or a chair

It has been estimated that at least 30% of patients with diabetes are undetected [20]. When screening a Belgian outpatient population with one known cardiovascular risk factor, diabetes was detected in 11% and an additional proportion of 3% had impaired glucose tolerance (IGT) [36]. The prevalence of diabetes was 7.8% in Swedish men and 5.1% in women aged 35–79 years with similar proportions reported from a Finnish middle-aged population [37,38]. The prevalence of diabetes may be considerably higher in selected high risk populations not the least those with CAD. In the Euro Heart Survey Diabetes and the Heart, patients admitted to hospital because of acute and stable CAD were investigated for the presence of diabetes and IGT. Only 29% of the 4961 patients had a normal glucose metabolism while 31% had known and 12% previously unknown diabetes. The remaining 28% of the patients had IGT [39]. Similar proportions were detected in patient populations with cerebral and peripheral vascular disease [40]. Thus, the combination of CVD and glucose perturbations is very common but underestimated in many previous studies because of lack of diagnostic accuracy in combination with a thorough investigation of the glucometabolic state.

Considerably less is known about the prevalence of the combination of diabetes and CHF. The most recent and extensive study of the prevalence of diabetes and CHF is that from the Reykjavík population [34], in which the prevalence of the combination of CHF and diabetes was 0.5% in men and 0.4% in women, increasing by age. Diabetes was found in 12% of those with CHF compared to only 3% of the controls without CHF. Thus, there was a strong association between diabetes and CHF (Figure 41.1).

Based on Framingham data, Rutter *et al.* [41] noted that the heart is prone to changes in the form of increased left ventricular mass and wall thickness with worsening glucose tolerance. Kannel *et al.* [4] and Gustafsson *et al.* [42] reported on the role of diabetes in CHF from a general and a hospitalized population, respectively. Their findings indicated a strong association between CHF and diabetes. Iribarren *et al.* [43], Bertoni *et al.* [44] and Nichols *et al.* [26], focusing on the role of CHF in patients

**Figure 41.1** Prevalence of congestive heart failure (CHF) in relation to glucometabolic state. Yellow bars, males; red bars, females; AGR, abnormal glucose regulation; DM, diabetes. Reproduced from Thrainsdottir *et al.* [34], with permission from American Diabetes Association.

with diabetes, noted that the prevalence of CHF varied between 1.9 and 22.3%. Finally, Amato *et al.* [14] found a strong association between diabetes and CHF in a population of elderly people. The outcomes of these studies have been summarized in Table 41.2.

### Incidence of CHF and glucose abnormalities

Recent results from the Framingham study indicate that the incidence of CHF has declined during the last five decades [45], but these data are not supported in other studies [46]. On the contrary, it seems that hospital admissions for CHF are increasing, resulting in higher health care expenditures for patients with this diagnosis [47]. Among British outpatients, the incidence of CHF has been reported to be 4.4/1000 person-years in men and 3.9/1000 in women, rising with age in both genders [48]. The incidence in Finland is similar among men, 4.0/1000 person-years, but lower in women 1.0/1000 person-years [49].

The age-standardized annual incidence of diabetes, reported to be 2.2 and 2.3/1000 person-years in Dutch men and women, respectively, is rather uniform in several European countries [50]. When turning to an elderly population, however, as in the Italian Campania study, the incidence was considerably higher at 6.1% per year. This is somewhat different from the observation in the Netherlands where the incidence decreased in the oldest age group [14,50].

Considerably less is known about the incidence of the combination of diabetes and CHF. Once more it seems as if the most recent and extensive study originates from the Reykjavík population. In this study, the age and gender standardized incidence of abnormal glucose regulation was 12.6/1000/year, diabetes 4.6/1000/year and CHF 5.3/1000/year (Figure 41.2). In addition, there was a strong association between the incidence of glucose abnormalities and CHF [51].

In the Framingham study, the incidence of CHF was twice that among males and five times higher in females with diabetes during 18 years of follow-up than patients free from diabetes. The excessive risk of CHF remained high even after the exclusion of patients with prior CAD [4]. In a general population of elderly Italians, the prevalence of diabetes was 9.6% per year in CHF patients [14].

## Pathophysiology

Myocardial structural and biochemical alterations can be identified in the failing heart, and many of them seems to be independent of the etiology of myocardial dysfunction. They include changes in myocardial energy production, altered expression of contractile proteins, a desynchronized excitation–contraction coupling,  $\beta$ -adrenergic receptor stimulation, myocyte depletion and increased activity of a number of cytokines. Many of these aberrations are found in diabetic heart. Here, some general features of the pathophysiology are followed by a discussion of more diabetes-specific factors.

### Congestive heart failure

CHF is a clinical syndrome originally induced by myocardial damage but subsequently influenced by the induction of an untoward neurohormonal response. Thus, norepinephrine, angiotensin II, endothelin and aldosterone are all linked to the vicious cycle of myocardial remodeling (Figure 41.3) which unopposed will cause successive deterioration of myocardial performance [52].

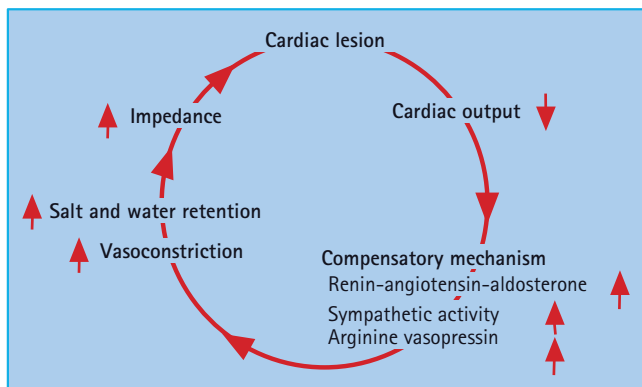

Metabolic conditions have a significant role in cardiac adaptation and remodeling. This leads to an increase of myosin heavy chain beta, altered troponin T (TnT) molecules, diminished

storage of creatinine phosphatases, and decreased sarcoplasmic ATPase activity, which may result in myocyte hypertrophy associated with impaired contractile function and less effective energy supply [53,54].

The myocardium has a high energy turnover with ATP as an important source of energy. The two pathways for energy supply are via the breakdown of free fatty acids (FFA) and of carbohydrates (Figure 41.4). The lipolytic pathway transfers FFA via  $\beta$ -oxidation to acetyl co-enzyme A (ACA), which enters the citric acid or Krebs cycle. The carbohydrate pathway produces pyruvate via glycolysis, glycogenolysis and lactate oxidation. Pyruvate is

**Figure 41.2** Incidence of abnormal glucose regulation, diabetes, congestive heart failure (CHF), abnormal glucose regulation and CHF, and diabetes and CHF expressed as number of incident cases/1000 person years among men (left) and women (right) by age. Reproduced from Thrainsdottir *et al.* [51], with permission from Oxford University Press.

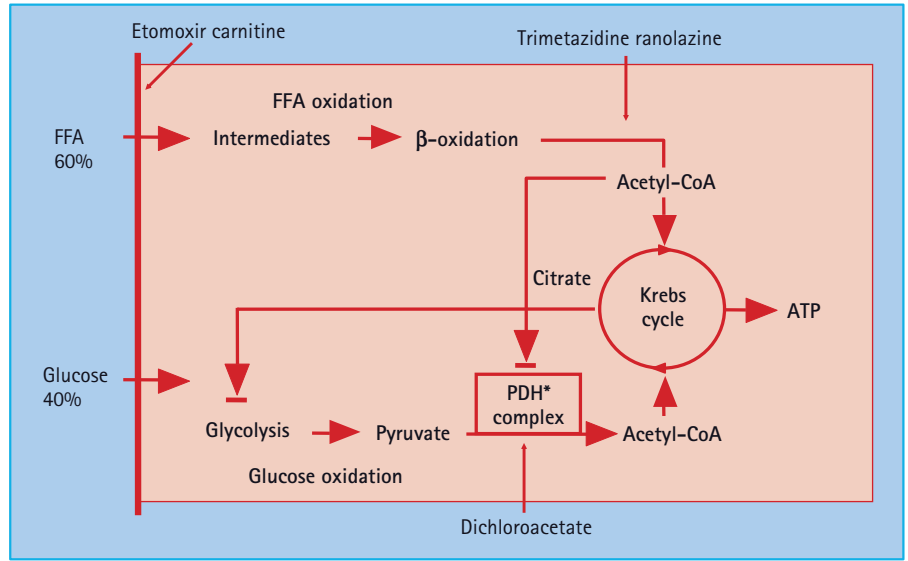

**Figure 41.3** Neurohormonal activation caused by depressed myocardial function leads to a vicious circle further compromising the already compromised myocardial function.

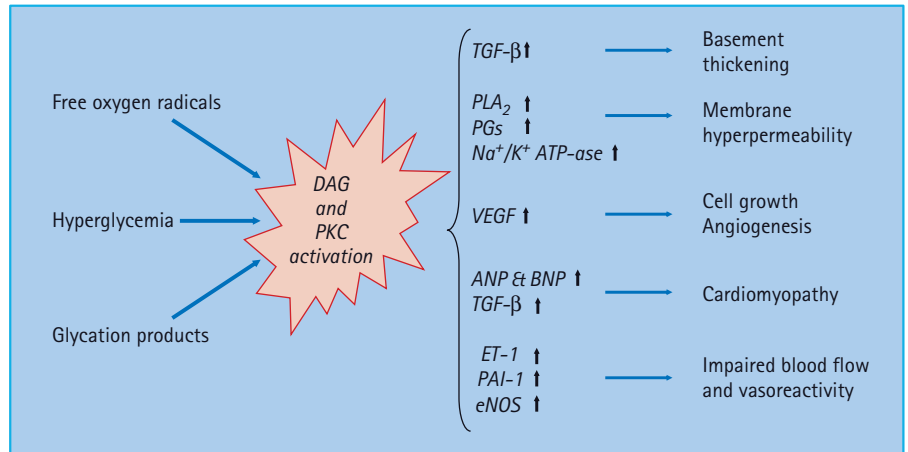

decarboxylated via pyruvate dehydrogenase to ACA, which enters the Krebs cycle. The dominant pathway for myocardial energy production is  $\beta$ -oxidation of FFA, but the myocardium is also dependent on glucose oxidation [55].

When the heart is subjected to ischemic stress or exposed to sustained enhancement of intraventricular pressure, it tends to change towards a more dominant glucose oxidation [56]. This may be counteracted by a reduction of the glucose transporter 4 (GLUT-4), which becomes reduced in CHF, hampering glucose transport over the cell membrane. At the same time, the heart is subjected to increased FFA concentrations, released via stress influenced by an increased sympathetic tone [57]. It is assumed that prolonged intracellular accumulation of FFA and its metabolites may cause myocardial dysfunction [58].

Besides these mechanisms, alterations in gene expression and inflammatory activity have been suggested to cause metabolic and mechanical disturbances in CHF [59–62]. All nucleated cells, including the cardiomyocyte, can produce pro-inflammatory cytokines as a response to injury such as MI, myocarditis or when the heart fails. Both tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and interleukin 6 (IL-6) levels increase in proportion to the severity and duration of CHF [59,60]. This cytokine release may trigger a cascade of events leading to myocardial structural alterations further deteriorating the clinical picture of CHF.

**Figure 41.4** Schematic illustration of myocardial energy production of relevance for congestive heart failure (CHF) patients with and without diabetes. **CHF and diabetes**

The main myocardial energy production is normally based on  $\beta$ -oxidation of FFA (70%) with a smaller contribution from glucose oxidation (30%) and lactate. FFA are produced by lipolysis of endogenous cardiac or exogenous stores of triglycerides. Oxidation of FFA is an effective supplier of energy in the form of ATP if the oxygen supply is sufficient. In conditions with limited oxygen availability, glucose oxidation will provide more energy per mole oxygen and support more work than FFA [63]. In the person with diabetes, glucose utilization for energy production is substantially lower, about 10% (Figure 41.4). The shift to an even more pronounced  $\beta$ -oxidation of FFA causes a higher oxygen utilization than under normal circumstances [64]. The major restriction to glucose utilization in the diabetic heart is the slow rate of glucose transport across the sarcolemmal membrane in the myocardium [65,66]. The impaired glucose oxidation in the diabetic heart can also result from a decreased rate of phosphory-

lation of glucose which subsequently limits the entry of glucose into the cell. The depressed phosphorylation is triggered by the increased metabolism of FFA [64]. Insulin deficiency enhances lipolysis thereby increasing circulating FFA [67]. People with diabetes are also known to have increased risk for other disturbances such as reduced myocardial blood flow and blunted hyperkinetic response to myocardial ischemia resulting in diminished myocardial function [68–71]. Indeed, CHF is an insulin-resistant state with an increased release of non-esterified fatty acids which are taken up in muscular tissue and downregulate glucose uptake and utilization [72].

Another consequence of hyperglycemia is oxidative stress and activation of processes triggered by an increased level of diacylglycerol and protein kinase C as depicted in Figure 41.5. Besides, many other unfavorable effects of the increased levels of inflammatory cytokines in heart failure patients may enhance insulin resistance [71,72].

---

## Prognosis

### CHF in general

During the past 30 years, mortality from CHD has declined markedly among patients free from diabetes. This decline has been substantially lower in men but is not seen in women with diabetes [73]. In the presence of CHF, the prognosis becomes poor [74]. In an English population, 1 month survival was 81% after incident CHF, declining to 57% after 18 months [8,75]. The annual mortality in a study of patients hospitalized for CHF was 10–20% with mild–moderate and 40–60% with severe symptoms [35]. The mortality in an elderly population with CHF recruited in Rotterdam was 47% during 6 years of follow-up. This is twice that of persons without CHF [74]. In a comparable Italian study, the mortality rate was 21.3% after 3 years [14]. Thus, CHF is a malignant disease irrespective of the underlying reason for myocardial dysfunction. Recent reports have been somewhat more encouraging. A 50-year follow-up of the Framingham data indicates that CHF survival has improved to some extent [45]. This observation is supported by a report based on the Swedish hospital discharge registry [76].

### Diabetes and CHF

CVD is the most prevalent complication of diabetes and is of major importance. Cardiovascular mortality in men with diabetes lies between the mortality for men with angina and MI [77]. In the USA, it has been estimated that 77% of all hospitalizations for chronic complications of diabetes are attributable to CVD [78]. T2DM doubles the risk of death from CHD, and T2DM diagnosed at the age of 55 years reduces life expectancy by about 5 years [79]. This makes mortality from CVD in people with diabetes but without previous MI similar to the mortality in patients with a history of MI but without diabetes [80].

The prognosis of patients with diabetes becomes even worse in the presence of CHF [81–84]. In the first DIGAMI study, performed in patients with diabetes and acute MI, CHF was the most common reason for morbidity and mortality, accounting for 66% of the total mortality during the first year of follow-up [85]. Diabetes is a serious prognostic factor for cardiovascular mortality in patients with left ventricular dysfunction caused by IHD [86]. In a general population in Reykjavik, the survival decreased significantly with the concomitant presence of both CHF and glucose abnormality even after adjustment for cardiovascular risk factors and IHD [87], which may serve as an indicator of the serious implication of the presence of diabetes along with CHF.

### Hyperglycemia and prognosis

The relationship between plasma glucose and mortality has been elucidated in several studies. According to the UK Prospective Diabetes Study (UKPDS), a 1% (11 mmol/mol) reduction in HbA<sub>1c</sub> is associated with a reduction of MI by 14% and CHF by 16%. In this study, the prognosis improved with a decrease in

HbA<sub>1c</sub> without any threshold or observed upper limit [88]. In the DECODE study, a 2-hour post load glucose was a better predictor of mortality than fasting blood glucose [89]. This may perhaps be seen as an indicator of the importance of post-prandial hyperglycemia and the potentially serious implication of IGT for myocardial function.

---

## Treatment

### General aspects

Evidence-based treatment of CHF relies on a combination of angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin receptor blockers (ARBs), beta-blockers, diuretics and aldosterone antagonists [5]. ACE inhibitors, ARBs and beta-blockers reduce mortality and improve symptoms in moderate to severe CHF with or without diabetes [90–93]. Diuretics are mandatory for symptomatic treatment of fluid overload, but should not be used in excess because they induce neurohormonal activation [94]. The addition of aldosterone antagonists is indicated in severe forms of CHF and may then improve longevity [95]; however, many patients are, although symptomatically improved, left with an unfavorable vital prognosis despite the best available pharmacologic treatment. A search for novel treatment modalities is therefore still ongoing. One of these is metabolic modulation with compounds that influence the disturbed metabolic pathways in CHF and which are thought to be of particular importance in patients with diabetes [55]. Attention has been paid to compounds that shift energy production from  $\beta$ -oxidation of FFA towards the energetically more efficient glucose oxidation under such conditions as in myocardial ischemia and CHF. Examples of such drugs are trimetazidine, ranolazine, etomoxir and dichloroacetate [96,97].

Various techniques have been used to study the efficacy of pharmacologic treatment in CHF. Among them are the general feeling of well-being as assessed by means of different questionnaires, and an estimation of physical capacity tested by exercise tolerance on a bicycle ergometer or treadmill. Two-dimensional echocardiography is the most commonly applied technique for investigating myocardial function [98–101]. A relatively newly developed technique, TDI assesses myocardial function in different myocardial segments. This technique is useful for diagnosing left ventricular dysfunction even before any symptoms or signs of CHF appear in subjects with diabetes [102–104].

Guidelines that specifically deal with diabetes and CVD including CHF have not been available until recently. Through a combined initiative by the European Society of Cardiology (ESC) and the European Association of the Study of Diabetes (EASD), guidelines on the management of diabetes, pre-diabetes and CVD were published in 2007 [105]. As outlined in this document, there are few trials that specifically address the treatment of patients with the combination of glucose abnormalities and CHF, causing a lack of specific evidence regarding the management of such patients. Current data are mostly based on analyses of subgroups

**Table 41.3** The effect of inhibition of the renin angiotensin system in congestive heart failure (CHF) trials by diabetic state.

Study [ref]	Participants (no)	Diabetes (%)	Outcome
CONSENSUS [109]	253	18	31% reduction of 1-year mortality
SAVE [114]	2231	22	19% all cause mortality risk reduction 21% risk reduction of cardiovascular morbidity
ATLAS [112]	3164	19	14% mortality risk reduction with high dose ACE inhibitor treatment
GISSI 3 [115]	18 131	15	30% reduction in mortality after 6 weeks

ACE, angiotensin-converting enzyme.

of patients with diabetes in large CHF trials. This results in potential shortcomings related to a poor definition of diabetes and hidden diabetes, actual glucose lowering therapy and also a risk for selection biases with an overrepresentation of less severe diabetes. With these limitations in mind, available data favor a proportionately similar efficacy in patients with and without diabetes. Because the absolute prognosis is considerably worse in patients with diabetes, the impact of therapy expressed as number of patients needed to treat to avoid an event (e.g. hospitalization for CHF or death) is considerably lower among these patients than their counterparts without diabetes.

### Pharmacologic therapy of CHF

#### ACE inhibition

ACE inhibitors are recommended both in asymptomatic myocardial dysfunction and overt CHF. As shown in Table 41.3, they reduce mortality and improve symptoms in moderate to severe CHF with and without diabetes [106–110]. Patients with diabetes represent rather large subgroups in several trials. In SOLVD, the effect of enalapril on compromised left ventricular function was similar in patients with and without diabetes [111]. In ATLAS, comparing a high and a low dose lisinopril treatment strategy, mortality reduction was at least as good in patients with as in those without diabetes [112]. The GISSI 3 and the SAVE trials reported beneficial effects on morbidity and mortality of ACE inhibitor treatment in post-MI patients with diabetes [113–115].

Because hypoglycemic episodes may be provoked by ACE inhibitor therapy in patients on glucose lowering therapy, it is recommended that plasma glucose is monitored in the early phase of the institution of an ACE inhibitor in patients on glucose lowering treatment [116,117].

**Figure 41.6** The impact of the beta-blocker metoprolol on the combined end-point mortality or hospitalization in congestive heart failure (CHF) patients with and without diabetes participating in the MERIT-HF trial [124,125]. Note that the relative risk reduction (given in % above bars) is independent of diabetic state but that the absolute mortality even with metoprolol treatment is considerably higher in the diabetic subgroup. Dark green bars, placebo; light green bars, metoprolol.

#### Angiotensin receptor blockers

The use of ARBs is an alternative to ACE inhibition and may even be used in combination with ACE inhibition in severe CHF. ARBs improve morbidity and mortality in CHF patients with and without diabetes [118,119].

#### Beta-blockers

Beta-blockade decreases myocardial FFA exposure and therefore such treatment has the capacity to influence the metabolic pathway favorably in patients with T2DM and CHF [120,121]. Subgroup analyses of patients with diabetes and moderate to severe CHF participating in large trials reveal that beta-blockers reduce mortality and improve symptoms. Therefore, beta-blockers are indicated as first-line treatment in patients with the combination of CHF and diabetes [122–126]. An example of the impact of beta-blockade (metoprolol) added to treatment with ACE inhibitors and diuretics in CHF patients with and without diabetes is given in Figure 41.6. It is worthy of note that the relative risk reduction following metoprolol is similar in the two groups. The remaining event rate is still substantially higher in the diabetic cohort than among those without diabetes.

#### Diuretics and aldosterone antagonists

Diuretics are mandatory for symptomatic relief of fluid overload. As already underlined, they should not be used in excess because they induce neurohormonal activation [94]. Loop diuretics are recommended rather than diuretics that may further impair glucose metabolism. The addition of aldosterone antagonists is indicated in severe forms of CHF and may improve longevity [127]; however, no information is available on the administration of aldosterone antagonists in patients with diabetes and CHF.

### Statins

It has been debated for some time whether statin treatment may impact morbidity and longevity in patients with CHF. Two recent clinical trials, the Controlled Rosuvastatin Multinational Study in Heart Failure (CORONA) and GISSI Heart Failure (GISSI-HF), were both negative in this respect [128,129]. It is therefore not indicated to include statin therapy as part of the management of CHF if not needed for other reasons.

### Glucose lowering treatment

#### General aspects

In accordance with the pathophysiologic aspects on CHF in patients with diabetes, it has been postulated that meticulous metabolic control may have beneficial effects on progress and prognosis. The European guidelines for the management of diabetes recommend that HbA<sub>1c</sub> should be <6.5% (48 mmol/mol) and plasma glucose fasting <6 mmol/L (<108 mg/dL) and postprandial <7.5 mmol/L (<135 mg/dL) [105]. The scientific evidence, as derived from properly designed clinical trials, behind these recommendations seem sparse even if they are somewhat more solid for type 1 diabetes (T1DM) than T2DM [130]. The negative outcome of some recent trials on aggressive glucose lowering have further underlined the uncertainty in this respect [131,132]; however, these trials did not specifically look at patients with CHF. Further studies are yet to be conducted on this category of patient before aggressive glucose normalization can be recommended as a possibility to improve their situation. Currently, it seems as if such assumptions reflect information from epidemiologic studies showing increased risk with increasing levels of plasma glucose and HbA<sub>1c</sub> starting well below what has currently been labeled as normal.

#### Glucose lowering agents

Regarding specific glucose lowering agents, there is some information available of importance for the choice of treatment in patients with or at risk for heart failure. The insulin sensitizers thiazolidinediones can provoke or worsen CHF because of their propensity to induce fluid retention. These drugs should be used with great caution in patients in New York Heart Association class I–II and are considered contraindicated in those in class III–IV [133–136]. Metformin is also contraindicated in CHF because of the risk of lactic acidosis.

Insulin treatment in patients with diabetes and CHF is under debate. The main effect of insulin is to decrease blood glucose, but it may also increase myocardial blood flow, decrease heart rate and cause a modest increase in cardiac output [137,138]. Beneficial effects on myocardial function have been reported, but also that insulin may be associated with increased morbidity [139] and mortality [140,141]. Further studies are needed to establish the specific role of insulin beyond the role as a glucose lowering agent in patients with diabetes and CHF.

In general, it may be summarized that there is very little information available of importance for the choice of agents for glycemic control in patients with diabetes and CHF. Thus, generally accepted management rules should apply [142].

### Diastolic congestive heart failure

Impaired myocardial diastolic function and endothelial dysfunction are early expressions of diabetes-related cardiovascular involvement causing a decreased myocardial blood flow reserve. It has been suggested that hyperglycemia-related early myocardial and microcirculatory disturbances are dynamic and that they may be reversed by improved metabolic control [143]. An observational study by von Bibra *et al.* [144], on patients subjected to intensified glucose control in clinical routine, gave support to the assumption that particularly insulin-based glycemic control may be useful. Unfortunately, these observations were not verified in a recent prospective study, the Diabetes mellitus And Diastolic Dysfunction (DADD) trial, randomly distributing patients with T2DM and early signs of diastolic dysfunction to insulin or oral based glucose normalization. The patients were selected to be free from previous cardiovascular events and signs of CHF or CAD [145]. It should be underlined that it is still too early to abandon the hypothesis of a favorable relation between glycemic control and myocardial diastolic dysfunction. It may be that the DADD patients were too healthy to react to normalization of glucose control. Thus, it would be of value to study new agents, such as incretins, in future trials and to recruit patients at a more advanced disease stage than those selected for the DADD study. The problem is then the obvious risk for biases caused by hypertension and CAD and other complications to diabetes. Accordingly, such protocols must include detailed examinations of the patients with this in mind.

### Metabolic modulators

Drugs, such as trimetazidine, etomoxir and dichloroacetate, whose mode of action is to shift myocardial metabolism from oxidation of FFA towards glycolysis have been tested in patients with myocardial dysfunction and diabetes. They act on different parts of the metabolic pathways as indicated in Figure 41.4. Their usefulness must be further explored in clinical trials of appropriate design until their therapeutic role can be considered established despite some recent promising results [146–148].

# 42

## Cerebrovascular Disease

**Colum F. Amory & Jesse Weinberger**

Mount Sinai School of Medicine, New York, NY, USA

### Keypoints

- Diabetes is a strong and independent risk factor for ischemic cerebrovascular disease with a relative risk of around two.
- Ischemic stroke in the patient with diabetes has worse outcomes, including a higher rate of mortality than in patients without diabetes.
- While transient ischemic attacks (TIA) appear to occur less frequently in those with diabetes, people with diabetes who experience a TIA are more likely to go on to have a completed stroke in the immediate period following.
- The patient with diabetes is predisposed to vascular events, including stroke, for a number of reasons including premature atherosclerosis, reduced response to nitric oxide and a general state of hypercoagulability.
- Prevention of stroke in the patient with diabetes is best accomplished through aggressive management of coexisting hypertension and hyperlipidemia, as well as lifestyle modification.
- Reduction of glycated hemoglobin as a proxy for good glycemic control is likely to be associated with a reduction of macrovascular events.
- Aggressive management of hyperglycemia in the acute stroke period may improve outcomes.

### Epidemiology of stroke in general

Cerebrovascular disease is a leading cause of morbidity and mortality. It is a highly prevalent disease with approximately 700 000 strokes occurring each year in the USA. Of these, 500 000 are first time events, while 200 000 are recurrent [1].

Stroke is the third leading cause of death in the USA, following heart disease and all forms of cancer. Thus, a woman is more than twice as likely to die from a stroke than she is from breast cancer, and one and a half times as likely as from lung cancer [2]. Furthermore, it is the number one reason listed for discharge diagnosis for patients discharged from hospitals to chronic care facilities. In total, the cost of stroke to the health care system in the USA was \$62.7 billion in the year 2007 [1].

Statistics in other countries are similar to those seen in the USA. The Oxford Vascular Study [3], which compiled stroke statistics for every person in the county of Oxfordshire, demonstrated an overall incidence of 1.62 strokes per 1000 patients per year. The WHO MONICA study looked at 21 populations in 11 countries, 10 European countries as well as China, and found an incidence of 125–361/100 000 patients in men, and 61–194/100 000 in women [4].

### Diabetes as a risk factor for stroke

There is strong evidence that diabetes mellitus, whether type 1 (T1DM) or type 2 (T2DM), is a strong risk factor for ischemic cerebrovascular disease (Table 42.1). Observational studies have demonstrated associations between the two diseases. A model created from data from the Framingham Heart Study showed that diabetes confers an increased relative risk of 1.4 in men and 1.72 in women [5]. The Honolulu Heart Study showed that diabetes increases the risk of thromboembolic stroke between two- to threefold over those without the disease in Japanese men living in Hawaii [6].

The effect of diabetes is stronger in ethnic minorities in the USA. The Greater Cincinnati and Northern Kentucky Stroke Study found that as a sole risk factor, diabetes increased the odds ratio for having an ischemic stroke by 2.1 in Caucasians; however, in African-Americans that odds ratio was increased by 2.7. These results held true across all age cohorts [7].

Similarly, the Northern Manhattan Study found that diabetes was a stronger risk factor for ischemic stroke among African-Americans and Caribbean Latinos than among Caucasians. In these ethnicities, diabetes increased stroke risk by 1.8 and 2.1, respectively, partly because of increased prevalence of the disease. The fraction of strokes that could be directly attributable to diabetes as a risk factor was 14% among African-Americans and 10% among Caribbean Latinos [8].

The Copenhagen City Heart Study found a difference in the effect of diabetes among men and women. Thus, while diabetes

**Figure 42.1** Lacunar infarct in the left posterior thalamus. (a) Diffusion weighted imaging, showing hyperintensity in the area of restricted diffusion, corresponding to acute ischemia. (b) Apparent diffusion coefficient image corresponding to the slice seen in (a), demonstrating hypointensity in the same distribution, confirming the presence of acute ischemia.

**Table 42.1** Risk factors for stroke.

Hypertension
Diabetes
Tobacco use
Hyperlipidemia
Atrial fibrillation
Carotid artery disease

increased the relative risk of first stroke, incident stroke and hospital admission for stroke among men by 1.5–2, among women the same relative risks were increased by 2–6.5 [9].

In addition to its effects as a sole risk factor, diabetes also exacerbates the effects of other risk factors. Thus, in patients with isolated systolic hypertension, diabetes confers additional risk of ischemic stroke or transient ischemic attack (TIA).

### Stroke in patients with diabetes

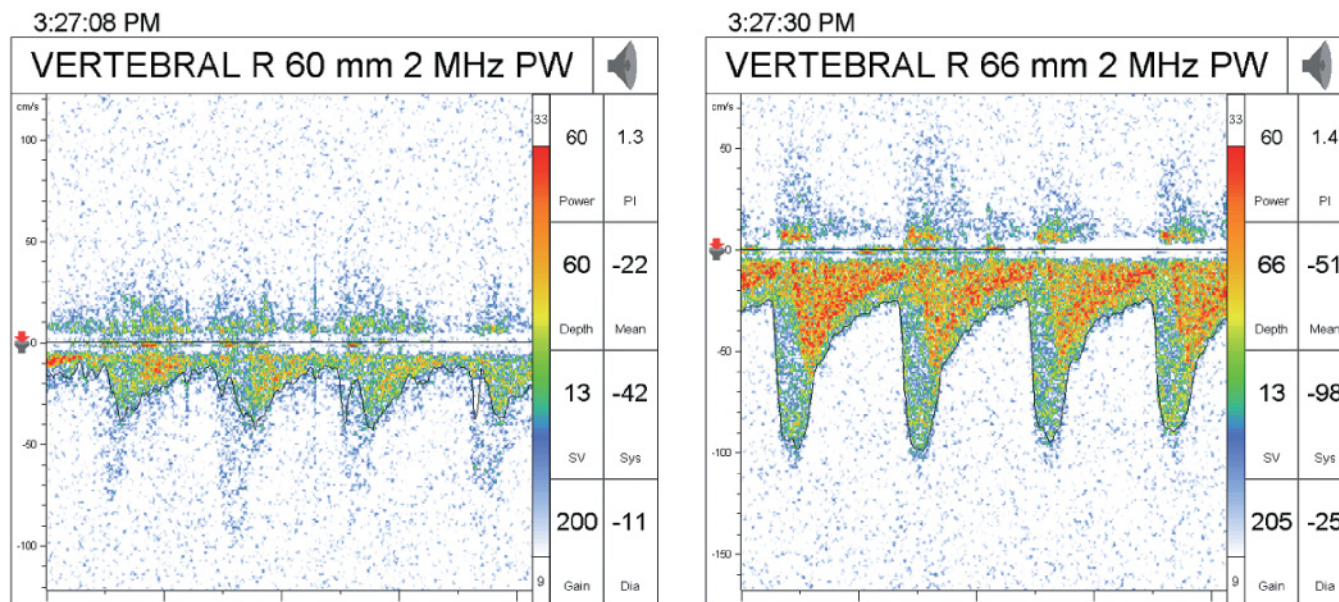

In epidemiologic studies, ischemic stroke occurs at a younger age in patients who have diabetes. They are also more likely to be

African-American. Among other risk factors, those with diabetes who have ischemic stroke are more likely to have hypertension, hyperlipidemia and to have experienced a myocardial infarction (MI) in the past [7].

Furthermore, diabetes increases the risk of death from stroke. In a prospective study in a Finnish cohort, men had an increased relative risk of 6 for mortality from ischemic stroke, while women had a relative risk of 8.2. These relative risks were higher than those for systolic blood pressure (BP), smoking or total serum cholesterol. In this cohort, the fraction of stroke deaths directly attributable to diabetes were 16% in men and 33.3% in women [10].

In terms of stroke subtype, diabetes is most commonly associated with lacunar infarcts. These are small deep infarcts in the territory of a single penetrating arterial branch. Conversely, the highest prevalence of diabetes is found in patients with demonstrable microvascular disease. Similarly, lacunar disease is more likely to be associated with diabetes than hemorrhages in the same location (Figure 42.1) [11–14].

Diabetes is associated with both extracranial and intracranial stenosis. In one study of 510 patients referred for asymptomatic carotid bruits, only 200 had extracranial stenosis by Doppler examination. Sixty-six had asymptomatic intracranial stenosis, of

**Figure 42.2** Intracranial vertebral artery stenosis as seen by transcranial Dopplers. The first image shows normal flow pre-stenosis, while the second image shows increased velocity of flow post-stenosis.

whom 37 had concurrent extracranial stenosis. Of the patients with intracranial stenosis, 19 had diabetes (Figure 42.2) [15].

TIA is less common in those with diabetes than in those not having the disease. This may indicate that patients with diabetes are more likely to present with completed infarct rather than reversible ischemia [16]; however, patients with diabetes who do present with TIA are more likely to go on to full-blown ischemic stroke in the next 2 days as predicted by the ABCD2 score. This score stratifies patients with TIA by the following factors: age greater than 60 years, BP greater than 140/90 mmHg, clinical features of motor or speech involvement, duration greater than 60 minutes and diabetes [17].

Diabetes is a risk factor for coronary artery disease (CAD), and thus for MI and subsequent development of atrial fibrillation. In one large retrospective study of the relation between diabetes and atrial fibrillation or atrial flutter, diabetes was found after logistic regression to be a strong independent predictor for atrial arrhythmias in a review of over 850 000 charts over a 10-year period. The odds ratio found for diabetes was 2.13, 95% confidence interval (CI) 2.10–2.16 [18]. In turn, atrial fibrillation has been repeatedly demonstrated to be a strong risk factor for cardioembolic stroke, with an estimated 75 000 strokes per year attributable to the arrhythmia [19].

Furthermore, diabetes increases the risk of cardiac embolization. The CHADS2 score is a validated method of stratifying risk of cardioembolic stroke in patients with atrial fibrillation. It assigns one point each for the presence of congestive heart failure (CHF), hypertension, age greater than 75 years, and diabetes, and two points for previous stroke or TIA. Each point increase was associated with a 1.5-fold increased risk of stroke. Diabetes alone, then, would increase the risk of stroke in a patient with atrial

fibrillation from 1.9 to 2.8 [20]. While the CHADS2 score is not perfect, and attempts have been made to make it more precise [21], it has the benefit of being very easy to use, thus guiding the non-stroke practitioner towards using anticoagulation in the appropriate section of the population.

In large observational studies, there has not appeared to be an association between diabetes and hemorrhagic strokes. By contrast, in the Hemorrhagic Stroke Project, a case–control study of young patients with intracerebral hemorrhage, diabetes conferred an adjusted odds ration of 2.4. The risk factor with the most impact was, as predicted, hypertension, which outweighed the contribution from diabetes by greater than twofold [22].

### Intermediate hyperglycemia and other risk factors

While it is well established that diabetes is a strong risk factor for ischemic stroke, forms of intermediate hyperglycemia are not so clearly indicated as risk factors. Selvin *et al.* [23] looked at people with and without diabetes in the Atherosclerosis Risk In Communities (ARIC) trial and compared hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) levels drawn at a specified visit, not necessarily related to time of incident stroke. With increasing tertiles of HbA<sub>1c</sub> across the normal distribution within each group, the risk of stroke increased in both those with diabetes and those without the disease, although it was only in those with diabetes that the difference achieved statistical significance [23].

In contrast, Myint *et al.* [24] abstracted data from the European Prospective Investigation into Cancer (EPIC) on HbA<sub>1c</sub> levels in patients without known diabetes and correlated these data with

stroke risk. In this population, it was only after HbA<sub>1c</sub> levels were higher than 7.0% (53 mmol/mol) that an increased risk of stroke was demonstrated, compared to those patients with HbA<sub>1c</sub> less than 5.0% (31 mmol/mol). Given that these patients are most likely to have undiagnosed diabetes, this finding may not implicate chronic hyperglycemia alone as the primary risk factor for stroke [24].

Insulin resistance (IR), another form of diabetes, likewise has demonstrated conflicting evidence for an association with stroke. The ARIC study investigated hyperinsulinemia in those without diabetes and found a mild increase in risk of stroke of 1.19 with each increase of 50 pmol/L of fasting insulin. After adjustment for other risk factors such as age, systolic BP and smoking, the increase in risk was not as well defined [25].

Obesity, a proxy for insulin resistance and intermediate hyperglycemia, has also been linked to stroke through a number of epidemiologic studies. For example, the Copenhagen City Heart Study found that body mass index (BMI) was independently associated with increased risk of stroke [26]. Similarly, the Nurses' Health Study found, as expected, an increasing risk of stroke with increasing BMI, with a relative risk of stroke of 2.37 (95% CI 1.60–3.50) seen in patients with BMI >32 kg/m<sup>2</sup> [27]; however, ARIC was unable to demonstrate any relationship between BMI and stroke, or between waist:hip ratio, a better measurement of abdominal obesity, and stroke [25]. In addition, when adjustment for cardiovascular risks was performed, the relative risk of BMI for stroke was once again attenuated.

Although these individual forms of intermediate hyperglycemia have not conclusively been shown to predispose people to stroke, the constellation of diseases together called the metabolic syndrome has been. The combination of hypertension, hyperlipidemia, IR and abdominal obesity creates an environment that is highly susceptible to vascular damage and ischemic sequelae.

In a Finnish cohort, the metabolic syndrome in the absence of diabetes or cardiovascular disease (CVD) was associated with stroke with a relative risk of around 2, after adjustment for multiple other risk factors [28]. Similarly, a cohort from the ARIC study who likewise was free of diabetes, coronary heart disease (CHD) or stroke, had an increased risk of 1.5–2.0 for ischemic stroke. In addition, when separating out each risk factor, there appeared to be a synergistic effect from the combination over the relative risks inherent in each component [29].

---

## Pathophysiology of ischemic stroke in diabetes

Diabetes predisposes patients to vascular thrombo-occlusive events in a number of ways. There is accelerated atherosclerosis in both large and medium sized vessels. There is disordered endothelial response and the blood of the patient with diabetes is hypercoagulable [30].

Carotid intima-media thickness (cIMT) is a useful proxy for early atherosclerosis, as it is easily measured by Doppler.

Furthermore, cIMT is associated with primary stroke, with an increased relative risk per standard deviation (0.163 mm) of 1.57 in patients who had not had a previous stroke [31]. It also predicts recurrent stroke, with each 0.1 mm of increase in cIMT associated with an increased risk of 18% [32].

Diabetes is associated with increased cIMT. The IR Atherosclerosis Study demonstrated an increase in common cIMT in patients with chronic diabetes, but not in those with newly diagnosed diabetes. Nor was there an association with internal cIMT [33].

Conversely, patients with diabetes and stroke have been found to have greater cIMT. In one study of 438 Japanese patients with T2DM, common cIMT was significantly higher in those who had stroke, even after adjustment for age, BMI and smoking status [34]. Similarly, in a Czech cohort, cIMT was increased in stroke patients with diabetes [35].

Atherosclerosis also affects the ability of endothelium to release nitric oxide (NO), a potent vasodilator. The diabetic blood vessel has either reduced NO production or altered NO metabolism. In addition to its vasodilating effects, NO protects against platelet aggregation and enables the blood vessel to withstand ischemic conditions. With decreased NO activity, the vessel will tend more towards vasoconstriction, with predictably poor response to ischemia.

Stroke patients have been demonstrated to have decreased NO in circulating blood, along with increased peroxynitrite (ONOO<sup>-</sup>), a reactive oxygen species. These results were particularly true in larger strokes. Because the measurements were performed for acute stroke, these levels are likely to represent the outcome of ischemia rather than the cause; however, the correlation supports a role for decreased NO in the effects of stroke [36].

The cerebral vasculature has a diminished response to inhibition of NO synthase (NOS). In a small study of men with diabetes treated with a synthetic NOS inhibitor, NG-monomethyl-L-arginine (L-NMMA), the blood flow through the internal carotid artery was significantly lower than in control subjects treated likewise [37].

As further indirect evidence of the role of NO in stroke, 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) have multiple beneficial effects beyond their most common, that of lowering plasma cholesterol. Among these effects is increasing expression of endothelial NOS as well as decreasing the activity of Rho-kinase, a proconstrictor enzyme [38]. Statins have been demonstrated to lower the risk of recurrent stroke in multiple large studies [39–41]. Whether the beneficial effect of statins in stroke is because of their cholesterol lowering effect, their ability to stabilize atherosclerotic plaques, their effects on vascular function or more likely a combination of all of the above, is very difficult to separate.

In addition to the above predisposing factors, the blood of the patient with diabetes is hypercoagulable. Studies have demonstrated increased thrombin generation [42], increased prothrombin fragments and increased thrombin–antithrombin III complexes [43]. Furthermore, the elevated prothrombotic

levels were significantly associated with macroangiopathic complications.

Thrombus formation is further promoted by platelet hyper-reactivity in the blood of the patient with diabetes. In patients with metabolic syndrome, platelets have been shown to have increased activity both through closure time as measured by the platelet function analyzer (PFA-100), increased fibrinogen binding after exposure to ADP, implying activation of the GPIIa/IIIb receptors, and by expression of activated ligands on the platelet surface [44]. In full-blown diabetes, platelets were hyperreactive as measured by light transmittance aggregometry and expression of surface ligands [45].

Thus, taken together, the person with diabetes has a vascular environment that is highly susceptible to thrombo-occlusive complications. With early atherosclerosis and disordered endothelial response, the conditions are predisposed to thrombophilia. The blood, in its hypercoagulable state combined with platelets that are highly active in themselves, is far more likely to form clots.

Lacunar strokes are caused by damage to smaller parenchymal vessels. The most common cause is microatheroma, as demonstrated in pathologic case series published by Fisher [46–48], the neurologist responsible for naming the lacunar syndromes. Lipohyalinosis and fibrinoid necrosis also cause microangiopathies, and both are most commonly found in the setting of chronic hypertension of severe acute BP elevations, as seen in hypertensive encephalopathy [49,50].

---

## Primary prevention of stroke in the patient with diabetes

Primary prevention of stroke is of paramount importance as the disability from stroke and health care costs associated with the acute and chronic care of stroke are so extensive. The approach to prevention in the patient with diabetes is of necessity multifactorial.

Medical therapy aimed at achieving normoglycemia is the foundation. The Diabetes Control and Complications Trial (DCCT) investigated intensive insulin regimens including subcutaneous insulin injections and external insulin pumps in those with T1DM. The goal for treatment was HbA<sub>1c</sub> levels of less than 6.05% (42 mmol/mol). The comparison group had no such goals outside of prevention of hyperglycemia or hypoglycemia [51].

The intensive treatment group achieved a reduction in the combined endpoints of non-fatal MI or stroke, cardiac death or revascularization procedure of 57%. The majority of this improvement was associated with the decrease in HbA<sub>1c</sub> [51].

Among oral hypoglycemic agents, metformin has been shown to decrease diabetes-related endpoints including stroke by 32% and diabetes-related mortality including stroke by 42% when compared with conventional therapy. Furthermore, it was more effective in reducing these outcomes when compared with other intensive therapies such as sulfonylureas (e.g. chlorpropamide or glibenclamide) or insulin. It should be noted that the HbA<sub>1c</sub> levels

were similar between the treatment groups, and so the benefits obtained were not explicable on the basis of improved glycemic control [52].

Rosiglitazone, a thiazolidinedione, has been linked with increased risk of MI and death from cardiovascular causes. Stroke was not assessed separately in the meta-analysis reporting these findings [53]. In a more recent multicenter, open-label trial directly assessing the effect of rosiglitazone on cardiovascular outcomes, the use of rosiglitazone was associated with a non-significant reduction in stroke (HR 0.72, 95% CI 0.49–1.06) [54]. Pioglitazone, another medication in the same class, was not associated with worse cardiovascular outcomes, including stroke, and, in fact, reduced a secondary outcome of all-cause mortality, non-fatal MI and non-fatal stroke by 16% [55].

The UK Prospective Diabetes Study (UKPDS) failed to show any reduction in macrovascular complications of T2DM despite an 11% reduction in HbA<sub>1c</sub> in the intensive treatment group. Microvascular complications such as retinopathy and neuropathy were significantly reduced [56]. A 10-year follow-up study of the same cohort after attempts to maintain treatment differences had desisted showed that the original treatment cohort had persistent decreases in microvascular complications as well as in MIs and deaths from any cause but not CVA [57]. Thus, glycemic control, at least in those with T2DM, has not been linked to a reduction in risk for stroke.

Given how susceptible people with diabetes are to the effects of other vascular risk factors such as hypertension and hyperlipidemia, the therapeutic regimen must also address these states. In treating hypertension in people with diabetes, the classes of medications with effects on the renin angiotensin system appear to have the greatest benefit.

The Hypertensive Old People in Edinburgh (HOPE) trial examined patients either with vascular disease (including CAD or stroke) or diabetes plus one other cardiovascular risk factor such as hypertension, tobacco use or elevated low density lipoprotein levels. In this high risk population, ramipril, an angiotensin-converting enzyme inhibitor (ACEi), decreased the risk of death from cardiovascular causes with a relative risk of 0.74 and reduced the risk of stroke with a relative risk of 0.68. As the mean reduction in BP was only 3/2, the benefits were not attributable to the BP lowering effect of the medication. The effect was similar whether or not the patients had had a stroke prior to enrollment [58].

The Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) trial examined patients with diabetes, hypertension and left ventricular hypertrophy. Participants were either treated with losartan, an angiotensin receptor blocker (ARB) or atenolol. Although, once again, both medications achieved the same reduction in BP, the primary endpoint of cardiovascular mortality, MI or non-fatal stroke was reduced with a relative risk of 0.76 in the Losartan group. Notably in this trial, only 40% of participants achieved a systolic BP of less than 140 mmHg, implying that further benefits would likely accrue with more intensive management [59].

A recent trial of intensive multifactorial medical management in patients with diabetes with microalbuminuria showed a reduction in all-cause mortality, cardiovascular mortality and cardiovascular events. The regimen was designed to achieve the following goals: HbA<sub>1c</sub> levels of less than 6.5% (48 mmol/mol), fasting total serum cholesterol levels of less than 175 mg/dL (4.5 mmol/L), systolic BP less than 130 mmHg and diastolic BP less than 80 mmHg. Stroke was not a pre-specified endpoint in this study; however, there were six strokes in six patients in the intensive medical group, compared with 30 strokes in 18 patients in the control group [60].

While antiplatelet treatment is recommended for the primary prevention of CAD, the Anti-Thrombotic Trialists' Collaboration meta-analysis failed to demonstrate a significant improvement in the primary prevention of ischemic stroke in patients with diabetes. Overall, there were nearly 5000 patients treated with aspirin, with only a 7% reduction in serious vascular events. The confidence interval was wide enough to include a possible 25% risk reduction, a number that is consistent with the prevention of secondary stroke in this population. It may be in this population at high risk, that the potential benefits of prophylactic aspirin outweigh the hemorrhagic complications [61].

Most of the early trials of antithrombotic medications were performed only on men. In the Women's Health Study, a study performed among female health professionals with no history of coronary or cerebrovascular disease, low dose aspirin (100 mg every other day) was associated with a 17% risk reduction in stroke, a result of a 24% risk reduction in ischemic stroke and a non-significant increase in hemorrhagic stroke. These findings were especially pronounced in women older than age 65 at the time of enrollment, as well as in the subgroup with diabetes [62].

### Treatment of acute stroke in the patient with diabetes

Treatment of acute stroke is limited by the vulnerability of the neuron to ischemic insult. With decreasing cerebral blood flow (CBF), the parenchyma becomes less likely to recover from even short durations of ischemia. With CBF less than 200 mL/kg of tissue, neurologic dysfunction begins to appear, but it is not until CBF falls below 100 mL/kg of tissue that irreversible ischemia occurs, in a matter of minutes [63].

Thrombolysis has been demonstrated to be effective in the treatment of acute stroke, as long as the medication is given within the first 3 hours after symptom onset, as defined by the last time the patient was seen at their neurologic functional baseline (Table 42.2). The National Institute of Neurologic Disorders (NINDS) trial of intravenous tissue plasminogen activator (t-PA) demonstrated a 30–50% increased likelihood of minimal or no disability 3 months after treatment. The thrombolysis was associated with a 6.4% chance of symptomatic intracranial hemorrhage, but mortality data at 3 months were not statistically different between the treatment and placebo groups [64].

**Table 42.2** Management of acute ischemic stroke.

0–3 hours	Intravenous t-PA
0–6 hours	Intra-arterial t-PA
0–8 hours	Mechanical clot retrieval (MERC device)

Permissive hypertension for the first 3–5 days

Aspiration precautions

DVT prophylaxis

Intravenous t-PA is the only acute intervention approved by the US FDA. Both intra-arterial t-PA and mechanical clot retrieval remain experimental, although widely used. IV t-PA should remain the standard of care when it is not contraindicated, with the other interventions to be used as auxiliary therapy

DVT, deep venous thrombosis; FDA, Food and Drug Administration; t-PA, tissue plasminogen activator.

Based on this trial, treatment with intravenous t-PA has become standard of care in this early time period. While recent data from the ECASS-III trial suggest that it is not only safe but clinically effective to a lesser degree in a select group of patients to give intravenous t-PA in the window between 3 and 4.5 hours, this has not yet become standard practice. In addition, patients with diabetes who had a previous stroke by history or on imaging were excluded from the trial [65].

Thrombolysis in the patient with diabetes and acute stroke is not as successful as in the general population. In one series of 27 patients treated with intravenous t-PA, none of the patients with diabetes achieved recanalization of the occluded artery as measured by transcranial Doppler [66]. The series was not large enough to demonstrate a significant difference. In another study examining which factors might predict major neurologic improvement in patients treated with intravenous t-PA, there was a trend towards patients with diabetes being less likely to achieve that improvement [67].

Beyond intravenous thrombolysis, intra-arterial thrombolysis has been examined in patients up to 6 hours after the onset of stroke symptoms. The Prolyse in Acute Cerebral Thromboembolism II (PROACT II) trial found that patients treated with intra-arterial urokinase had a 58% relative risk reduction to achieve minimal or no functional disability at 90 days after treatment. Mortality rates were comparable, and recanalization rates were highly improved with the medication [68]. Current guidelines support the use of intra-arterial thrombolysis in the period of time between 3 and 6 hours, but the medication has not been approved by the US Federal Drug Administration (FDA) for this indication [69].

In one case series of 100 patients treated with intra-arterial thrombolysis with urokinase, diabetes was associated with poor functional outcome at 3 months. It was not associated with symptomatic intracranial hemorrhage [70], but because diabetes is independently associated with worse outcomes following acute

ischemic stroke, it is not clear whether these data have any meaning for clinical practice.

Hyperglycemia at the time of stroke treatment is associated with worsened outcomes. In a series of 73 patients treated with intravenous t-PA, age, diabetes, admission glucose greater than 140 mg/dL (7.8 mmol/L) and early reocclusion on transcranial Doppler imaging were significantly associated with worsened functional outcome as defined by a score of greater than 3 on the modified Rankin scale, however, after logistic regression, only the hyperglycemia remained as an independent predictor of poor outcome. In particular, it was associated with larger infarct size, lesser degree of neurologic improvement and worse clinical outcome if recanalization was achieved [71].

Similarly, baseline hyperglycemia is associated with a greater likelihood of going on to symptomatic intracranial hemorrhage after intravenous thrombolysis. There appears to be a dose-response relationship between levels of serum glucose and likelihood of hemorrhage. This was especially true when levels were >11.1 mmol/L (200 mg/dL), where 25% of patients had symptomatic intracranial hemorrhage. In a repeat analysis substituting the presence of diabetes for glucose levels, diabetes was associated with an odds ratio of 3.61 for all hemorrhages and 7.46 for symptomatic hemorrhage [72].

Furthermore, both those patients who acutely worsened and those patients who showed lack of improvement at 24 hours were more likely to have elevated blood glucose at baseline. Hyperacute worsening in patients treated with either intravenous or intra-arterial thrombolysis, or both, was not surprisingly associated with intracerebral hemorrhage and lack of recanalization, but it was also associated with higher serum glucose. With every increase of 50 mg/dL glucose, the odds ratio for worsened outcome was 1.50, and the odds ratio for mortality was 1.38. Even in those patients who did achieve recanalization, higher blood glucose predicted worse outcomes [73].

Similarly, serum glucose greater than 144 mg/dL, as well as cortical involvement and time to treatment were independent predictors of lack of improvement at 24 hours after treatment with intravenous thrombolysis. The odds ratio for hyperglycemia was 2.89. Furthermore, lack of improvement at 24 hours predicted poor functional outcome at 3 months [74].

While these data are understandably disheartening, they should by no means be taken to imply that patients with diabetes and acute stroke should not receive thrombolysis, nor that these patients do not benefit from the treatment. Furthermore, it is not clear whether the hyperglycemia that is seen in patients with acute stroke and diabetes is secondary to the ischemic insult as a stress response, or instead part of the chronic diabetic state and thus purely a complicating factor.

Interestingly, one study examined how persistent hyperglycemia differed from transient hyperglycemia in functional outcomes as well as in mortality. When hyperglycemia was present at baseline and when measured 24 hours after admission, it was inversely associated with neurologic improvement in the first 7 days, 30-day functional outcome and 90-day negligible depend-

ence. At the same time, persistent hyperglycemia was positively associated with increased mortality at 90 days, and parenchymal hemorrhage. When hyperglycemia was absent at baseline but present at 24 hours after admission, it was likewise inversely associated with 90-day negligible dependence, and positively associated with death and parenchymal hemorrhage. In this study, baseline hyperglycemia alone (without persistence at 24 hours) was not associated with poor outcomes. These data suggest that it may not be the stress response hyperglycemia that causes damage in the acute stroke setting [75].

Intensive treatment of hyperglycemia may be associated with improved outcomes, as has been demonstrated in the cardiac literature for MIs [76]. A small pilot study found that hyperglycemic patients could be treated with insulin infusions safely, but the numbers were too small to compare functional outcomes at 1 month [77]. The use of insulin drips in another study to maintain glucose levels at 5.0–7.2 mmol/L (90–130 mg/dL) in patients with acute ischemic stroke, started no later than 12 hours after the onset of symptoms, was associated with a trend towards better functional outcomes and minimal or no neurologic symptoms as measured by the National Institutes of Health (NIH) stroke scale. There were hypoglycemic episodes in the group treated with the continuous infusion, but the majority of these were asymptomatic [78]. Clearly, further study is required on this subject.

Hyperglycemia, as defined by serum glucose >400 mg/dL, was a contraindication for inclusion in the NINDS trial for some of the reasons above, as well as that extreme hyperglycemia can cause focal neurologic deficits that mimic stroke [64]. Current guidelines recommend starting aggressive glycemic control if serum glucose is >200 mg/dL, while acknowledging that levels >140–185 mg/dL may still be harmful [69]. While it may be reasonable to attempt to bring down the glucose level and see if any focal symptoms improve or resolve, and then treat with thrombolysis if no improvement is seen, this approach has yet to be tested.

In terms of oral hypoglycemics in the acute stroke setting, one study looked at the role of sulfonylureas taken pre-stroke and during the acute hospitalization. Sulfonylureas have an effect on ATP-sensitive Kir6.2 potassium channels which are regulated by the sulfonylurea receptor 1 (SUR1) receptor, like pancreatic  $\beta$ -cells, and which are open only during ischemic episodes, causing cell death. Theoretically, then, treatment with sulfonylureas should be neuroprotective during ischemia. Although the numbers were small, and patients with more severe strokes (NIH stroke scale greater than 9) were excluded, patients on the medication were more likely to have a decrease of four points on the NIH stroke scale or a score of 0, and were more likely to achieve an excellent functional recovery at discharge. The effect was particularly noticeable in non-lacunar strokes [79].

Further care for the acute stroke patient is best handled in a certified stroke unit, with multidisciplinary care from a team consisting of vascular neurologists, stroke-trained registered nurses, physical therapists, occupational therapists, and speech

and swallow specialists. This care results in around a 25% reduction in mortality [80].

BP control in acute ischemic stroke is a subject of ongoing debate. Current thinking still supports the concept of permissive hypertension in the peri-stroke period. Most vascular neurologists would allow the blood pressure to remain untreated until the systolic BP rises >220 mmHg or the diastolic BP >120 mmHg. The period over which permissive hypertension should be allowed is also controversial. Typically, the BP is left untreated for the first 3–5 days after stroke [69].

The majority of medical complications after stroke relate to the disability associated with neurologic deficits. Thus, deep venous thrombosis (DVT) and aspiration pneumonitis are the two complications that stroke units need to prevent. Prevention of DVT is accomplished through subcutaneous anticoagulation with either heparin or low molecular weight heparin with or without external compressive devices [69]. Initiation of treatment is typically immediately on admission, regardless of the size of infarct. One unblinded study looked at heparin versus enoxaparin and found a reduction in thrombosis with the low molecular weight heparin [81].

Prevention of aspiration is more complicated. Protection of the airway is often compromised in the acute period after stroke. Frequent suctioning and positioning helps to prevent aspiration. Swallow evaluations should be undertaken before oral nutrition is started in any patient in whom dysphagia is suspected. Placement of nasogastric tubes (NGT) is often required for nutrition, and frequently patients will require percutaneous endoscopic gastrostomy (PEG) tube for long-term provision of nutrition. Hydration is necessary, either intravenously before enteral access is established, or via NGT or PEG tubes to prevent dehydration and electrolyte abnormalities. Antibiotics should be started in any patient suspected of infection, and fever should prompt aggressive search for a source. Hyperthermia itself causes neurologic deterioration, so antipyretics should be administered [69].

## Secondary prevention of stroke in diabetes

The management of the patient with diabetes after stroke is similar to that for primary prevention as outlined above (Table 42.3). The seventh report of the Joint National Committee on prevention and treatment of hypertension recommends that people with diabetes should be maintained at a BP <130/80 mmHg, and that it will likely take multiple antihypertensive medications to achieve this goal [82]. As suggested by the studies described above, ACEi and ARB provide greater protection against cardiovascular events including stroke.

Similarly, the National Cholesterol Education Program [83] and subsequently the Endocrine Society [84] have published guidelines on the management of cholesterol in people with diabetes. Diabetes should be considered a CHD risk equivalent and, as such, cholesterol should be lowered aggressively. This is par-

**Table 42.3** Prevention of ischemic stroke in the patient with diabetes.

Tight glycemic control
Antihypertensives with ACEi or ARB
Anticholesterol treatment, especially with HMG-CoA-reductase inhibitors (statins)
Lifestyle modifications (e.g. tobacco cessation, weight loss)
Antiplatelet therapy (either aspirin, clopidogrel or dipyridamole) or
Anticoagulation in patients with atrial fibrillation

ACEi, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; HMG-CoA, 3-hydroxy-3-methyl-glutaryl-Coenzyme A.

ticularly true in those with diabetes who have had a stroke. These patients are considered high risk for CHD, and their levels should be lowered at least to <100 mg/dL, with <70 mg/dL an ideal. In combination with the data on statins and stroke described above, all those with diabetes and stroke should be started on a statin.

Antiplatelet therapy should be started in all patients who have had a non-cardioembolic ischemic stroke (Table 42.3). While the Anti-thrombotic Trialists' Collaboration meta-analysis failed to show benefit in patients with diabetes, post hoc analysis of data from the Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study found that people with diabetes treated with clopidogrel had a decreased rate of stroke, MI or death of 15.6% compared to 17.7% risk in those treated with aspirin [85]. Similarly, in a post hoc subgroup analysis of a study of cilostazol, those with diabetes had a decreased rate of recurrent stroke on the medication when compared with placebo, with a relative risk reduction of 41.7%. This finding was especially true in patients with lacunar stroke [86]. These findings need to be verified by further trials.

In patients who have had ischemic stroke secondary to extracranial carotid stenosis, carotid endarterectomy remains the preferred treatment of choice for carotid artery stenosis greater than 70% (Figure 42.3). For degrees of stenosis of 50–70%, the benefits of surgery are much smaller, and decisions to treat will depend on the complication rate at local institutions [19]. Carotid artery stenting for symptomatic carotid artery stenosis is still being studied. To this point, unless there is significant risk of undergoing the surgery, such as clinically significant cardiac disease or pulmonary disease, contralateral carotid artery occlusion or history of previous radical neck surgery or neck radiation therapy, carotid endarterectomy is still preferable. In these high risk situations, carotid artery stenting is not inferior to the surgery [87]. Diabetes alone is not enough to categorize a patient as high risk.

People with diabetes and atrial fibrillation, paroxysmal or otherwise, should be anticoagulated with warfarin to a goal International Normalized Ratio (INR) of 2.0–3.0. The risk reduction associated with treatment with anticoagulation is 68%, with an absolute risk reduction in the annual stroke rate from 4.5% to 1.4% [88]. This reduction in risk is so strong that one study estimated that a patient would have to fall 295 times in one year for the risk of subdural hematoma secondary to trauma to

**Figure 42.3** Computed tomography angiography with iodinated contrast of the neck. There is mild stenosis seen at the origin of the right internal carotid artery. There is critical stenosis (“string sign”) at the origin of the left internal carotid artery, corresponding to severe atherosclerotic plaque.

outweigh the benefits gained from anticoagulation [89]. There is no reason to assume this is any different for patients with diabetes.

## Conclusions

Diabetes is a strong risk factor for ischemic stroke, and stroke in patients with diabetes is both more severe in presentation and outcome and more recalcitrant to acute treatment. While many etiologies of stroke are made more common by diabetes, the most common type of stroke found in patients with diabetes is lacunar microvascular infarction. Prevention of stroke in the patient with diabetes is best served through aggressive management of concurrent hypertension and hyperlipidemia. Careful glycemic control likely reduces the risk of stroke as well, but the risk reduction is not nearly as robust. Antiplatelet therapy also has important role; a single antithrombotic agent is sufficient for the prevention of ischemic stroke. Hyperglycemia in the acute phase after ischemic stroke is associated with poor outcomes, and aggressive management likely improves functional recovery.

## Peripheral Vascular Disease

**Henrik H. Sillesen**

Department of Vascular Surgery, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark

### Keypoints

- Peripheral arterial disease is very common, affecting up to 30% of all people with diabetes.
- Amputations are much more common in patients with diabetes and occur 5–8 times more often than in those without the disease.
- Atherosclerosis is common in people with diabetes, and measurement of ankle blood pressure may identify both people with and without diabetes at an early asymptomatic stage.
- People with diabetes have atherosclerotic lesions located more peripherally than people without diabetes and therefore are more commonly inoperable for technical reasons.
- People with diabetes have more complications to surgery, both locally (infections) and systemically (e.g. cardiac, pulmonary) than people without diabetes.
- Treatment of atherosclerosis in diabetes is basically the same as in patients without diabetes.

### Introduction

Peripheral vascular disease includes diseases to arteries and veins outside the thoracic region. Because of the limitations of a chapter in a textbook dealing with diabetes, this chapter mainly covers the three most common arterial diseases: peripheral arterial disease (PAD), carotid artery disease and aortic aneurysmatic disease (AAA). Other, rarer manifestations of atherosclerotic disease (e.g. renovascular hypertension, abdominal angina and ischemia of the upper extremity) are mentioned briefly. Special considerations in patients with diabetes are dealt with in relevant sections; for example, infection in an ischemic foot in a patient with diabetes is described in the section on critical limb ischemia.

Atherosclerosis is the main cause of peripheral arterial vascular disease, and the overall pathogenesis is covered in Chapter 39. It is important to appreciate that the pathogenetic mechanisms of clinical atherosclerosis are dual: chronic obstructive and thrombotic. Whereas the chronic obstructive mechanism is the main cause of lower limb ischemia, also in patients with diabetes, it is often preceded by a thrombotic event; a patient with mild claudication suddenly experiences significantly shortening of walking distance or sudden onset of rest pain. Or, the seemingly healthy person suddenly develops claudication. Of course, a heart attack or stroke in a patient with claudication is also a thrombotic event in a patient with chronic obstructive disease.

In general, patients with diabetes more often develop symptoms of atherosclerotic complications, they do it at a younger age

and they are more difficult to treat and have more complications with treatment (especially with invasive treatment).

### Peripheral arterial disease

Peripheral arterial disease is a chronic condition that, like atherosclerosis in other vascular beds, develops over decades. The World Health Organization (WHO) definition includes exercise-related pain and/or ankle brachial index (ABI) <0.9. On average, symptoms from the lower limbs develop 5–10 years later than from the coronary circulation. Acute ischemia may develop because of:

- 1 Thrombosis in a vessel with pre-existing atherosclerotic plaques and/or stenosis;
- 2 Embolism (e.g. from mural thrombus in the heart);
- 3 An arterial lesion upstream; or
- 4 As a result of trauma.

Diabetes is a major contributor to PAD.

PAD is traditionally divided into four stages (Fontaine):

- 1 Asymptomatic (ABI <0.9);
- 2 Functional pain (claudication);
- 3 Rest pain; and
- 4 Non-healing ulcers or gangrene.

### Incidence

In the most recent population-based studies in Western Europe, the incidence of symptomatic PAD is 3–4% among 60- to 65-year-olds, increasing to 15–20% in persons 85–90 years of age [1–3]. Similar findings have been reported in the USA. Looking at asymptomatic cases where the ABI is <0.9, the incidence is much

higher, and approximately 20% of all persons above 65 years of age, ranging from 10% in persons 60–65 years of age to almost 50% of those aged 85–90 years [1–3]. Critical limb ischemia, defined as ABI <0.4 or rest pain and/or non-healing ulcers, occurs in 1% of persons aged 65 years or older.

### **Incidence of PAD in people with diabetes**

The incidence of PAD in people with diabetes depends on the usual atherosclerosis risk factors and duration of diabetes. There are only few demographic studies studying the general population. Using ABI <0.9 as selection criteria, Lange *et al.* [4] found a prevalence of 26.3% in people with diabetes compared to 15.3% in people without diabetes when screening 6880 Germans above 65 years of age, of whom 1743 had diabetes. Similar findings have been reported by others: 20–30% of those with diabetes have PAD [5,6]. Claudication is twice as common in those with diabetes than those who do not have diabetes.

### **Pathophysiology**

It is outside the scope of this chapter to describe the pathophysiology of PAD in detail (see Chapter 39); however, in brief, the pathophysiology of PAD in those with diabetes is similar to that of a non-diabetic population. The abnormal metabolic state that accompanies diabetes directly contributes to the development of atherosclerosis. Pro-atherogenic changes include increases in vascular inflammation and alterations in multiple cell types. Both mechanisms of atherosclerotic complications are of importance in PAD (gradual narrowing resulting in stenosis and acute thrombosis in existing atherosclerotic lesion). Obviously, the long-term accumulation of lipids in the vessel wall is important and sudden local thrombosis can occur at any time, although in most cases this happens after symptoms (claudication) have developed.

To reach the stage of critical limb-threatening ischemia, advanced atherosclerosis has developed. Often, multiple segments of the arterial tree from the aorta to the foot are affected (stenotic and/or occluded). In people with diabetes, the atherosclerotic lesions are more peripherally located than in people without diabetes. Whereas the iliac and femoral arteries are most commonly stenotic and/or occluded in individuals without diabetes, in those with diabetes, it is most often the crural arteries that are severely affected by atherosclerosis. This poses a challenge for revascularization because the results in general are better the more proximal the reconstruction.

In order to develop ischemic non-healing ulcers, perfusion has to be very poor. The most reliable method for assessment of peripheral perfusion in those with diabetes is measurement of toe pressure. A toe pressure below 20–25 mmHg signals a poor chance of healing of a peripherally located ulcer. The special considerations related to the potentially dramatic course of infection in a diabetic foot are dealt with in Chapter 44.

### **Asymptomatic stage**

The asymptomatic stage of PAD is especially interesting because it is associated with an approximately threefold increased mortal-

ity compared to matched controls [7,8]. This excess mortality is caused by accompanying cardiovascular disease (CVD). Asymptomatic PAD can be identified by a very simple test: measurement of ankle blood pressure. This test takes only a few minutes and is expressed as the ABI, where the ankle pressure is divided by the highest of the two arm blood pressures (BPs). In this manner, variations in BP between measurements do not influence the test result. Not only is an ABI <0.9 associated with increased mortality from cardiovascular causes, but also the level of ABI reduction is predictive: the lower the ABI the worse prognosis [7].

Identifying an asymptomatic person with an ABI <0.9 is not a case for evaluation with respect to revascularization of the lower limbs, but a case for serious preventive cardiovascular medicine.

### **Claudication**

Claudication is experienced by the patient as pain in lower limb muscles appearing after walking, most often in the calf, the thigh and more rarely in the buttocks. The walking distance eliciting the pain is very variable, beginning after 10–15 meters in severe cases, whereas other patients will report pain only when walking fast uphill for more than 500 meters for example. It is important for both the patient and the treating physician to understand that claudication, although it may be incapacitating for a few, and troublesome for many, signals severe vascular disease systemically, and that cardiovascular morbidity and mortality is high (elevated 3–4 times compared to matched controls).

### **Rest pain**

Rest pain typically begins at night when the patient is in the horizontal position. The positive effect of gravity on lower limb perfusion is then abolished. The patient typically complains about pain in the toes or feet during the night and most have experienced that standing or sitting up relieves the pain. Many patients will sleep sitting in a chair.

In patients with diabetes, symptomatology may differ because of coincidental peripheral neuropathy. Just like myocardial ischemia can be masked, symptoms from the lower extremity may be missing even though peripheral ischemia exists. This is especially important when a patient with diabetes presents with a small ulcer or wound on the lower limb, even if the patient thinks there is a good explanation for developing the ulcer, such as a relevant trauma. The lack of symptoms to signal peripheral ischemia combined with the risk of escalating infection in a diabetic foot has prompted many diabetologists to recommend routine assessment of peripheral circulation at regular intervals in all people with diabetes.

### **Non-healing ulcers**

Non-healing ulcers often begin after minor trauma (e.g. hitting a toe against a chair or by using shoes that are too small). In some cases the ulcers develop without any trauma and those will often progress to gangrene if not treated. Ischemic ulcers develop on

**Figure 43.1** Measurement of ankle pressure using Doppler technique.

toes or on the foot, typically at points where shoes are in firm contact. Thus, they are usually easy to discriminate from venous ulcers, which are located at the level of the ankles or lower calf.

Rest pain, non-healing ulcers and/or gangrene are often referred to as critical ischemia. The “diabetic foot” is dealt with in Chapter 44.

### Diagnosis

Most often the history and objective findings will ensure the diagnosis, but measurement of ankle blood pressure will quantify the ischemia and can be used to monitor changes in the disease (Figure 43.1). In some patients with diabetes, the media of smaller arteries become calcified making them incompressible. Thus, very high ankle pressures resulting in elevated ABI ( $>1.3$ ) signals mediasclerosis and should be recognized as a falsely elevated measurement. In fact, ABI  $>1.3$  is associated with a marked increased mortality because media sclerosis is found in patients with diabetes and those with renal failure.

Because small arteries are rarely affected by media sclerosis, measurement of toe pressure is an alternative for assessment of PAD. Use of the strain gauge technique is most commonly used (Figure 43.2). Toe pressure also is useful for prediction of healing of ulcers and amputation wounds.

### Prognosis

The risk of amputation is only 1–2% at 5 years. Twenty-five percent of patients with claudication will experience a worsening of their symptoms from the lower legs; however, 75% will be unchanged or improve without revascularization [9]. In contrast the “systemic” risk is huge. Mortality in 5 years will be 15–25% and many more will have non-fatal myocardial infarction (MI) or stroke.

The risk of a patient with diabetes and PAD is much higher than that of the average patient with PAD. The patient with diabetes has an 8 times greater risk of amputation at the level of the

**Figure 43.2** Measurement of toe pressure using strain gauge technique.

transmetatarsal bones or above than the non-diabetic population [10]. In addition to the already severely increased mortality of PAD, patients who additionally have diabetes have a further doubling of their risk of death [10–12].

### Treatment

Treatment of patients with symptoms from the lower limb therefore involves two aspects:

- Treatment of symptoms from the lower limb; and
- Prevention of cardiovascular complications

The former includes lifestyle modification, medical therapy and interventional therapy by either percutaneous transluminal angioplasty (PTA) or open surgery, whereas the latter includes lifestyle modification and preventive medical therapy.

It is beyond the scope of this chapter to detail all aspects of lifestyle modification and preventive medical therapy; however, it is extremely important for the reader to understand that patients with PAD derive as much or greater benefit from lifestyle modification and aggressive preventive medical therapy than any other group of patients (see Chapter 40). Most of the lifestyle changes which are beneficial to the patient with diabetes will benefit the PAD aspect as well, especially smoking cessation, regular exercise, weight loss and dietary changes.

Medical prevention follows the same guidelines as that of other clinical atherosclerotic manifestations such as ischemic heart disease and can be summarized as follows: aggressive statin treatment almost irrespective of cholesterol levels (Heart Protection Study and American Heart Association guidelines), antiplatelet therapy and BP control. In this chapter, only details of lifestyle modification and medical therapy relevant to PTA and surgery are discussed.

### **Treatment of symptoms from the lower limb**

The vast majority of patients should be managed without invasive intervention PTA (and/or surgery). Because the risk of cardiovascular complications (cardiac and cerebral) is much higher than the risk of amputation, the main focus should be on preventive measures in order to halt the atherosclerotic process. The conservative approach with respect to revascularization is especially important for patients with diabetes because of the increased risk of surgical complications and poorer results of revascularization. One exception is patients with critical limb ischemia. Early revascularization before widespread infection can be limb-saving.

Exercise therapy has proven effective for improvement of walking distance, and regular exercise for 3 months can be expected to improve walking distance by 200–250% [13]. Because exercise also reduces cardiovascular morbidity and mortality, it cannot be stressed enough (for both the patient and the physician) that this is extremely important. Because the effect on walking distance is so good, and because it is important for survival, exercise therapy should always be tried before considering interventional treatment. There are only few exceptions where interventional treatment may be considered early on:

- 1 Patients with very short walking distance, not being able to carry out important daily responsibilities such as their work; and
- 2 Patients at risk of amputation (rest pain and non-healing ulcers).

The dilemma of explaining to patients that the symptoms they are experiencing from the lower limb are signaling high cardiovascular risk rather than lower limb risk is challenging. First of all, there is (or has been) a general perception that atherosclerosis in the limb is less dangerous than in other locations. The author hopes that the introductory remarks in this chapter have changed this potential misperception for the reader. Medical therapy for claudication includes cilostazol and statins. Treatment with both may be expected to improve walking distance by 30–50% and the latter furthermore reduces the cardiovascular risk. Other drugs have not proven useful in improving walking distance significantly [14].

### **Interventional treatment**

Interventional treatment (endovascular or open surgery) for PAD is indicated when:

- Exercise and other lifestyle modification has failed to improve symptoms to an acceptable state;
- Claudication is incapacitating; or

- Critical limb ischemia is present (rest pain, non-healing ulcers and/or gangrene).

Again, for the patient with diabetes, the indication for revascularization should be considered very carefully in patients only with claudication. The choice between PTA and open surgical management depends on the location and extent of disease. In general, endovascular treatment can be expected to perform well in cases of shorter lesions whereas open surgery is preferred in cases of extensive occlusive disease. Obviously, whenever comparable results can be obtained, PTA is preferred for the simple reason that it is less invasive and associated with less complications than open arterial reconstructions. In patients with severe co-morbidity that might complicate the outcome of open surgery, PTA would be preferred even though theoretically surgery would be the treatment of choice if only patency of the revascularization procedure was considered.

The arterial lesions causing obstruction of blood supply to the lower limb are most often located in the distal abdominal aorta just proximally to the aorta–iliac bifurcation, in the iliac arteries, and in the common and superficial femoral arteries. The arteries in the calf, the anterior and posterior tibial and the peroneal artery, are often involved in those with critical ischemia and with diabetes. In general, when patients with diabetes present with symptoms, they have a more distal involvement with open vessels to the level of the popliteal artery and then occlusive disease of the calf vessels and sometimes also the arteries in the foot. The results of revascularization for patients with diabetes with toe or foot ulcers are worse than the general population partly because reconstructions yield better results with respect to patency when the lesions are more centrally located.

### **Percutaneous transluminal angioplasty**

In principle, PTA can be performed anywhere between the heart and the feet. The more centrally located the lesions being treated, the better the results, especially with PTA. Also, the shorter the stenosis or occlusion, the better the results, and stenting improves patency in most cases. Endovascular-treated common iliac arteries, as an example, remain patent in 60–80% of cases after 5 years and thereafter they may be redilated. Primary stenting has become the preferred treatment in most cases. Obviously, because complications are rare, and this procedure is associated with the best results, the tendency to offer PTA for iliac artery obstruction is greater than for occlusive disease more peripherally located.

PTA of the superficial femoral artery (Figure 43.3) may relieve symptoms, but the results depend on the extent of disease. The longer the lesion, the greater the risk of early reocclusion. Stenting appears to improve patency, at least for longer lesions (Table 43.1) [15]. When the indication for PTA is claudication, patency is better than if the indication is critical ischemia. This difference relates to the more extensive nature of the disease in the case of critical limb ischemia and may also relate to poor run-off vessels. The 3-year patency is 48%, which may be improved to 64% if stenting is added. In case of critical limb ischemia, the results at

<sup>†</sup> Secondary patency.

3 years show a patency of 30% without stenting and 63% with stenting (Table 43.1) [15]. PTA of crural vessels is also feasible; however, the long-term results are not good. Data on limb salvage with PTA of crural vessels alone are scarce. Adjunctive medical therapy to improve patency following PTA and stenting, with anticoagulation and/or antiplatelet therapy, has been tested only in a few trials. Antiplatelet drugs improve patency, and the combination of aspirin and clopidogrel may be beneficial [16].

### Open surgical revascularization

Open surgical revascularization still dominates as the treatment of choice in cases of critical limb ischemia, because of the extensive nature of the atherosclerotic lesions in these patients. For claudication, open surgical treatment is rarely performed, while for extensive disease of the distal aorta and iliac arteries, the aorto-bifemoral bypass remains the procedure with the best long-term outcome. In addition, femoral–femoral cross-over bypass may be performed for unilateral iliac artery occlusion. Also, endarterectomy, as described below, may be an option for treatment of claudication. Only one trial has compared open surgery with endovascular treatment of critical limb ischemia, the Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial [17]. The primary efficacy outcome measure was amputation-free survival, but because approximately two-thirds of the endpoints were deaths, only one-third of the endpoints really determined which procedure was best. Within 6 months post-operatively, there was no difference in the primary endpoint, but thereafter bypass patients seemed to do better [17].

In general, two surgical techniques are used: endarterectomy and bypass. Endarterectomy is performed by separating the intima from the media, and in this manner the atherosclerotic lesion can be removed. Endarterectomy can be used in cases with severe occlusive lesions of limited anatomic extension, in the external iliac or in the common femoral artery. The advantage of this technique is that it can often be performed without the use of artificial graft material and patency is excellent. Bypass is preferred when the obstructive and/or occlusive lesions are extensive (e.g. total superficial femoral artery occlusion or multiple serial lesions warranting a femoral–crural bypass) (Figure 43.4). Bypass surgery can be performed with artificial materials or with auto-

**Figure 43.4** Long superficial femoral artery occlusion treated with femoro-popliteal bypass.

logous veins. For bypass of aortic or iliac artery origin, artificial grafts are almost always used. This is because there is no easily removable vein with similar dimensions that can be used in these locations. Also, Dacron or polytetrafluoroethylene (PTFE) grafts perform very well in the aorto-iliac-femoral region. For peripheral bypasses, typically originating from the common femoral artery, autologous vein grafts are preferred for two reasons: they last longer (much better patency) (Table 43.1) and they carry less risk of infection. For longer bypasses, such as from the common femoral to the popliteal artery below the knee, a saphenous bypass is performed leaving the vein *in situ*. This means that the vein is left in its original anatomic location; however, the proximal and distal ends are anastomized to the arterial system. The venous valves are cut with a knife mounted on a catheter and side branches are occluded. In this manner, the vein retains its nervous innervations and native vascularization.

#### **Complications of endovascular treatment**

Complications relate mainly to the site of puncture and the risk of peripheral embolization. “Systemic” cardiovascular complications are rare. Hematoma in the groin access point is common;

however, it only rarely requires any action to be taken. Development of an iatrogenic pseudo-aneurysm is seen in 0.5–1% of cases and can easily be treated with ultrasound-guided compression or ultrasound-guided thrombin injection.

#### **Complications of open surgical treatment**

These can be divided into local and systemic categories. The former relate to the actual incisions and dissections including wound healing and infections. Whereas complications from accidental damage to other organs and/or structures are very rare, wound healing problems and infections are unfortunately quite common. In particular, surgery on the lower limb involving the groin and peripheral incisions have wound complications in 10–20% of cases (e.g. hematoma, lymph oozing or necrosis of the wound) [18]. Infections are seen in 3–5% of cases, approximately one-third involving the vascular reconstruction. Infection of the vascular reconstruction is more frequent when using artificial graft material [18].

Systemic complications to open surgical revascularization relate to the surgical trauma and to the stress response. In vascular reconstructions involving the aorta and other central arteries, the cardiopulmonary complication rate is considerable. Implantation of an aorto-bifemoral bypass graft is associated with a 30-day mortality of 2–5% and a rate of “general” complications of 10–15% (e.g. pulmonary, cardiac, renal, prolonged stay at the intensive care unit, stroke and deep venous thrombosis) [18]. Systemic complications to peripheral revascularizations occur less frequently; however, they are considerable. When the indication is claudication, the morbidity with respect to general complications is low, 2–4%; however, in cases of critical ischemia and peripheral bypass surgery, the morbidity increases to 10% with a 30-day mortality of 3–5%. This difference in morbidity is a reflection of the more advanced level of generalized atherosclerotic disease in patients with critical ischemia. In patients with diabetes, complications are more common especially with open surgery. A doubling of risk should be expected.

#### **Results of endovascular and open surgical reconstructions**

These are summarized in Table 43.1. In general, when treating more centrally located arterial obstruction, the long-term results are better. In addition, treating patients with claudication results in better long-term outcome than operating on patients with limb-threatening ischemia. This difference relates to the generally poorer condition of the peripheral circulation in cases of critical ischemia with better run-off vessels in the patient with claudication.

In peripheral reconstructions, vein grafts perform better. It may seem unrewarding to treat patients with critical limb ischemia with a peripheral bypass using an artificial graft when there is only a 50% chance of being patent at 1 year; however, if the alternative is amputation and/or very poor quality of life (i.e. severe rest pain), 1 year with a functioning graft may very well be worthwhile for both the patient and surgeon. Limb salvage as a result is almost always better than patency of the reconstruction

**Table 43.2** Separation of threatened from viable extremities.

Category	Description/prognosis	Findings		Doppler signals	
		Sensory loss	Muscle weakness	Arterial	Venous
Viable	Not immediately threatened	None	None	Audible	Audible
Threatened					
a. Marginal	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) inaudible	Audible
b. Immediate	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	(Usually) inaudible	Audible
Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

because in many cases, once the ischemic limbs with tissue loss have healed, the “need” for amputation becomes less. Patients with diabetes typically have poorer outcome of vascular reconstructions, with patency rates that are inferior to those without diabetes. Patients with diabetes have more complications to treatment, not only infections but also systemic complications are more common.

### Acute lower limb ischemia

This condition is most often caused by thrombosis in existing atherosclerosis (i.e. a patient with previous symptoms of chronic PAD). Another common cause is thrombosis of a popliteal aneurysm. Embolism remains a common cause, although not as often as in the past because of better anticoagulant therapy for patients with atrial fibrillation. Eighty percent of emboli are of cardiac origin; however, aneurysms of the aorta or peripheral aneurysms may give rise to peripheral emboli.

Other causes include trauma and iatrogenic lesions (e.g. from arteriography with puncture of the femoral artery). Aortic dissection may cause lower limb ischemia as well as acute deep venous thrombosis (phlegmasia coerulea dolens). Incidence in Western Europe is 300–400 per million per year.

### Pathophysiology

Thrombosis is caused by plaque rupture and subsequent thrombosis. Distal to the acute occlusion, arterial flow is slow and when combined with a hypercoagulable condition, it may lead to further thrombosis. The degree of ischemia depends on the location and the degree of collateral development. Therefore, thrombosis is often better tolerated than embolism because patients with existing atherosclerosis most often has developed collaterals.

Emboli will typically occlude an artery at a bifurcation; in the lower limbs, at the aortic bifurcation (saddle embolus), iliac artery and femoral artery bifurcation. Sixty percent of cardiac emboli will end in the lower limbs, 15% in the arms and the rest in the brain and other organs. Microemboli, typically from aneurysms, affect small peripheral arteries, and are thus the cause of “blue toe” syndrome.

### Symptoms

Acute ischemia is characterized by pallor, pain, pulselessness, paresthesia and paresis (the 5 P’s). Symptoms may begin dramati-

cally and in some cases the late signs of ischemia, paresthesia and paresis occur within a few hours. More often, symptoms begin with pain and paresthesia and later sensory and muscular paresis. Acute ischemia is traditionally divided into three classes (Table 43.2).

### Diagnosis

Diagnosis is often easy with typical clinical signs. ABI will be low, if measurable at all. Imaging with either duplex ultrasound, magnetic resonance angiography (MRA) or digital subtraction angiography (DSA) is possible but may delay treatment. In cases of thrombosis, it is most often desirable to perform arteriography with subsequent thrombolysis in order to visualize the underlying pathology causing the thrombosis.

### Prognosis

If revascularization is possible before irreversible ischemia has occurred, the limb can be salvaged and normal function regained. Co-morbidity is high in cases of acute ischemia; when acute revascularization is needed the procedure-related mortality is 10–20% because of release of toxic substances from ischemic tissue combined with existing cardiac disease.

### Treatment

Thrombosis in existing atherosclerotic lesions may be treated by endovascular or open surgery. The former is preferred if revascularization is not imminent. By catheter-directed intra-arterial thrombolysis, the underlying atherosclerotic lesions will be exposed and may in some cases be treated by PTA and/or stenting. In other cases, bypass surgery may be needed. Inoperable cases may be converted into operable cases by thrombolysis because distal thrombosis most often makes surgery (and PTA) useless when there are no run-off vessels. Another advantage of thrombolysis is that emergency surgery is converted into a less urgent intervention. Emboli can be treated by embolectomy by inserting a balloon catheter, either in the femoral or popliteal artery, and retracting the emboli after inflating the balloon (Figure 43.5). Some cases of embolism may also be treated by thrombolysis.

### Prevention

Arterial emboli have a high recurrence rate and the underlying case should be treated, if possible; corrective treatment for atrial

**Figure 43.5** Embolectomy performed with a balloon catheter.

fibrillation and resection or exclusion of aneurysms. If the source of embolism cannot be eliminated, anticoagulation must be considered.

### Atherosclerosis of renal and mesenteric arteries

#### Renal artery obstruction

Renal artery obstruction can cause severe hypertension and renal failure but interventional treatment may improve both conditions. Today, open surgical management is only rarely performed because endovascular management is much less invasive and feasible in the majority of cases. Open surgery, thrombo-endarterectomy or bypass, is performed when renal artery disease is combined with other pathology such as aortic occlusion or AAA.

#### Mesenteric artery occlusive disease

Mesenteric artery occlusive disease may cause abdominal angina. Just like atherosclerotic lesions in other locations, many cases are asymptomatic and probably do not need intervention with regard to the obstructive disease, but lifestyle changes and medical preventive treatment are indicated. Patients with classic symptoms – post-prandial pain occurring 10–20 minutes after a meal and weight loss – often benefit from revascularization; however, many patients have less obvious symptoms, and the mere occurrence of a lesion on one of the three main vessels supplying blood to the gastrointestinal tract (celiac trunk, superior and inferior mesenteric artery) does not warrant interventional treatment. In general, a single lesion in one of the three arteries is seldom thought to cause ischemia. Diagnosis is possible by ultrasound of the suprarenal vessels in most cases, otherwise computed tomography arteriography (CTA), MRA or DSA may be needed. Interventional treatment today is mainly balloon angioplasty and stenting. Long occlusions of the superior mesenteric artery and/or occlusive mesenteric disease combined with other

pathology of the aorta may be treated by open surgery (e.g. aorto-mesenteric bypass).

### Ischemia of the arms

Atherosclerosis and ischemia of the arm are much less common than in the lower limb. The most common location for development of atherosclerosis in the arteries supplying the upper extremity is in the brachiocephalic trunk and subclavian arteries central for the origin of the vertebral arteries. Rarely, occlusive lesions are located more peripherally in the subclavian or axillary arteries. Takayasu vasculitis may also cause upper extremity ischemia.

#### Typical symptoms of chronic arm ischemia

These include “claudication”; i.e. pain when using the arm. In typical cases pain is encountered when performing tasks with the arms elevated, such as hanging laundry, or other physical use of the arm. Critical ischemia with rest pain or gangrene is rare but may occur. Diagnosis is easy with lack of pulses at palpation. Measurement of bilateral BP and ultrasound may locate and quantitate the stenotic lesion. If BP cannot be measured by auscultation, a Doppler device may be used as for measurement of ankle BP. Additionally, or in case of severe ischemia, finger pressure measurement by strain gauge technique may be used. Upper arm angiography by CT, MRA or DSA may be supplemental.

The prognosis is often good because development of critical ischemia and the necessity for amputation is rare. Patients with finger gangrene should be investigated for vasculitis.

Treatment of upper extremity atherosclerosis is similar to that of atherosclerosis in other vascular distributions: risk factor reduction by lifestyle changes and preventive medications for all, and revascularization in some. In fact, only rarely is interventional treatment indicated, but in cases of incapacitating functional pain and/or critical ischemia, revascularization should be considered. Endovascular treatment dominates because of its less invasive nature for lesions near the origin of the brachiocephalic trunk and subclavian arteries. For lesions that cannot be treated by endovascular techniques, such as long lesions or lesions that cannot be crossed by a guide wire, bypass surgery is indicated (carotid–subclavian bypass). Peripheral bypass of the upper extremity (e.g. at the level of the brachial artery) is rare and patency is poor.

#### Acute arm ischemia

This is most often caused by embolization, but alternatively can be caused by thrombosis in an existing stenosis such as of the subclavian artery. Whereas the former may be treated easily by embolectomy via a small incision in the cubital fossa, the latter may be more complex to treat, perhaps requiring intra-arterial thrombolysis before vascular reconstruction. Embolism is most often of cardiac origin, either from atrial fibrillation, mural thrombus in the heart or valve disease. Vascular causes include a subclavian aneurysm or stenosis. Microemboli may occur periph-

erally and present as gangrene of one or more fingers. Extravascular causes include a cervical rib. Obviously, eradication of the embolic source is crucial, if possible. Treatment of the peripheral ischemia may include thrombolysis, but in most cases collaterals develop and amputation does not become necessary.

### Aortic aneurysmal disease (abdominal aortic aneurysm)

This section focuses on abdominal aortic aneurysms (AAA) because thoracic aortic aneurysms are not considered part of peripheral vascular disease. The main difference between those with and without diabetes with respect to treatment of aneurysms is that patients with diabetes are more prone to complications after surgery; however, because of the nature of preventive surgery for aneurysms, this only rarely causes changes in management once the risk of surgery has been weighed against non-surgical treatment.

Aneurysm of the aorta is a common condition in the elderly, especially in the infra-renal aorta. An artery by definition becomes aneurysmal when the diameter locally increases more than 50% compared to the “normal” diameter proximal or distal to this site. In case of the infra-renal aorta, an aneurysm is present when the diameter exceeds 30 mm.

The prevalence of AAA is approximately 5% in men over 70 years of age; however, only a minority of them will have a size that mandates surgery (diameter >5–6 cm). In patients with other atherosclerotic manifestations, such as PAD or carotid disease, the incidence of AAA is 2–3 times greater than in persons without. Also, there is a 2:1 ratio of AAA occurring in men:women. Finally, the tendency to develop AAA is partly inherited, as the risk for a male with a father or brother with AAA is approximately 20%. People with diabetes seem to have a slightly lower incidence of AAA; approximately 80% of the prevalence of those without diabetes [19].

### Pathophysiology

Arteries enlarge with age, and the diameter of the infra-renal aorta is normally below 20 mm in a 70-year-old male. If the wall weakens locally, an aneurysm develops. A true aneurysm develops when all three layers in the arterial wall are involved and dilate as in the case of the typical infra-renal AAA. False aneurysms or pseudo-aneurysms develop after iatrogenic trauma, such as PTA or other transfemoral procedures, and at arterial anastomotic sites. Finally, dissection occurs when a rupture of the intima allows blood to enter between the layers of the artery wall.

Aortic aneurysms may rupture, leading to almost certain death. It is estimated that 80–90% of patients with ruptured AAA die before they get to hospital. Ruptured AAA causes an estimated 2–3% of all deaths among men, whereas the number for women is 1%.

In most AAA there is an atherosclerotic degeneration of the vessel wall that dilates; however, it is unclear why atherosclerosis in some patients results in occlusive disease and in others in aneurysm development. Accelerated breakdown of elastin has a role in AAA development. Simultaneous presence of both occlu-

sive and aneurysmal disease is common in many patients. Inflammatory aneurysms are present in 5–10% of AAA where the aortic wall is thickened as part of perianeurysmal or retroperitoneal fibrosis.

### Symptoms from AAA

Symptoms are rare and so most cases are asymptomatic. Diagnosis is often made coincidentally, as when a patient complains of slight upper gastric pain and has an ultrasound of the gallbladder, which discloses the AAA. Also typically, a patient may complain of back pain and have a lumbar X-ray where the AAA is discovered. Whether the patient's pain was really related to the AAA or to gallstones or to the back is often difficult to ascertain.

Some patients will sense a pulsation in the abdomen, while large aneurysms may cause discomfort or compress surrounding organs, mainly the gastrointestinal tract. The main risk is rupture which, when intraperitoneal, most often leads to immediate death. If rupture is into the retroperitoneal space, a hematoma may be contained and the patient may survive for hours. Rupture and development of a hematoma lead to pain in the abdomen and/or back. Chronic rupture is rare because almost all cases will be fatal within hours.

Aneurysms may cause peripheral embolization, causing a cyanotic or gangrenous toe as the first symptom.

### Diagnosis

Diagnosis of AAA is easy. Ultrasound is very accurate in making the diagnosis and estimating the diameter of the aneurysm (Figure 43.6). In the few cases where ultrasound is inconclusive, a primary CT scan may be necessary. Otherwise, CT or MR scanning is only performed when the size of the AAA dictates to an extent that intervention should be considered. Arteriography is rarely performed for AAA; however, in cases of both AAA and symptoms of PAD, an arteriogram may be warranted for planning of the revascularization procedure. A patient with acute abdominal pain in pre-shock should always be suspected of ruptured AAA.

**Figure 43.6** Ultrasound image of abdominal aortic aneurysm. Notice the presence of large thrombus inside the aneurysm sac.

**Prognosis**

The risk of rupture relates to the size of the aneurysm. When the diameter exceeds 6 cm, the annual risk of rupture is 10–20%, whereas the risk of rupture in case of an AAA with a diameter of 3–4 cm is less than 1%. Aneurysms tend to expand; small aneurysms dilate 1–2 mm/year whereas larger aneurysms may expand 2–3 times faster. Smoking and hypertension seem to increase the rate of growth. Rupture is associated with 90% mortality – the survival for those who reach the hospital and have immediate surgery is approximately 50–60%. Concomitant coronary disease is responsible for a 50–100% increased mortality of aneurysm patients even when aneurysm mortality is disregarded.

**Treatment**

Treatment of AAA involves, in addition to surgery for some, the same preventive treatment that is given to other patients with atherosclerotic manifestations: lifestyle changes and medical therapy with platelet inhibitors, statins and BP control.

Treatment of ruptured AAA is always interventional (open surgical or endovascular) unless the patient's overall condition is considered too poor to attempt rescue. In some cases, a fatal AAA may be a dignified death; for example, in an elderly patient with both end-stage renal failure and heart failure. Symptomatic non-ruptured aneurysms should be treated acutely or subacutely because of the risk of imminent rupture.

Treatment of large asymptomatic AAA reduces AAA mortality [20], and those with asymptomatic AAA should be offered elective interventional treatment if the risk of rupture exceeds the risk of the procedure, and if the patient is fit for the procedure and expected to have some good quality years remaining. Because any procedure for treatment of AAA either carries a considerable perioperative risk or involves a very long postoperative period with potential reinterventions, the decision to offer interventional treatment is not always easy and almost always a decision is made with the patients and their families.

The choice between treatment modalities is made keeping these facts in mind: open surgery is a well-proven procedure with known risks and long-term results, including an overall 3–5% perioperative mortality, but limited AAA morbidity after the procedure. Endovascular aneurysm repair (EVAR) has been shown to have lower perioperative morbidity: 1.5% for EVAR compared to 4.5% for open surgery [21–23]. Because the long-term results of EVAR are unknown (5–10 years), continuous surveillance with annual CT or ultrasound is necessary. Until recently, the number of reinterventions because of either migration or failure of the implanted device, both leading to endo-leak (blood re-entering the excluded aneurysm sac which is thereby again at risk of rupture) were considerable; however, recent data show improvement and is 10–15% at 3 years [23].

As an example of choice of treatment modality, a 65-year-old man with a 6-cm AAA and no other known co-morbidity should be offered treatment, preferentially open surgery, because his perioperative risk will be low (i.e. 2–3%), whereas the annual risk of rupture is approximately 10%. At the other end of the spectrum is the 80-year-old man with previous coronary artery bypass graft surgery and with a similar-sized AAA of 6 cm. His risk with open surgery includes >10% 30-day mortality in addition to a considerable risk of other complications. Endovascular treatment could be a good alternative for this patient if he is expected to live at least 3–5 years.

EVAR has been thought to be a treatment alternative for patients unfit for open surgery. The EVAR-2 trial tested this hypothesis and patients found unfit for open repair were randomized to either conservative management or EVAR. Survival was not improved by EVAR and it was poor in both groups: approximately 50% of patients in both groups were dead at 3 years and only one-quarter of deaths was aneurysm-related [24]. Thus, being found unfit for surgery in this study indicated a poor prognosis in general that EVAR did not affect.

Open surgical treatment with resection of the aneurysm and replacement of the diseased part of aorta with an artificial graft

**Figure 43.7** Abdominal aortic aneurysm treated by resection and implantation of aorto-bi-iliac bypass graft.

**Figure 43.8** Abdominal aortic aneurysm treated by endovascular repair. (A) First the bifurcated graft is inserted via the right femoral artery and fixed by stenting at the proximal and distal end of the graft. The left limb (2) is inserted via the left femoral artery and connected to the main graft. (B) Insertion of an aorto-uni-iliac endograft (1) combined with a femoro-femoral bypass graft (3) is used when one of the iliac arteries (2) cannot be passed.

has been performed for more than 40 years (Figure 43.7). Complications of open surgical repair relate to the considerable surgical trauma of this major procedure. Approximately 10–20% will develop general complications such as cardiac, pulmonary and renal complications in addition to prolonged stay at the intensive care unit and stroke.

Endovascular treatment of AAA involves inserting a collapsed prosthesis via the femoral artery, placing it below the renal arteries, deploying and fixing it (stenting) under X-ray guidance. The technique mostly used today involves inserting a bifurcated graft from one femoral artery and then placing the other limb via the contralateral femoral artery (Figure 43.8). Complications to EVAR are few in the perioperative period, but a considerable number of patients will need reinterventions, which in most cases can be performed by endovascular techniques. These include placement of another proximal stent because of endo-leak and embolization of inferior mesenteric or internal iliac arteries.

### Screening

The value of population-based screening for AAA is now well documented. A recent meta-analysis of the four randomized controlled trials found aneurysm-related mortality to be reduced by 43% in people being offered screening [25]. Today, it is recommended in many countries that men older than 65 years and previous smokers undergo ultrasound screening. Family members who are direct descendants of those so affected should also undergo screening.

### Peripheral aneurysms

Aneurysms may develop at other locations, popliteal and femoral arteries being the second and third most common locations. More than 50% of patients with peripheral aneurysms also have an AAA. Symptoms are different in the sense that rupture is less

common; however, symptoms derived from compression (popliteal vein thrombosis, pain and other symptoms of nerve compression), peripheral embolization or thrombosis of the aneurysm most often bring the patient to medical attention.

Treatment is the same as for AAA: general prevention against atherosclerotic disease and intervention in symptomatic cases. Popliteal aneurysms are generally treated surgically by exclusion and bypass or by resection and replacement by a short graft. Femoral aneurysms are treated by resection and placement of a graft. Endovascular management is possible; however, graft thrombosis and failure of stent graft material have so far made indications unclear. Large asymptomatic peripheral aneurysms should probably be treated by either open or endovascular surgery; however, no documentation is available at this time that such treatment is beneficial.

Aneurysms of visceral or renal arteries may occur but are rare. Treatment is interventional when they are large. Endovascular management is under development, however, its indications are unsettled.

## Carotid artery disease

This section focuses on stroke and carotid disease because cerebrovascular disease in general is dealt with in Chapter 42. The relationship to atherosclerosis for many patients with stroke is well documented, although stroke, unlike other ischemic conditions, has other common pathogenetic mechanisms.

It is very important to discriminate between symptomatic disease and asymptomatic cases. Patients with recent cerebrovascular symptoms and an ipsilateral stenosis are comparable with patients with a recent acute coronary event: the risk of a new

thromboembolic event is very high and diagnostic workup and treatment should be started immediately. The pathogenetic mechanism is similar to that of an acute coronary event with plaque rupture and subsequent thrombosis; however, in the case of the carotid, embolization into a cerebral artery is much more common than thrombotic occlusion of the carotid artery itself. Perhaps the larger diameter of the carotid artery explains this difference.

The prevalence of carotid stenosis is high. Among patients with acute cerebrovascular symptoms, an ipsilateral stenosis of greater than 50% diameter reduction is found in 15–20% of cases. In patients with other clinical atherosclerotic manifestations, a carotid stenosis is found in 20–30%.

### Pathophysiology and symptoms

See Chapter 42, dealing with cerebrovascular disease.

### Prognosis

The risk of stroke is increased in the presence of carotid stenosis. For asymptomatic patients with a carotid stenosis exceeding 60% diameter reduction, the annual risk of ipsilateral stroke is approximately 2%. When carotid stenosis is related to recent ipsilateral cerebral ischemic symptoms (symptomatic stenosis), the risk is much higher, especially just after the first event. The 30-day risk of stroke in patients with previous cerebrovascular symptoms is as high as 10% when an ipsilateral carotid stenosis is present. Thereafter, the risk gradually declines and after a year it is approximately 2–3% annually, similar to asymptomatic carotid stenosis. The 3-year risk of ipsilateral stroke is 25–30% in symptomatic patients with a stenosis greater than 70% diameter reduction.

### Diagnosis

Diagnosis of carotid disease should be carried out by duplex ultrasound scanning (Figure 43.9). The accuracy of the method is well documented both for identification and quantification of degree of stenosis. Many surgeons will perform endarterectomy based only on ultrasound examination.

### Treatment

Treatment of patients with carotid stenosis is like that of any other condition related to atherosclerosis: treatment of the atherosclerotic disease itself and treatment of local manifestations. Risk factor reduction, including changes in lifestyle, is exactly the same as for patients with other clinical manifestations of atherosclerosis, although there may be regional variation in the choice of antiplatelet agents. Aggressive lipid-lowering reduces both the risk of recurrent stroke and the risk of coronary events especially in this patient group [26–28].

It is important to realize that any intervention for carotid stenosis is performed to prevent future “local” events (stroke). Thus, the risk of the intervention itself should be weighed against the absolute risk of an event. Furthermore, the most common complication of surgery and stenting is ipsilateral stroke, the event that the procedure is supposed to prevent. Most important, the

**Figure 43.9** B-mode ultrasound image of carotid stenosis. Top part is echolucent indicating high content of lipid/necrotic core; bottom part is echogenic indicating a fibrous plaque.

overall risk of the patient should be weighed against the absolute risk reduction derived from the procedure.

### Symptomatic carotid stenosis

Symptomatic patients with carotid stenosis benefit from endarterectomy when the stenosis is greater than 50–70% diameter reduction and neurologic symptoms are within 6 months of surgery [29,30]. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and European Carotid Surgery Trialist’s Collaborative Group (ECST) trials [29,30] randomized simultaneously, but independently, symptomatic patients with carotid stenosis to best medical treatment or best medical treatment plus endarterectomy. Both trials showed significant benefit (50% relative risk reduction) in patients with greater than 70% stenosis (diameter reduction), whereas the group with 50–69% stenosis had only a marginal effect. Patients with stenoses <50% had no benefit.

Recent reanalysis of the pooled data from these two trials, however, showed that the time interval between onset of neurologic symptoms and surgery was the most important predictive factor of benefit for the patient [31]. The earlier the operation, the greater the benefit. The overall absolute risk reduction of approximately 15% conveyed by endarterectomy could be doubled when patients received surgery within 2 weeks of symptoms. With the knowledge gained during the last 10–15 years concerning the vulnerable plaque and plaque rupture, this finding does not come as a great surprise; however, when these trials were designed, this pathogenetic mechanism of acute ischemia was unknown.

Also, sex, age and degree of stenosis are factors that influence the benefit of surgery [31]. Male sex, older age and severity of stenosis all increase the risk of future stroke in patients with stenosis without any increased risk of the surgical procedure, thus, the overall benefit is greater.

#### Asymptomatic carotid stenosis

Asymptomatic carotid stenosis is more controversial, although two major trials have shown a small but statistically significant benefit of surgery. First, the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial showed a 50% relative risk reduction of ipsilateral stroke, but the absolute risk reduction was marginal, only 1% per year [32]. Later, the Asymptomatic Carotid Surgery Trial (ACST) reproduced these findings [33]. Taking into consideration that the average annual mortality during the trials were 3–4%, in addition to other ischemic events which were unaffected by the procedure, it may be questioned whether the cost–benefit is reasonable both for the patient and society. The medical treatment offered during these trials was much poorer than that recommended today; thus, the outcomes of these trials may not be reflective of the risk in these patients today. If or when better criteria for selection of patients at higher risk becomes available, selective surgery for high-risk cases of asymptomatic carotid stenosis may yield greater or even much greater benefit.

#### Technical considerations

Technically, carotid endarterectomy may be performed in two ways: classic endarterectomy (Figure 43.10) or eversion endarterectomy. In the latter, the internal carotid artery is divided from the bifurcation, and endarterectomy is performed by everting the vessel wall, thereby removing the carotid lesion. After the stenosis has been removed, the bifurcation is reconstructed by reanastomosing the internal carotid to the bifurcation.

Carotid endarterectomy may be performed under general or local anesthesia. Classically, general anesthesia has been preferred; however, this has carried the challenge of monitoring cerebral circulation during clamping of the carotid artery. A variety of methods have been used ranging from electroencephalography, stump pressure, distal internal carotid artery pressure, evoked potentials, near-infrared spectroscopy, transcranial Doppler and more. None of these methods have proven ideal, so some surgeons use a shunt on a selective basis, whenever their method for monitoring indicates risk of cerebral ischemia during clamping, whereas others use a shunt routinely. By contrast, performing endarterectomy under local anesthesia gives the surgeon the opportunity to communicate with the patient during clamping. Having the patient awake and responsive during surgery may be the best monitoring of cerebral function during clamping. Also, local anesthesia may carry less cardiac and pulmonary risk. Smaller trials and a recent meta-analysis indicate superiority of local anesthesia [34]; however, recently the General Anesthesia versus Local Anesthesia for carotid surgery (GALA) trial reported its results after randomizing 3529 patients to either universal or

**Figure 43.10** Carotid endarterectomy where the intima–media complex is dissected free of the adventitia and removed.

local anesthesia for carotid endarterectomy – there was no difference in the risk of perioperative stroke or death [35].

#### Carotid stenting

This has not yet been proven in randomized clinical trials to prevent ipsilateral ischemic events. Seven randomized controlled trials have been published to compare stenting with endarterectomy; however, they have only focused so far on comparison of perioperative complications. The two most recent trials, the EVA-3S and the SPACE trial, failed to show an advantage of the less invasive carotid stenting method with respect to perioperative events [36,37]. In fact, the EVA-3S trial was stopped early because of excess complications in the stenting group [36]. A recent Cochrane meta-analysis, including all seven randomized controlled trials, favors surgery with respect to the primary outcome of perioperative death and ipsilateral stroke [38]. Nevertheless, it is important to acknowledge that technology does develop rapidly and some of the trials may have used devices and/or technologies that are already outdated. Similarly, there may be differences in trial design, and criticism has been raised specifically as to the training of investigators in some studies. Interestingly, stenting appears to be associated with higher complication rates when performed early after neurologic symptoms and in the elderly – the two strongest indications. Finally, it is important to keep in mind that stenting should be evaluated in

long-term studies, and not only compared with endarterectomy, but also with medical therapy, which has been improved dramatically the last 10–20 years.

Carotid revascularization prior to coronary artery bypass surgery has been practiced in some institutions whereas others have not found it useful. The potential advantage is avoiding cerebral ischemia during the relative hypotension “on pump”; however, the complications of carotid revascularization have outweighed the gains, as evaluated by recent reviews.

It may be questioned whether the evidence for endarterectomy is outdated. Three of the four major trials proving endarterectomy to be of value for symptomatic and asymptomatic surgery were performed when the only fairly constant preventive medication given was aspirin. The last trial randomized 8–10 years ago and only 30% of patients were taking statins. It is stated in the design of these trials that hypertension and hypercholesterolemia were treated when present; however, in that era, the treatment goals for both hypertension and hypercholesterolemia were much more lax than they are now. Also, new drugs have been introduced and their benefit documented since these trials randomized patients (e.g. statins, newer antiplatelet agents, dual antiplatelet therapy and newer antihypertensive drugs). It may be speculated that if these drugs were used systematically, the risk in patients with carotid stenosis would be much less, not least in those with vulnerable plaques. Therefore, new trials are needed to test how today’s medical therapy compares with intervention and if the best medical therapy remains inferior to surgery or stenting. New trials are *not* unethical – it is unethical not to undertake new trials.

## Foot Problems in Patients With Diabetes

**Andrew J.M. Boulton**

Department of Medicine, University of Manchester and Manchester Royal Infirmary, Manchester, UK and Miller School of Medicine, University of Miami, Miami, FL, USA

### Keypoints

- Diabetic foot problems remain the most common cause of hospital admissions amongst patients with diabetes in Western countries.
- Up to 50% of older patients with type 2 diabetes have risk factors for foot problems.
- Up to 85% of lower limb amputations are preceded by foot ulcers.
- All patients with diabetes should be screened for risk of foot problems on an annual basis: those with risk factors require regular podiatry, patient education and instruction in self-foot care.
- Most foot ulcers should heal if pressure is removed from the ulcer site, the arterial circulation is sufficient and infection is managed and treated aggressively.
- Any patient with a warm unilateral swollen foot without ulceration should be presumed to have an acute Charcot neuroarthropathy until proven otherwise.

### Introduction

*“Superior doctors prevent the disease. Mediocre doctors treat the disease before evident. Inferior doctors treat the full-blown disease.”*  
[Huang Dee, China, 2600 BC]

The Chinese proverb suggests that inferior doctors treat the full-blown disease, and until recent years, this was sadly the case with diabetic foot disease. Realizing the global importance of diabetic foot disease, the International Diabetes Federation (IDF) focused on the diabetic foot throughout the year 2005, during which there was a worldwide campaign to “put feet first” and highlight the all too common problem of amputation amongst patients with diabetes throughout the world. To coincide with World Diabetes Day in 2005, *The Lancet* launched an issue almost exclusively dedicated to the diabetic foot: this was the first time that any major non-specialist journal had focused on this worldwide problem; however, major challenges remain in getting across important messages relating to the diabetic foot:

- 1 Foot ulceration is common, affecting up to 25% of patients with diabetes during their lifetime [1].
- 2 Over 85% of lower limb amputations are preceded by foot ulcers and diabetes remains the most common cause of non-traumatic amputation in western countries [2].
- 3 Prevention is the first step towards solving diabetic foot problems. Although it was estimated that a leg is lost to diabetes

somewhere in the world every 30 seconds, a more important fact is that up to 85% of all amputations in diabetes should be preventable [2].

4 Reductions in amputations will only be achieved if health care professionals from all specialties realize that, as Brand once stated, “pain is God’s greatest gift to mankind”: it is the loss of pain that permits patients with neuropathy to develop ulcers and continue walking on them despite the presence of often overwhelming infection [3].

5 Strategies aimed at preventing foot ulcers are cost-effective and can even be cost-saving if increased education and effort are focused on those patients with recognized risk factors for the development of foot problems [4].

6 Diabetes is now the most common cause of Charcot neuroarthropathy in Western countries, another condition that should be generally preventable [3].

Much progress in our understanding of the pathogenesis and management of the diabetic foot has been made over the last quarter century. This has been matched by an increasing number of publications in peer-reviewed journals. Taken as a percentage of all PubMed listed articles on diabetes, those on the diabetic foot have increased from 0.7% in the 1980–1988 period to more than 2.7% in the years 1998–2004 [3]. Prior to 1980, little progress had been made in the previous 100 years despite the fact that the association between gangrene and diabetes was recognized in the mid-19th century [5]. For the first 100 years following these descriptions, diabetic foot problems were considered to be predominantly vascular and complicated by infection. It was not until during the Second World War, for example, that McKeown performed the first ray excision on a patient with diabetes and osteomyelitis but good blood supply: this was performed under

the encouragement of Lawrence, who had diabetes himself and was co-founder of the British Diabetic Association, now Diabetes UK [6].

In the last two decades many major national and international societies were formed including diabetic foot study groups and the international working group on the diabetic foot was established in 1991. New editions of two leading international textbooks on the diabetic foot have been published in recent years [7,8], and a number of collaborative research groups are now tackling many of the outstanding problems regarding the pathogenesis and management of diabetic foot disease.

In this chapter, the global term “diabetic foot” will be used to refer to a variety of pathologic conditions that might affect the feet of people with diabetes. Initially, the epidemiology and economic impact of diabetic foot disease are discussed, followed by the contributory factors that result in diabetic foot ulceration. The potential for prevention of these late sequelae of neuropathy and vascular disease are discussed, followed by a section on the management of foot ulcers. The chapter closes with a brief description of the pathogenesis and management of Charcot neuroarthropathy, an end-stage complication of diabetic neuropathy. Throughout, cross-referencing will be provided to other chapters that also cover aspects of diabetic foot disease, particularly those on diabetic neuropathy (see Chapter 38), peripheral vascular disease (see Chapter 43), bone and rheumatic disorders in diabetes (see Chapter 48) and infection (see Chapter 50).

## Epidemiology and economic aspects of diabetic foot disease

As foot ulceration and amputation are closely inter-related in diabetes [2], they will be considered together in this section. A selection of epidemiologic data for foot ulceration and amputa-

tion, originating from studies from a number of different countries [9–17], is provided in Table 44.1. Globally, diabetic foot complications remain major medical, social and economic problems that are seen in all types of diabetes and in every country [18]; however, the reported frequencies of amputation and ulceration vary considerably as a consequence of different diagnostic criteria used as well as regional differences [19]. Diabetes remains a major cause of non-traumatic amputation across the world with rates being as much as 15 times higher than in the non-diabetic population.

Although many of the studies referred to and listed in Table 44.1 were well conducted, methodologic issues remain which make it difficult to perform direct comparisons between studies and/or countries. First, definitions as to what constitutes a foot ulcer vary and, secondly, surveys invariably include only patients with previously diagnosed diabetes, whereas in type 2 diabetes, foot problems may be the presenting feature. In one study from the UK, for example, 15% of patients undergoing amputation were first diagnosed with diabetes on that hospital admission [20]. Third, reported foot ulcers are not always confirmed by direct examination by the investigators involved in the study. Finally, as can be seen from the table, in those studies that assess the percentage of the population that had risk factors for foot ulceration, 40–70% of patients fell into that category. Such observations clearly indicate the need for all diabetes services to have a regular screening program to identify such high risk individuals.

## Health economics of diabetic foot disease

In addition to causing substantial morbidity and even mortality, foot lesions in patients with diabetes additionally have substantial economic consequences.

Diabetic foot ulceration and amputations were estimated to cost US health care payers \$10.9 billion in 2001 [21,22].

Corresponding estimates from the UK based upon similar methodology suggested that the total annual costs of diabetes-related foot complications was £252 million [23]; however, similar problems to those noted with epidemiology exist when comparing data on the costs of diabetic foot lesions relating to methodology but also as to whether direct and indirect costs were included. Moreover, few studies have estimated costs of the long-term follow-up of patients with foot ulcers or amputations [2].

The most recent data from the USA suggest that in 2007 \$18.9 billion was spent on the care of diabetic foot ulcers, and \$11.7 billion on lower extremity amputations [24]. Having estimated the total cost of diabetic foot disease to be \$30.6 billion in 2007, the authors went on to estimate the potential savings based upon realistic reductions in ulceration and amputation, to be as high as \$21.8 billion. Such strong economic arguments may help to drive improvements in preventative foot care which could potentially lead to significant savings for health care systems.

## Etiopathogenesis of diabetic foot lesions

*“Coming events cast their shadow before.”* [Thomas Campbell]

If we are to be successful in reducing the high incidence of foot ulcers and ultimately amputation, a thorough understanding of the pathways that result in the development of an ulcer is increasingly important. The words of the Scottish poet, Thomas Campbell, can usefully be applied to the breakdown of the diabetic foot. Ulceration does not occur spontaneously; rather it is the combination of causative factors that result in the development of a lesion. There are many warning signs or “shadows” that can identify those at risk before the occurrence of an ulcer. It is

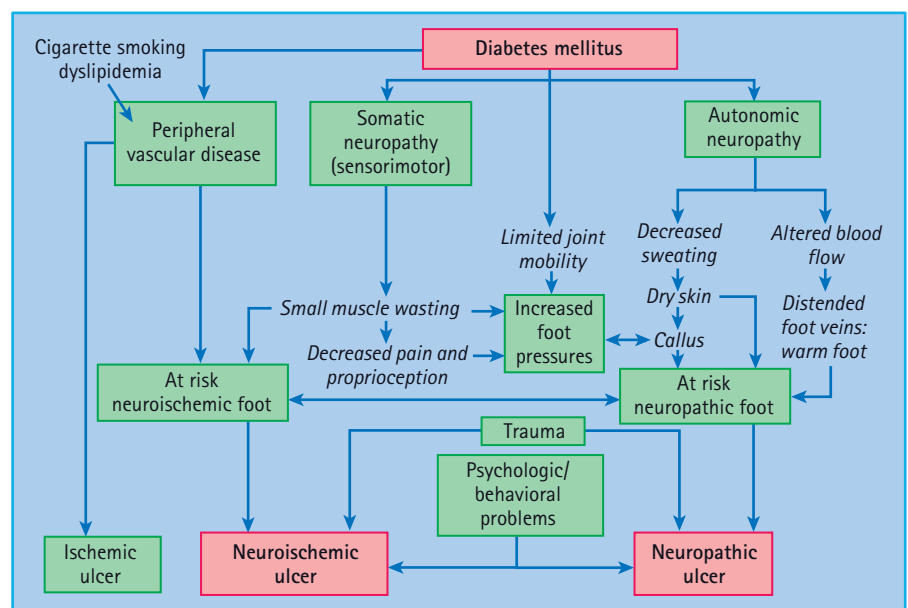

not an inevitable consequence of having diabetes that ulcers occur: ulcers invariably result from an interaction between specific pathologies in the lower limb and environment hazards. The breakdown of the diabetic foot traditionally has been considered to result from an interaction of peripheral vascular disease (PVD), peripheral neuropathy and some form of trauma. Other causes are also briefly described.

### Peripheral vascular disease

Although described in detail in Chapter 43, brief mention of the role of PVD in the genesis of foot ulcers must be made here. PVD tends to occur at a younger age in patients with diabetes and is more likely to involve distal vessels. Reports from the USA and Finland have confirmed that PVD is a major contributory factor in the pathogenesis of foot ulceration and subsequent major amputations [25,26]. In the pathogenesis of ulceration, PVD itself in isolation rarely causes ulceration: as will be discussed for neuropathy, it is the combination of risk factors with minor trauma that inevitably leads to ulceration (Figure 44.1). Thus, minor injury and subsequent infection increase the demand for blood supply beyond the circulatory capacity and ischemic ulceration and the risk of amputation ensues. In recent years, neuroischemic ulcers in which the combination of neuropathy and PVD exists in the same patient, together with some form of trauma, are becoming increasingly common in diabetic foot clinics.

### Diabetic neuropathy

As discussed in Chapter 38, the diabetic neuropathies represent the most common form of the long-term complications of diabetes, affect different parts of the nervous system and may present with diverse clinical manifestations [27]. Most common amongst the neuropathies are chronic sensorimotor distal symmetrical

**Figure 44.1** Pathways to foot ulceration in diabetes. Reproduced from Boulton *et al.* [7], with permission.

polyneuropathy and the autonomic neuropathies. It is the common sensorimotor neuropathy together with peripheral autonomic sympathetic neuropathy that together have an important role in the pathogenesis of ulceration.

**Sensorimotor neuropathy**

As noted in Chapter 38, this type of neuropathy is very common and it has been estimated that up to 50% of older patients with type 2 diabetes have evidence of sensory loss on clinical examination and therefore must be considered at risk of insensitive foot injury [27]. This type of neuropathy commonly results in a sensory loss confirmed on examination by a deficit in the stocking distribution to all sensory modalities: evidence of motor dysfunction in the form of small muscle wasting is also often present. While some patients may give a history (past or present) of typical neuropathic symptoms such as burning pain, stabbing pain, paresthesia with nocturnal exacerbation, others may develop sensory loss with no history of any symptoms. Other patients may have the “painful-painless” leg with spontaneous discomfort secondary to neuropathic symptoms but who on examination have both small and large fiber sensory deficits: such patients are at great risk of painless injury to their feet.

From the above it should be clear that a spectrum of symptomatic severity may be present with some patients experiencing severe pain and at the other end of the spectrum, patients who have no spontaneous symptoms but both groups may have significant sensory loss. The most challenging patients are those who develop sensory loss with no symptoms because it is often difficult to convince them that they are at risk of foot ulceration as they feel no discomfort, and motivation to perform regular foot self-care is difficult. The important message is that neuropathic symptoms correlate poorly with sensory loss, and their absence must *never* be equated with lack of foot ulcer risk. Thus, assessment of foot ulcer risk must *always* include a careful foot examination after removal of shoes and socks, whatever the neuropathic history [27].

**The patient with sensory loss**

A reduction in neuropathic foot problems will only be achieved if we remember that those patients with insensitive feet have lost their warning signal – pain – that ordinarily brings patients to their doctors. Thus, the care of a patient with sensory loss is a new challenge for which we have no training. It is difficult for us to understand, for example, that an intelligent patient would buy and wear a pair of shoes three sizes too small and come to the clinic with extensive shoe-induced ulceration. The explanation is simple: with reduced sensation, a very tight fit stimulates the remaining pressure nerve endings and is thus interpreted as a normal fit – hence the common complaint when we provide patients with custom-designed shoes that “these shoes are too loose”. We can learn much about the management of such patients from the treatment of patients with leprosy [28]. Although the cause of sensory loss is very different from that in diabetes, the end result is the same, thus work in leprosy has been

very relevant to our understanding of the pathogenesis of diabetic foot lesions. It was Brand (1914–2003) who worked as a surgeon and a missionary in South India, who described pain as “God’s greatest gift to mankind” [29]. He emphasized the power of clinical observation to his students and one remark of his that was very relevant to diabetic foot ulceration was that any patient with a plantar ulcer who walks into the clinic without a limp must have neuropathy. Brand also taught us that if we are to succeed, we must realize that with loss of pain there is also diminished motivation in the healing of, and prevention of, injury.

**Peripheral sympathetic autonomic neuropathy**

Sympathetic autonomic dysfunction of the lower limbs leads to reduced sweating and results in both dry skin that is prone to crack and fissure, and to increased blood flow (in the absence of large vessel obstructive PVD) with arteriovenous shunting leading to the warm foot. The complex interactions of the neuropathies and other contributory factors in the causation of foot ulcers are summarized in Figure 44.1.

**Other risk factors**

Of all the other risk factors for ulceration (Table 44.2) one of the most important is a past history of similar problems. In many series this has been associated with an annual risk of re-ulceration of up to 50%.

**Other long-term complications**

Patients with other late complications, particularly nephropathy, have been reported to have an increased foot ulcer risk. Those most at risk are patients who have recently started dialysis as treatment of their end-stage renal disease [30]. It must also be remembered that those patients with renal transplants and more recently combined pancreas–renal transplants are usually at high risk of ulceration even if normoglycemic as a result of the pancreas transplant.

**Table 44.2** Factors increasing risk of diabetic foot ulceration. More common contributory factors shown in bold.

Edema
Ethnic background
Poor social background

**Figure 44.2** The high risk neuropathic diabetic foot demonstrating high arch, prominent metatarsal heads, clawing of toes and callus under first metatarsal head.

#### **Plantar callus**

Callus forms under weight-bearing areas as a consequence of dry skin (autonomic dysfunction), insensitivity and repetitive moderate stress from high foot pressure. It acts as a foreign body and causes ulceration [31]. The presence of callus in an insensate foot should alert the physician that this patient is at high risk of ulceration, and callus should be removed by the podiatrist or other trained health care professional.

#### **Elevated foot pressures**

Numerous studies have confirmed the contributory role that abnormal plantar pressures play in the pathogenesis of foot ulcers [3,32].

#### **Foot deformity**

A combination of motor neuropathy, cheiroarthropathy and altered gait patterns are thought to result in the “high risk” neuropathic foot with clawing of the toes, prominent metatarsal heads, high arch and small muscle wasting (Figure 44.2).

#### **Ethnicity and gender**

The male sex has been associated with a 1.6-fold increase of ulcers [11]. With respect to ethnic origin, data from cross-sectional studies in Europe suggests that foot ulceration is more common in European subjects than other racial groups: for example, the North-West Diabetes Foot Care Study in the UK showed that the age-adjusted prevalence of diabetic foot ulcers (past or present) for Europeans, South Asians and African-Caribbeans was 5.5%, 1.8% and 2.7%, respectively [33]. Reasons for these ethnic differences certainly warrant further investigation. In contrast, in the southern USA, ulceration was much more common in Latino Americans and Native Americans than in White people of Northern European ancestry [34]; however, more recent data

confirmed this increased risk in Latinos, despite the foot pressures being actually lower in this group [35].

#### **Pathway to ulceration**

It is the combination of two or more risk factors that ultimately results in diabetic foot ulceration (Figure 44.1). Both Pecoraro *et al.* [25] and later Reiber *et al.* [36] have taken the Rothman model for causation and applied this to amputation and foot ulceration in diabetes. This model is based upon the concept that a component cause (e.g. neuropathy) is not sufficient in itself to lead to ulceration, but when the component causes act together, they result in a sufficient cause which will inevitably result in ulceration. Applying this model to foot ulceration, a small number of causal pathways were identified: the most common triad of component causes, present in nearly two out of three incident foot ulcer cases, was neuropathy, deformity and trauma. Edema and ischemia were also common component causes. Other simple examples of two component causeways to ulceration are loss of sensation and mechanical trauma such as standing on a nail, wearing shoes that are too small; or neuropathy and thermal trauma (e.g. walking on hot surfaces or burning feet in the bath); finally, neuropathy and chemical trauma may result in ulceration from the inappropriate use for example of chemical “corn cures.” Similarly, this model can be applied to neuroischemic ulcers where the three component causes comprising ischemia, trauma and neuropathy are often seen.

### **Prevention of diabetic foot ulcers**

#### **Screening**

It has been estimated that the vast majority of foot ulcers are potentially preventable, and the first step in prevention is the identification of the “at risk” population. Many countries have now adopted the principle of the “annual review” for patients with diabetes, whereby every patient is screened at least annually for evidence of diabetic complications. Such a review can be carried out either in the primary care center or in a hospital clinic.

A taskforce of the American Diabetes Association recently addressed the question of what should be included for the annual review in the “comprehensive diabetic foot examination (CDFE)” [37]. The taskforce addressed and concisely summarized the recent literature in this area and recommended, where possible using evidence-based medicine, what should be included in the CDFE for adult patients with diabetes. Whereas a brief history was regarded as important, a careful examination of the foot including assessing its neurologic and vascular status was regarded as essential. There is a strong evidence base to support the use of simple clinical tests as predictors of risk of foot ulcers [11,37]. A summary of the key components of the CDFE is provided in Table 44.3. Whereas each potential simple neurologic clinical test has advantages and disadvantages, it was felt that the 10-g monofilament had much evidence to support its use hence the recommendation that assessment of neuropathy should comprise the

use of a 10 g monofilament plus one other test. In addition to those simple tests listed in Table 44.3, one possible test for neuropathy was assessment of vibration perception threshold. Although this is a semi-quantitative test of sensation, it was included as many centers in both Europe and North America have such equipment. As can be seen from Table 44.3, this is not regarded as essential, but strong evidence does support the use of vibration perception threshold as an excellent predictor of foot ulceration [38,39].

With respect to the vasculature, the ankle brachial index was recommended although it was realized that many centers in primary care may not be able to perform this in day-to-day clinical practice.

### Intervention for high-risk patients

Any abnormality of the above screening test would put the patient into a group at higher risk of foot ulceration. Potential interventions are discussed under a number of headings, the most important of which is education.

#### Education

Previous studies have suggested that patients with foot ulcer risk lack knowledge and skills and consequently are unable to provide appropriate foot self-care [40]. Patients need to be informed of the risk of having insensate feet, the need for regular self-inspection, foot hygiene and chiropody/podiatry treatment as required, and they must be told what action to take in the event of an injury or the discovery of a foot ulcer. Recent studies summarized by Vileikyte *et al.* [41,42] suggests that patients often have distorted beliefs about neuropathy, thinking that this is a circulatory

problem and link neuropathy directly to amputation. Thus, an education program that focuses on reducing foot ulcers will be doomed to failure if patients do not believe that foot ulcers precede amputations. It is clear that much work is required in this area if appropriate education is to succeed in reducing foot ulcers and subsequently amputations. The potential for education and self-care at various points on the pathway to neuropathic ulceration is shown in Figure 44.3.

There have been a small number of reports that assess educational interventions, but these have mostly been small single-center studies. In the most recently published study, even though the foot care education program was followed by improved foot care behavior, there is no evidence that such targeted education was associated with a reduced incidence of recurrent foot ulcers [43]. It has been suggested that patients find the concept of neuropathy difficult to understand: they are reassured because they have no discomfort or pain in their feet. It may be that using visual aids (which can also be used for diagnosis of the at risk foot) may help patients to understand that there is something different about their feet compared with their partner's, for example. This might include the use of the administered indicator plaster (Neuropad): when applied to the foot this changes color from blue to pink if there is normal sweating [44]. The absence of sweating such as in a high risk foot, results in no color change enabling patients to see that there is something different about their feet. A similar visual aid is the PressureStat (Podotrack) (Figure 44.4) [45]. This is a simple inexpensive semi-quantitative footprint mat that is able to identify high plantar pressures. The higher the pressure, the darker the color of the footprint. Similarly, this can be used as an educational aid and might help the patient realize that specific areas under their feet are at particular risk of ulceration.

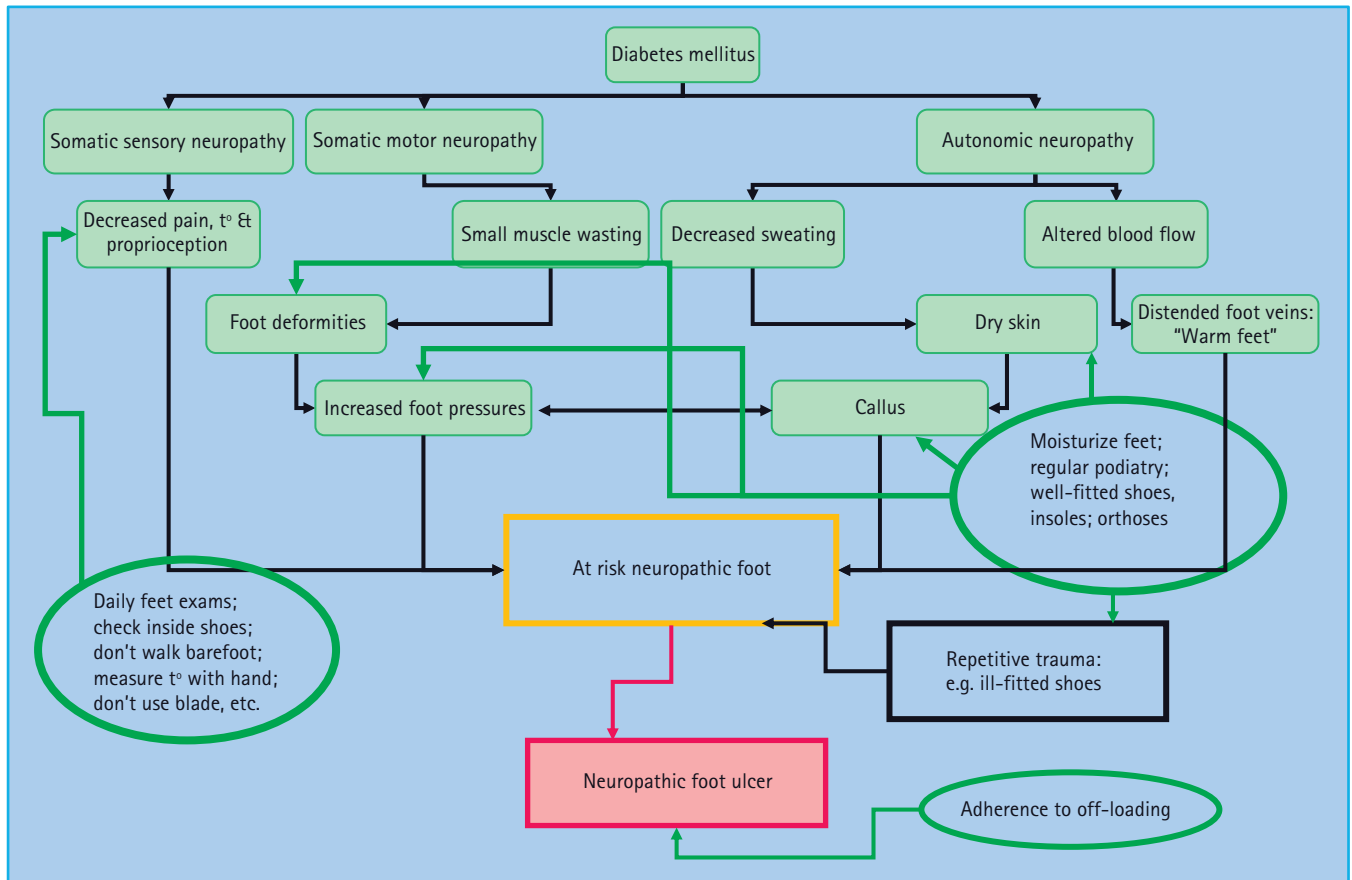

In summary, foot care education is believed to be crucial in the prevention of ulceration, although there is little support for this from randomized controlled trials. Further studies in this area are therefore urgently required.

#### Podiatry/chiropody

Although not available in every country, regular nail and skin care from a podiatrist/chiropodist is essential in the high-risk neuropathic foot. Attempted self-care has been reported in several cases to cause ulceration and similarly self-care of calluses should be discouraged. Chiropodists and podiatrists should be attached to the foot care team if available and can also educate the patient while treating the feet.

#### Footwear/orthoses/hosiery

Inappropriate footwear is a common cause of foot ulceration in insensitive feet, whereas good footwear can reduce ulcer occurrence [40]. This statement is supported by randomized controlled trials [46]. There is evidence from the literature also to support the use of specialist hosiery which might reduce foot pressures and give all round protection to high risk neuropathic feet [47,48].

**Figure 44.3** The potential for education and self-care in prevention of neuropathic foot ulcers. t°, temperature. Courtesy of L. Vileikyte MD, PhD.

### Self-monitoring of skin temperature

It has been known for some time that prior to skin breakdown and ulceration, the involved area of the foot tends to warm up as a consequence of local inflammation. In an appropriately designed, randomized controlled trial, Lavery *et al.* [49] randomized patients with a history of neuropathic foot ulceration to one of three groups, the main intervention being self-monitoring of skin temperature of both feet: those patients who received this skin temperature thermometer were advised to rest or contact their foot clinic should there be a maintained difference in temperature between the two feet. This study clearly showed that those patients who monitored their skin temperatures and followed the advice had a markedly reduced incidence of recurrent ulceration (8% vs 30%). Thus, infrared temperature home monitoring might help to identify the “pre-ulcerative” foot and permit intervention prior to actual skin breakdown. A more recent study has provided further support for this notion [50].

### Injected liquid silicone

Injected liquid silicone under high pressure areas of the diabetic foot has been used for some years in the USA and is supported by a randomized controlled trial [51] which confirmed that those patients receiving active agent had reduced foot pressures and

increased subcutaneous tissue under the high pressure areas of the forefoot. This therapy is now available in certain European countries, and a follow-up study [52] confirmed that the effect of this “injectable orthosis” lasts for up to 2 years, although booster injections may be required from time to time.

## Foot ulcers: diagnosis and management

### Foot ulcer classification

Despite increasing efforts in the early identification and preventative foot care education of high risk patients, foot ulcers continue to be a major issue in diabetes management and may indeed be the presenting feature of type 2 diabetes. The principles of management depend up a careful assessment of the causative factors, the presence or absence of infection, the degree of neuropathy and/or ischemia in the foot. Before discussing the management of specific types of ulcers, it is important to consider how to classify foot lesions. Numerous classification systems for diabetic foot ulcers have been proposed [53] but only a few are described here.

The most widely used foot ulcer classification system worldwide at the time of writing is the Meggitt–Wagner grading, as shown in Table 44.4. Despite its wide use, this system does lack

specificity and it does not refer to the neuropathic, ischemic or infective status of the ulcers.

The newer University of Texas (UT) wound classification system is currently widely used (Table 44.5) [54]. This is based

upon the Meggitt–Wagner system but with the addition of grades of infection and ischemia. In a comparative study of these two systems, the UT system was shown to be a useful predictor of outcome although the Meggitt–Wagner system was still confirmed to be useful [55]. A high risk foot with pre-ulcerative lesions (Wagner 0, UT1A) is shown in Figure 44.5. The two more recently described classification systems, S(AD) SAD system, (size (area, depth), sepsis, arteriopathy and denervation) and the PEDIS (perfusion, extent, depth, infection, sensation) systems appear to have some advantages over the earlier systems, but are not in widespread use [53]. Thus, the UT system will be used to describe ulcer classification here.

**Wound healing in the diabetic foot**

Wound healing is a tissue response to injury and passes through the phases of inflammation, chemotaxis, cellular proliferation, extracellular matrix deposition and finally wound remodeling and scarring. Diabetes may influence foot wound healing in a number of different ways including an impairment of the peripheral circulation, altered leukocyte function, disturbed balance of cytokines and proteases and even chronic hyperglycemia itself [3,56]. Thus, foot ulcers in patients with diabetes are recalcitrant to healing because of many cellular and molecular aberrations. When compared with normal acute wound healing, chronic foot ulcers are often stalled in the chronic inflammatory phase with impaired granulation tissue formation. A key question is therefore: is there a fundamental impairment of wound healing in diabetes, and if so, what are the molecular/cellular impairments and are they specific to chronic wounds? A number of studies have reported abnormalities in cytokines and growth factors in tissue from chronic diabetic foot ulcers [57–59]. Most recently, it has been suggested that levels of matrix metallopro-

**Figure 44.4** A black and white pressure distribution of one footstep using PressureStat: the darkest areas represent highest pressures, in this case under metatarsal heads 1 and 3 and the hallux.

**Table 44.4** Meggitt–Wagner classification. Modified from Oyibo *et al.* [55].

Grade 0	No ulcer, but high risk foot (deformity, callus, etc)
Grade 1	Superficial ulcer
Grade 2	Deep ulcer, may involve tendons but not bone
Grade 3	Deep ulcer with bone involvement, osteomyelitis
Grade 4	Localized gangrene (e.g. toes)
Grade 5	Gangrene of whole foot

**Table 44.5** The University of Texas ulcer classification system.

Stage	Grade			
	0	1	2	3
A	High risk foot: no ulcer	Superficial ulcer	Deep ulcer to tendon/capsule	Wound penetrating bone/joint
B	+Infection	+Infection	+Infection	+Infection
C	+Ischemia	+Ischemia	+Ischemia	+Ischemia
D	+Infection and ischemia	+Infection and ischemia	+Infection and ischemia	+Infection and ischemia

**Figure 44.5** Wagner grade I ulcer, UT1A foot ulcer, showing a rim of callus and a punched out neuropathic ulcer in the metatarsal head region with no evidence of infection.

teinasases (MMP) are important in predicting the likelihood of wound healing and a high level of MMP-1 seems essential to wound healing [59].

Another contributory factor to impaired wound healing in diabetes appears to be repetitive pressure on the wound. The pivotal role of offloading is therefore considered in the next section.

### Offloading

A normal individual with a foot wound will limp: it has been known for some time that neuropathic plantar foot wounds will heal satisfactorily when offloaded in a Total Contact Cast (TCC) [3]. The principle of TCC management is that pressure is mitigated but, in addition, the device is irremovable thus enforcing compliance with therapy. A number of randomized controlled trials have compared the TCC with other removable offloading devices in plantar diabetic foot ulcers and invariably, healing is most rapid in those randomized to TCC treatment [3,60]. As it is known that the Removable Cast Walkers (RCW) redistribute pressure in a similar manner to the TCC, however, the question remained as to why the TCC usually demonstrated superiority in terms of speed of wound closure. The most likely explanation

which is that of patient non-compliance, was confirmed in a study of 20 subjects with plantar neuropathic diabetic foot ulcers who were provided with RCWs and their total activity was recorded both from the waist, and from an activity monitor hidden in the RCW. It transpired that patients only wore the RCW for 28% of all footsteps [61]. Subsequent to this observation, it was proposed that an RCW might be rendered irremovable by wrapping it with one or two bands of plaster of Paris, therefore addressing most of the disadvantages of the TCC but preserving irremovability. A subsequent randomized controlled trial of this modified, irremovable RCW versus the TCC showed that healing times were identical [62].

The impact of appropriate offloading on the histopathologic features of neuropathic diabetic foot ulcers was reported by Piaggese *et al.* [63]. These authors confirm that appropriate offloading resulted in the foot wound appearing more like an acute wound with reparative patterns, angiogenesis and fibroblast proliferation and the presence of granulation tissue. In contrast, biopsies from wounds that had not previously been offloaded confirmed the presence of hyperkeratosis, fibrosis and chronic inflammation. These observations certainly suggest that appropriate offloading is associated with change in the histology of neuropathic foot ulcers including the reduction of inflammatory and reactive components and the acceleration of wound healing.

Another important consideration is the importance of emotional distress (e.g. depression and anxiety) on wound healing in patients with diabetes [64]. Such effects may have direct and indirect effect on wound healing. The direct effects include altered catecholamine and steroid secretion in addition to an imbalance of cytokines which might directly impair wound healing. Indirectly, those patients who are depressed, for example, are less likely to adhere to treatment advice such as wearing an RCW at all times when walking. These important observations have previously been neglected by clinicians and if any patient with a plantar foot ulcer treated by an RCW shows no sign of healing, consideration should be given to compliance and the possibility of rendering the RCW irremovable as noted above.

As might be deduced from the above discussion, offloading is an essential component to the management of predominantly neuropathic plantar foot ulcers. This would include most UT 1A and 2A ulcers. Casts may also be used in the presence of localized infection in neuropathic foot ulcers (Figure 44.6). There is also evidence to support the use of offloading devices in the management of neuroischaemic ulcers but only if they are not clinically infected (UT 1C, 2C) [65].

For those patients treated with irremovable cast walkers, it is recommended that the cast be removed initially on a weekly basis for wound assessment, débridement and cleansing. Healing can generally be achieved in a period of 6–12 weeks in a cast: it is strongly recommended that after the plantar wound has healed, that the cast be worn for a further 4 weeks to permit the scar tissue to firm up. Thereafter, the patient may be gradually transferred to appropriate footwear which may need extra depth or in the case of severe deformity, custom moulded.

**Figure 44.6** Radiograph from a patient with a deep neuropathic ulcer under the right fifth metatarsal head. Gas in the tissues is not uncommon in radiographs of neuropathic foot ulcers as patients lacking pain sensation are able to walk despite the ulcer, “pumping” gas into the tissue. In this example, however, the gas makes it difficult to assess whether osteomyelitis is present.

### Dressings

The danger of dressings and bandages is that some health care professionals may draw from them a false sense of security, believing that by dressing an ulcer they are curing it. Nothing could be further from the truth for a neuropathic ulcer. The three most important factors in the healing of a diabetic foot ulcer are: freedom from pressure, freedom from infection and good vascularity. The purpose of dressings is to protect the wound from local trauma, minimize the risk of infection and optimize the wound environment which should be moist in most cases. The evidence base to support the choice of any particular dressing is woefully inadequate with few trials generally hampered by small numbers, inappropriate comparators and poor study design [66,67]. There

is little evidence that any specific dressing will have a major impact on the rate of wound healing.

### Management of infection

One of the first steps in the management of a foot ulcer is to determine whether infection is present or not: remember that all foot ulcers are colonized with potentially pathogenic organisms and it is generally accepted by the international working group on the diabetic foot that the diagnosis of infection in the diabetic foot ulcer remains a clinical one [68]. Thus, the presence of signs such as purulent discharge, erythema, local warmth and swelling which suggests infection requiring appropriate treatment.

### Clinically non-infected ulcers

Where ulcers are not infected and predominantly neuropathic (UT grades 1A, 2A), the use of antibiotics may be withheld as Chantelau *et al.* [69] have shown that with appropriate wound management, patients do equally well with or without systemic antibiotics in a randomized controlled trial. Nevertheless, frequent review, débridement and callus removal together with offloading are essential parts of management of neuropathic foot ulcers and should signs of infection develop, antibiotics may be needed. For those ulcers with an ischemic component which do not have gross signs of infection (UT 1C, 2C) antibiotics should probably be given in most cases as the combination of infection and ischemia in the diabetic foot are a common cause of ultimate lower extremity amputation.

### Clinically infected ulcers

Non-limb-threatening infected ulcers (UT 1B, 1D, 2B, 2D) can generally be treated on an outpatient basis, and oral broad-spectrum antibiotics should be used initially until results of sensitivities are obtained. As reviewed by Lipsky, two sets of international guidelines have been published in recent years [68,70,71]. One important aspect of these recent guidelines has been the development of criteria by which to classify the severity of a diabetic foot infection. Generally, mild infections are relatively superficial and limited, moderate infections involve deeper tissues and severe infections are accompanied by systematic signs or symptoms of infection or metabolic disturbances [68]. Any ulcer with clinical evidence of infection should have tissue taken and sent for culture and sensitivity in the microbiology department. Although superficial swabs are commonly taken, deep (preferably tissue) specimens are preferable in terms of accuracy of diagnosis [68]. Most infective ulcers are polymicrobial, often with a mixture of anaerobes and aerobes. Unfortunately, a systematic review of antimicrobial treatments for diabetic foot ulcers revealed that few appropriately designed randomized controlled studies have been conducted and it was difficult to give specific guidelines as to antibiotic regimens for specific infective organisms [72]; however, if there is any suspicion of osteomyelitis (signs such as a sausage-shaped toe or the ability to probe to bone may suggest this diagnosis) should have a radiograph taken of the infected foot and possibly further investigations (see below and Chapter 50). The

antibiotic prescription for a clinically infected non-limb-threatening foot ulcer without evidence of osteomyelitis should be guided by sensitivities after these are available from tissue specimens: when sensitivities are known, targeted appropriate narrow-spectrum agents should be prescribed. Suitable broad-spectrum antibiotics to start as soon as the clinical diagnosis of infection is made while waiting for sensitivity from the microbiology department would include drugs such as clindamycin or the amoxicillin–clavulanate combination [68].

### **Limb-threatening infection**

Patients with limb-threatening infection usually have systemic symptoms and signs and require hospitalization with parenteral antibiotics. Deep wound and blood cultures should be taken, the circulation assessed with non-invasive studies initially, and metabolic control is usually achieved by intravenous insulin infusion. Early surgical débridement is often indicated in such cases, and initial antibiotic regimens should be broad-spectrum until sensitivities are determined from cultures. Examples of initial antibiotic regimens include: clindamycin and ciprofloxacin, or flucloxacillin, ampicillin and metronidazole. One problem with interpreting sensitivities is the question as to whether the organism isolated is simply a colonizing bacteria or is it a true infecting organism? One technique, the polymerase chain reaction (PCR) assay has been shown to be effective at identifying many virulent organisms [68]. A recent study from France [73] showed the potential advantages of using this new technique in the rapid distinction between colonizing and virulent infecting organisms.

An increasing problem in diabetic foot clinics is the antibiotic-resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA). In most cases, MRSA is isolated as an opportunistic colonizing organism following the treatment with often inappropriate long duration broad-spectrum antibiotics. If MRSA is felt to be an infecting organism, there are useful new agents such as linezolid [68], which can be given parenterally or orally and are effective against such organisms. There is a suggestion that larval therapy [74] might be useful in eradicating MRSA that is contaminating diabetic foot wounds.

### **Osteomyelitis**

As discussed in Chapter 50, the diagnosis of osteomyelitis is a controversial topic, and several diagnostic tests have been recommended. Amongst these, “probing to bone” has been shown to have a relatively high predictive value whereas plain radiographs are insensitive early in the natural history of osteomyelitis. In most clinical cases, however, the diagnosis is ultimately made by a plain X-ray of the foot (Figure 44.7). Magnetic resonance imaging (MRI) is having an increasing role in the diagnosis as it has high sensitivity [75]. The combination of an ulcer area  $>2 \times 2$  cm, a positive probe to bone test, an elevated sedimentation rate and an abnormal radiograph are most helpful in diagnosing the presence of osteomyelitis in the diabetic foot whereas a negative MRI makes a diagnosis much less likely [76]. The most

recent review on this topic suggests that a combination of clinical and laboratory findings together can significantly improve diagnostic accuracy for osteomyelitis in the diabetic foot: the specific combination of ulcer depth with serum inflammatory markers appears to be particularly sensitive [77]. Contrary to traditional teaching, it is increasingly recognized that some cases of localized osteomyelitis can be managed by long-term (10–12 weeks) antibiotic therapy [78]; however, localized bony resection after appropriate antibiotic therapy remains a common approach. Those cases with osteomyelitis confined to one bone without involvement of a joint are most likely to respond to antibiotic therapy particularly in the absence of peripheral vascular disease. It must be pointed out that data to inform treatment choices in osteomyelitis of the diabetic foot for randomized controlled trials are limited and further research is urgently needed [79].

### **Adjunctive therapies**

A number of newer approaches to promote more rapid healing in diabetic foot lesions have been described over the last two decades. Some of those are mentioned below but many were also recently reviewed by the International Working Group on the Diabetic Foot [80].

### **Growth factors**

A number of growth factors and other agents designed to modify abnormalities of the biochemistry of the wound bed or surrounding tissues have been described, but there is still no consensus as their place in day-to-day clinical practice [80]. One example is platelet-derived growth factor (PDGF) which is available for clinical use in a number of countries. Whereas there is some support for their use for randomized clinical studies [81], their expense together with the fact that most neuropathic ulcers can be healed with appropriate offloading, have limited their use. Unfortunately, PDGF together with other topically applied agents such as epidermal growth factor do not have sufficient robust data to support their day-to-day use in routine clinical practice.

### **Hyperbaric oxygen**

Hyperbaric oxygen (HBO) has been widely promoted for the management of non-healing diabetic foot ulcers particularly in the USA, for some years. Many of the reported studies have been poorly designed or anecdotal and have given rise to serious concerns about the widespread use of this treatment [82]; however, there have been several small well-designed randomized controlled trials to assess the efficacy of HBO in ischemic diabetic foot wounds [83]. Whereas the systematic review of the International Working Group that considered HBO accepted that there was some evidence to support its use, it is clear that more data are required from larger controlled trials not only to confirm efficacy but also to clarify which wounds might best benefit from this expensive treatment [80,84].

### **Negative pressure wound therapy**

Over the past several years negative pressure wound therapy (NPWT) using vacuum-assisted closure has emerged as a com-

monly employed option in the treatment of complex wounds of the diabetic foot [85]. Previous work has suggested that the application of negative pressure optimizes blood flow, decreases local tissue edema and removes excessive fluid and pro-inflammatory exudates from the wound bed. There is now controlled trial evidence for the use of NPWT in both local postoperative wounds in the diabetic foot [86] and, more recently, in the management of complex but non-surgical diabetic foot ulcers [87]. It is clear that this treatment helps promote the formation of granulation tissue, but its cost will limit its use to those complex diabetic foot wounds not responding to standard therapies.

### Bioengineered skin substitutes

Similar to other treatments in this group of adjunctive therapies although there is some evidence to support the use of bioengineered skin substitutes in non-infected neuropathic ulcers, its use of somewhat restricted by cost [80]. A systematic review on this topic concluded that the trials assessed were of questionable quality and until high quality studies were performed, recommendations for the use of these skin substitutes could not be made [88].

---

## Charcot neuroarthropathy

Charcot neuroarthropathy (CN) is a non-infective arthropathy that occurs in a well-perfused insensate foot. Although the exact mechanism underlying the development of CN remains unclear, progress has been made in our understanding of the etiopathogenesis of this disorder in the last decade. It is clear that the classic neurotraumatic and neurotrophic theories for the pathogenesis of acute CN in diabetes do not address certain key features of the disease [89]. If the former theory were correct, CN would be much more common and should be symmetrical: in contrast, acute CN is relatively rare amongst patients with neuropathy and is usually asymmetrical, although there is an increased risk of developing CN in the contralateral foot some years later.

CN occurs in a well-perfused insensate foot. Typically, patients present with a warm, swollen foot and contrary to some of the earlier texts, may be accompanied by pain or at least discomfort in the affected limb. The affected patient tends to be slightly younger than is usual for the patient presenting with a diabetic foot ulcer and typically presents with a warm swollen foot which may or may not be painful. Although a history of trauma may be present, the trauma is rarely of sufficient severity to account for the abnormalities observed on clinical examination (Figure 44.7). Although CN is characterized by increased local bone resorption, the exact cellular mechanisms contributing to this condition remain unresolved. Recently, receptor activator of nuclear factor  $\kappa$ B ligand (RANKL) has been identified as an essential mediator of osteoclast formation and activation. It has been hypothesized that the RANKL/osteoprotegerin (OPG) pathway may play an important part in the development of acute CN [89]. It has subsequently been confirmed that peripheral blood monocytes

**Figure 44.7** This radiograph displays two main abnormalities: (a) changes of osteomyelitis and septic arthritis involving the first metatarso-phalangeal joint, with destruction of the distal first metatarsal and proximal area of the proximal phalanx of the great toe; and (b) chronic changes of Charcot neuroarthropathy in the first cuneiform/metatarsal area.

isolated from patients with CN and cultured in the presence of macrophage colony-stimulating factor led to an increased osteoclast formation when compared to healthy and diabetic controlled monocytes [90]. These observations suggested that RANKL-mediated osteoclastic resorption occurs in acute CN. Thus, the RANKL-dependent pathway is important in the pathogenesis of acute CN suggesting that in the future, inhibition of RANKL might be useful in management.

As discussed in Chapter 48, the treatment of the foot in CN depends upon the stage in which the disease is diagnosed. In the acute phase, there is evidence that offloading of the affected foot by use of a plaster cast is the most effective method of reducing disease activity and local inflammation. Use of the cast should continue until the swelling and hyperemia have resolved and the skin temperature differential is 1°C or less, at which time custom moulded shoes with appropriate insoles are indicated [91]. Bisphosphonates are potent inhibitors of osteoclast activation and intravenous pamidronate has been shown to be useful in reducing disease activity in acute CN [92]. Larger randomized controlled trials are required to confirm these preliminary observations.

The management of advanced CN with bone deformity requiring reconstructive surgery is beyond the scope of this chapter and the reader is referred to recent reviews [93].

## Conclusions

There can be no doubt that despite our efforts in early identification, prevention and aggressive treatment of diabetic foot problems, that the incidence of diabetic foot disease is likely to increase in the next few decades with the global explosion in of the prevalence in type 2 diabetes reviewed elsewhere in this book. It is also clear that diabetic foot disease carries not only a significant morbidity, but even mortality: Armstrong *et al.* [94] pointed out that the outlook for those with diabetic foot disease is worse than many malignant diseases. There is increasing recognition of the multifactorial nature of complications which led Young *et al.* [95] to review the survival of their patients with diabetic foot lesions over the last 13 years. They reported that survival has improved and this has been accompanied by the adoption of an aggressive cardiovascular risk management policy which should be encouraged in all patients with diabetic foot disease. The ultimate prognosis for the limb with a diabetic foot lesion depends upon the presence or absence of an ischemic component: it has been shown that patients with higher Wagner or UT gradings and severity are more likely to end up with minor or even major amputation. Thus, neuropathic foot lesions generally carry a good prognosis, whereas those with a significant ischaemic components are more likely to require the input of the vascular surgeon (see Chapter 43).

## The team approach

It should be clear that the spectrum of diabetic foot problems requires the involvement of individuals from many specialties. The diabetic foot cannot be regarded as the sole responsibility of the diabetologist, and a number of reports over the last decade have promoted the benefits of a multidisciplinary approach to diabetic foot care [96]. This started in the early 1990s when the concept of the “annual review” was adopted by most national diabetes societies. This requires that all patients with diabetes be screened on an annual basis for evidence of long-term complications [97]. There is increasing evidence from a number of long-term studies that the adoption of this approach not only in hospital but in community care, has been associated with a reduced incidence of foot problems [98–101]. The improved management of diabetic foot care in the district of Leverkusen, Germany, ultimately resulted in a 37% reduction in non-traumatic amputations in patients with diabetes; however, this took more than 10 years after the establishment of specialist foot care [98]. Two studies from the UK [99,100] have reported reductions of up to 60% in diabetic amputations and both of these followed either the introduction of multidisciplinary team work in the community or the improved organization of general diabetes care. Finally, a sustained reduction in major amputations has been reported from Sweden over the last 20 years suggesting that a substantial decrease in diabetes-related amputations can not only be achieved, but maintained over a long period of time [101].

The team approach, involving diabetologists working together with surgeons (orthopedic and vascular), specialist nurses, podiatrists, orthotists and often many other health care professionals is therefore strongly recommended in the management of complex lesions of the diabetic foot. It should be remembered, however, it is the patient at risk of, or with foot ulceration, who must be regarded as the most important in this team. Without the patient’s willing participation, there is little that other team members can achieve to improve the overall outlook for the diabetic foot in the 21st century.

## Sexual Function in Men and Women with Diabetes

**David Price**

Morrison Hospital, Swansea, UK

### Keypoints

- The prevalence of erectile dysfunction (ED) in men with diabetes increases with age and is about 35–50% overall.
- Penile erection occurs as a result of engorgement of the erectile tissue following vascular smooth muscle relaxation in the corpus cavernosum mediated by nitric oxide (NO), which is derived from both parasympathetic nerve terminals and the vascular endothelium.
- ED in diabetes is largely brought about by failure of NO-mediated smooth muscle relaxation secondary to endothelial dysfunction and autonomic neuropathy.
- ED is an early indicator of endothelial dysfunction and a marker of increased cardiovascular risk.
- Phosphodiesterase 5 inhibitors are first-line treatment and act by inhibiting the breakdown of cyclic guanosine monophosphate, the second messenger in the NO pathway, and hence enhance erections under conditions of sexual stimulation.
- Other options are intracavernosal injection of prostaglandin E (alprostadil), transurethral alprostadil, vacuum therapy and surgical insertion of penile prostheses.
- In women with diabetes, sexual dysfunction is less common and usually undeclared, but there is an increased risk of vaginal dryness and arousal disorder.
- Contraception and family planning are especially important in women with diabetes. Although there is little consensus amongst diabetes professionals about the preferred method of contraception for women with diabetes, it appears that most currently available methods of contraception are suitable.
- Hormone replacement therapy (HRT) can be considered for treating menopausal symptoms in women with diabetes on a short-term basis, but HRT is not justified in asymptomatic women.

### Male erectile dysfunction

The advent of effective oral treatments has changed the management of erectile dysfunction (ED) in diabetes considerably. Diabetologists and general practitioners can now offer treatments that are easy to use and generally effective. This change, however, has been a long time coming. As recently as 1993, ED was regarded as the most neglected complication of diabetes [1]. Since then, there has been a transformation in attitudes to the subject, in which diabetes professionals have led the way. Previously, ED was generally believed to be psychogenic in origin, even when associated with diabetes, and hence the management was considered to be the preserve of psychosexual counselors. We now accept that ED is a complication of diabetes that can and should be managed by diabetes professionals.

### Physiology of erectile function

Tumescence is a vascular process under the control of the autonomic nervous system. The erectile tissue of the corpus cavernosum behaves as a sponge, and erection occurs when it becomes engorged with blood. As shown in Figure 45.1, dilatation of the

arterioles and vasculature of the corpus cavernosum leads to compression of the outflow venules against the rigid tunica albuginea [2,3]. Thus, smooth muscle relaxation is the key phenomenon in this process, as it leads to increased arterial inflow and reduced venous outflow [4]. The process is under the control of parasympathetic fibres, which were previously known as non-adrenergic non-cholinergic neurones, as the neurotransmitter was unknown; but it is now clear that nitric oxide (NO) is the agent largely responsible for smooth muscle relaxation in the corpus cavernosum. It is produced both in the parasympathetic nerve terminals and is generated by NO synthase in the vascular endothelium. Within the smooth muscle cell of the corpus cavernosum, NO stimulates guanylate cyclase, leading to increased production of the second messenger, cyclic guanosine monophosphate (cGMP), which induces smooth muscle relaxation, probably by opening up calcium channels (Figure 45.2) [5,6].

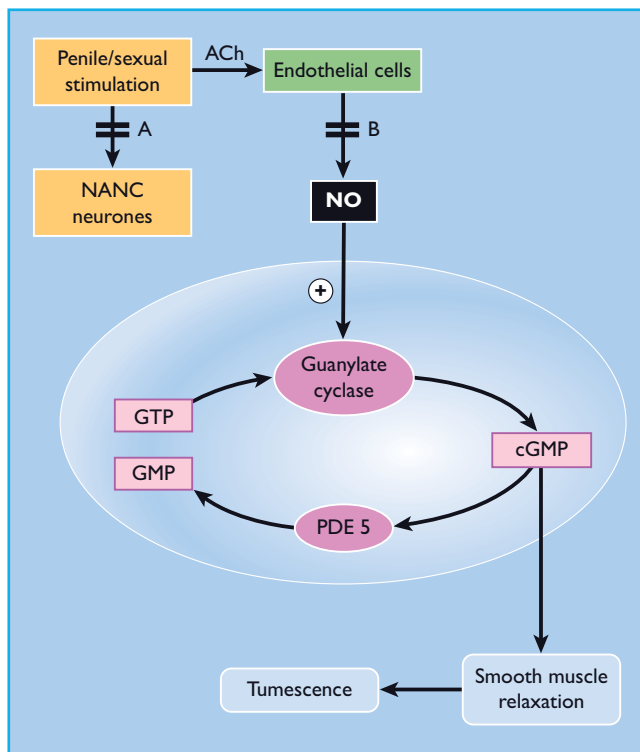

There is some evidence that neuronally derived NO is important in initiation, whereas NO from the endothelium is responsible for maintenance of the erection [7].

### Pathophysiology of erectile dysfunction in diabetes

In men with diabetes there is evidence that ED is caused by failure of NO-induced smooth muscle relaxation caused by both autonomic neuropathy and endothelial dysfunction [7,8]. Many men with diabetes report that in the early stages they do not have a

**Figure 45.1** Diagrammatic representation of the corpus cavernosum. During tumescence, dilatation of the helicine and cavernosal arteries produces expansion of the cavernosal space and compression of the outflow venules against the rigid tunica albuginea.

**Figure 45.2** Pathophysiology of erectile function in diabetes. Diagrammatic representation of the pathways leading to the relaxation of a corpus cavernosal smooth muscle cell. In diabetes, there are defects in nitric oxide-mediated smooth-muscle relaxation from neuropathy of the non-adrenergic non-cholinergic (NANC) fibers (a) and endothelial dysfunction (b). ACh, acetylcholine; cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate; NO, nitric oxide; PDE 5, phosphodiesterase type 5.

problem initially achieving an erection but that they cannot maintain it. This would suggest that in these individuals failure of endothelium-derived NO occurs before significant autonomic neuropathy.

More recently, other potential abnormalities have been described which may contribute to the development of ED in diabetes. Endothelium-derived hyperpolarizing factor (EDHF) has a role in endothelium-dependent relaxation of human penile arteries [9] and this is significantly impaired in penile resistance arteries in men with diabetes [10]. Impaired EDHF responses might therefore contribute to the endothelial dysfunction of diabetic erectile tissue.

A further body of evidence suggests increased oxygen-free radical levels in diabetes may reduce the vasodilator effect of NO. In particular, the formation of products of non-enzymatic glycosylation to produce advanced glycosylation end-products (AGEs) generates reactive oxygen species which impairs NO bioactivity [11]. In animal models, inhibition of AGE formation improves endothelium-dependent relaxation and restores erectile function in diabetic rats [12,13].

Other pathophysiologic changes known to occur in diabetes have been postulated to contribute to ED. Non-enzymatic glycation of proteins has been reported to impair endothelium-dependent relaxation of aorta in rats [13,14].

Other factors, not limited to diabetes, may also contribute to the development of ED in men with diabetes. Structural changes associated with large vessel disease are commonly associated with ED in diabetes; however, this is usually associated with functional changes of widespread endothelial dysfunction in diabetes and it is difficult to separate the relative importance of the two factors.

**Other factors contributing to erectile dysfunction in diabetes**

In addition to endothelial dysfunction and autonomic neuropathy, ED is associated with other conditions common in diabetes, such as hypertension and large-vessel disease [15]. Furthermore, men with diabetes are more likely to be taking medications that can impair erectile function (Table 45.1). Antihypertensive agents

**Table 45.1** Medications associated with erectile dysfunction.**Antihypertensives**

Thiazide diuretics  
 Beta-blockers  
 Calcium-channel blockers  
 Angiotensin-converting enzyme (ACE) inhibitors  
 Central sympatholytics (methyldopa, clonidine)

**Antidepressants**

Tricyclics  
 Monoamine oxidase inhibitors  
 (NB: selective serotonin re-uptake inhibitors can cause ejaculatory problems)

**Major tranquilizers**

Phenothiazines  
 Haloperidol

**Hormones**

Luteinizing hormone-releasing hormone (goserelin, buserelin)  
 Estrogens (diethylstilbestrol/stilbestrol)  
 Anti-androgens (cyproterone)

**Miscellaneous**

5-alpha reductase inhibitors (finasteride)  
 Statins (simvastatin, atorvastatin, pravastatin)  
 Cimetidine  
 Digoxin  
 Metoclopramide  
 Allopurinol  
 Ketoconazole  
 Non-steroidal anti-inflammatory agents  
 Fibrates

**Drugs of "abuse"/"social" drugs**

Alcohol  
 Tobacco  
 Marijuana  
 Amfetamines  
 Anabolic steroids  
 Barbiturates  
 Opiates

are commonly reported to be associated with ED, although much of the evidence is anecdotal; beta-blockers and thiazide diuretics are the most commonly reported culprits [16], alpha-blockers perhaps have the lesser risk [17]. Finally, it should be remembered that there are many other potential causes of ED unrelated to diabetes, from which men with diabetes are not immune (Table 45.2).

**Clinical aspects of erectile dysfunction in diabetes**

ED becomes more common with age. In a population-based study in Massachusetts, USA, the prevalence of complete erectile failure was reported to be 5% in men in their forties and 15% in those over 70 years [15]. The prevalence in diabetic men is significantly higher and also increases with age. In a survey of men attending a hospital diabetic clinic in the UK, the prevalence of

 Drug and alcohol abuse  
 Structural abnormalities of the penis

**Figure 45.3** The prevalence of erectile dysfunction by age of men attending a hospital diabetic clinic [1].

**Figure 45.4** The prevalence of erectile dysfunction by duration of diabetes in a population-based study [19].

ED increased from 13% amongst 30-year-olds to 61% amongst men aged over 60 years (Figure 45.3) [1]; overall, the prevalence was 38%. The prevalence of ED in diabetes in a general practice population was reported to be even higher, at 55% [18]. These data would suggest that ED is the most common clinically apparent complication of diabetes in men.

The presence of other medical conditions increases the risk of ED. A population-based survey of 600 men in Brazil, Italy, Japan and Malaysia in 2000 examined the prevalence of ED and its relationship to other diseases and lifestyles. The prevalence of ED among men with diabetes rose from 25% at age 40–44 years to 70% at age 65–70 years [19]. Cardiovascular disease increased the risk of ED. The prevalence was 31.7% in men with diabetes only, 40% in men with diabetes and heart disease and 46.5% in those with diabetes and hypertension. The prevalence also increased with duration of diabetes (Figure 45.4). Men with diabetes who smoked and reported below average levels of physical activity had a fourfold increase in the prevalence of ED.

### Erectile dysfunction as a risk factor for cardiovascular disease

There is convincing evidence of an association of between ED and cardiovascular disease [20–22]. This may be because they share common risk factors. Increased waist measurement and reduced physical activity, both important risk factors for ischemic heart disease, considerably increase the risk of ED [23–25]. The risk of ED is also increased in men with hyperlipidemia [26].

Recent studies have suggested that the association between ED and cardiovascular disease may be brought about by more than shared risk factors and may arise because they are both manifestations of endothelial dysfunction. There has been considerable interest in recent years in the role of the vascular endothelium in the pathogenesis and progression of atherosclerosis [27]. It is clear that the endothelium has important and complex endocrine and paracrine functions, and one of its most important products is NO (previously known as endothelium-derived relaxing factor). NO possesses potent antiatherogenic properties, inhibits platelet aggregation and regulates vascular tone [28]. As described

above, NO derived from both nerve terminals and the vascular endothelium has a central role in the physiology of erection. Therefore, there are theoretical grounds to believe that the ED might be an early marker of endothelial dysfunction and hence an important risk factor for cardiovascular disease. There is now good evidence that ED is an early marker of endothelial dysfunction [29]. Thus, the association between ED and increased cardiovascular risk may be a case of shared common soil, in particular endothelial dysfunction and microvascular disease. In practical terms this means cardiovascular risk should be assessed in any man with ED whether diabetic or not. A man with type 2 diabetes (T2DM) and ED has approximately double the risk of developing coronary heart disease than a similar man without ED [22].

### Smoking and alcohol consumption

Smoking greatly increases the risk of developing ED. A follow-up of the Massachusetts Male Aging Study reported that cigarette smoking almost doubled the risk of developing ED after about 7 years [15]. A similar finding was reported by the large Health Professionals' Follow-up Study [24].

In contrast to tobacco, it is well established that moderate alcohol consumption reduces the risk of a cardiovascular event. It is interesting that drinking alcohol in moderation also appears to reduce the risk of becoming impotent [23].

### Quality of life issues

That ED can significantly worsen a man's quality of life is not in doubt. Unfortunately, there are few good data to show objectively the impact ED can have on quality of life measures, and even fewer to show the impact of treating ED. A survey by the Impotence Association found symptoms of lowered self-esteem and depression in 62% of men; 40% expressed concern with either new or established relationships, and 21% blamed it for the break-up of a relationship [30]. In another series in general practice, it was reported that 45% of men with diabetes stated that they thought about their ED all or most of the time, 23% felt that it severely affected their quality of life and 10% felt it severely affected their relationship with their partner [18].

### Assessment and investigation of erectile dysfunction in diabetes

#### Clinical assessment

In most cases, an impotent man will have taken a long time to pluck up the courage to discuss his problem with a doctor and will undoubtedly be anxious. Almost invariably, however, once the subject has been broached, men with ED and their partners do not usually have any difficulty discussing the problem. A description of the nature of the ED should be obtained, not least to ensure that the patient is complaining of ED and not another related problem, such as premature ejaculation. The key features in the history of ED are listed in Table 45.3. Ideally, the man's partner should be present, but most men attend the consultation alone. If the partner is present, talking to her without the patient present can reveal interesting and useful insights into the problem.

**Table 45.3** Key features in the clinical history of erectile dysfunction in diabetes.

Onset usually gradual and progressive
Earliest feature often inability to sustain erection long enough for satisfactory intercourse
Erectile failure may be intermittent initially
Sudden onset often thought to indicate a psychogenic cause (but little evidence to support this)
Preservation of spontaneous and early morning erections does not necessarily indicate a psychogenic cause
Loss of libido consistent with hypogonadism, but not a reliable symptom.
Impotent men often understate their sex drive for a variety of reasons

**Table 45.4** Key physical signs to note on examination of the patient with erectile dysfunction.

Any features of hypogonadism
Manual dexterity – may preclude physical treatment (e.g. intracavernosal injection)
Protuberant abdomen
External genitalia:
Presence of phimosis
Testicular volume

General physical examination may give clues as to the etiology of ED and the choice of treatment. The key features of the physical examination are listed in Table 45.4.

### Investigation of erectile dysfunction in diabetes

The suggested investigations of ED in diabetes are listed in Table 45.5. It is now widely accepted that it is not helpful to try to determine whether or not ED is psychogenic in origin, particularly when managing a man with diabetes and ED. Few investigations are needed, but it is worth excluding other treatable causes of ED: in practical terms, hypogonadism is the only treatable one. There is probably no significant relationship between diabetes and hypogonadism, and therefore gonadal function should only be assessed in men with diabetes and ED if it is considered worthwhile looking for a coincidental problem causing hypogonadism. Some men presenting with ED will not have attended any form of clinic for many years, so the consultation provides an opportunity to address other health issues. For the reasons given above, consideration should be given to assessing the patient's cardiovascular status. The consultation also provides an opportunity to address the management of the patient's diabetes.

### General advice

Most men with diabetes and their partners seeking treatment for impotence are middle-aged, have been married for many years and require only simple common-sense advice. Specialist psychosexual counseling is not needed for most couples: several series

**Table 45.5** Investigation of erectile dysfunction in diabetes.

Serum testosterone if libido reduced or hypogonadism suspected (ideally taken at 9 am)
Serum prolactin and luteinizing hormone if serum testosterone subnormal
Assessment of cardiovascular status if clinically indicated:
Electrocardiography (ECG)
Serum lipids
Glycosylated hemoglobin, serum electrolytes if clinically indicated

have reported that diabetologists can offer an effective service for the treatment of ED without the support of psychosexual counselors [31–34]. It is important that the cause of the ED is explained, as many patients will blame themselves. They should be advised that if they wish to resume sexual relations they will require long-term treatment, as spontaneous return of erectile function in diabetes occurs only rarely [35].

Treating ED in an attempt to save a failing relationship is rarely successful and may make the situation worse. The assistance of a suitably qualified psychosexual counselor should be considered in this situation. Referral to a counselor should also be considered if there is any suggestion of severe anxiety, loss of attraction between partners, fear of intimacy or marked performance anxiety. Any other medical problems should be addressed. Improving poor metabolic control may help general well-being, but poor control should not be used as a reason to refuse or delay treatment. Patients who smoke should be advised to stop for reasons of general health, although there is no good evidence that stopping smoking will improve erectile function in a man with diabetes and ED.

Many men with diabetes will be taking medication known to cause ED. Experience has shown that changing the treatment in an attempt to improve sexual function rarely works and may cause delays and frustration for the patient. It is therefore not advisable unless there is a strong temporal relationship between starting treatment and the onset of ED.

### Treatment options

The advent of effective oral therapies has transformed the management of ED. These should be offered as first-line therapy to men with diabetes and ED, and the other treatment options should be reserved for those in whom oral therapy is contraindicated or ineffective.

#### Oral agents

##### *Phosphodiesterase 5 inhibitors*

Phosphodiesterase type 5 (PDE 5) is an enzyme found in smooth muscle, platelets and the corpus cavernosum. The mechanism of action of PDE 5 inhibitors is shown in Figure 45.2. During tumescence, there is an increase in the intracellular concentrations of NO, which produces smooth muscle relaxation via the second messenger cGMP. This is broken down in turn by PDE 5. Hence, PDE 5 inhibitors can enhance erections under conditions of

sexual stimulation. There are currently three PDE 5 inhibitors licensed for the treatment of ED: sildenafil (Viagra), tadalafil (Cialis) and vardenafil (Levitra).

*Clinical trial data.* Sildenafil was the first PDE 5 inhibitor. Early small trials showed it was a highly effective treatment for ED in men with and without diabetes [36,37]. The first large study was published in 1998. A total of 532 men with ED of mixed etiology were studied. In the group given sildenafil, 69% of all attempts at intercourse were successful, compared with 22% in those given placebo [38]. Other studies in men with ED of mixed etiology have shown success rates of 65–77% [39,40]. Studies of sildenafil in other patient groups have reported success rates of approximately 70% in hypertension [41], 76% in spinal cord injury [42], 63% in spina bifida [43] and 40% following radical prostatectomy [44].

In men with diabetes, the success rates for sildenafil have been reported to be 56–59% in the treatment of ED [37,45]. A study in elderly men reported success rates of 69% overall and 50% in subjects with diabetes [46]. Most of these studies of sildenafil have been short-term. A trial examining the long-term efficacy of sildenafil in men with ED from a variety of causes reported that only 52% continued to use it after 2 years [47]. This figure may seem surprisingly low, but it is certainly considerably higher than for any other type of ED treatment.

#### Other PDE 5 inhibitors

Sildenafil was soon followed by tadalafil (Cialis) [48–50] and vardenafil (Levitra) [51,52]. All three appear to be similar in efficacy and safety but there are differences in duration of action and adverse effect profiles as described below.

*Adverse effects.* The most common adverse effects related to PDE 5 inhibitors are headache, dyspepsia and flushing. Headache and flushing might be expected, as they are vasodilators. The dyspepsia is usually mild and may be caused by relaxation of the cardiac sphincter of the stomach.

Abnormal vision is experienced by about 6% of men taking sildenafil; this may be because the drug has some activity against PDE 6, which is a retinal enzyme. Of more concern are the reports of non-arteritic anterior ischemic optic neuropathy (NAION). This is a rare syndrome characterized by sudden, sometimes unilateral, often reversible, visual loss. Since 2002 there have been case reports of this condition occurring in association with the use of PDE 5 inhibitors, particularly sildenafil [53,54]. NAION is rare but potentially serious as it can, exceptionally, lead to blindness. It would appear it is more common in men with increased cardiovascular risk [55]. The manufacturers of sildenafil estimated the incidence of NAION in 13 000 men receiving sildenafil from pooled safety data from clinical trials and observational studies to be 2.8 cases per 100 000 patient-years of sildenafil exposure [56]. The authors reported this to be similar to estimates reported in general US population samples (2.52 and 11.8 cases per 100 000 men aged over 50 years). It is therefore unknown if

**Table 45.6** Adverse effects of phosphodiesterase 5 (PDE 5) inhibitors (%). The prevalence quoted for each adverse effect is for the top dose used in each study.

	Sildenafil [59,60]	Tadalafil [59,61,62]	Vardenafil [63,64]
Headache	8.1–9.3	8.0–21	5–11
Flushing	7.4–8.1	3.0–9.0	5.4–10
Back pain	2.5	4.6–9.0	0
Dyspepsia	2.7–3.0	4.1–17	2.3
Nasal congestion	2.7–4.1	2.0–5	10
Dizziness	2.5	1.6	
Diarrhea	2.5	0.8	
Abnormal vision	1.4	0	
Muscle cramps	4.1	3–7	

PDE 5 inhibitor use increases the risk of NAION but in any case it is a very rare condition and should not discourage the appropriate use of these agents.

The adverse events from the key trials of PDE 5 inhibitors in men with diabetes are given in Table 45.6. In all the studies, the discontinuation rate from adverse effects has been very low.

*Reasons for PDE 5 inhibitor non-responsiveness.* The mechanism of action of sildenafil would suggest that it would be ineffective without the presence of sufficient bioavailable NO in the penile vasculature. Thus, either significant autonomic neuropathy or endothelial dysfunction would be expected to reduce the efficacy of a PDE 5 inhibitor. Slightly surprisingly, two small studies have reported no differences in the presence of autonomic or endothelial function between sildenafil “responders” and “non-responders” [29,57]. It has been reported that failure to respond to sildenafil is more likely in men with long-standing and severe ED [58]; however, no single factor precludes a successful outcome, and in practical terms it is worth trying sildenafil in all men with ED unless there is a contraindication.

*Cardiovascular safety of PDE 5 inhibitors.* The launch of sildenafil, the first PDE 5 inhibitor, was soon followed by case reports of cardiovascular events and deaths associated with its use. By contrast, there is now good evidence that PDE 5 inhibitors are not associated with increased cardiovascular risk [65,66]. A questionnaire survey of over 5000 sildenafil users reported that adverse cardiovascular events were no more frequent than expected for a comparable population [67]. A retrospective analysis of 36 clinical trials of tadalafil involving over 14 000 men reported no increase in cardiovascular adverse events [68]. Indeed, there is accumulating evidence that PDE 5 inhibitors reduce blood pressure slightly and improve endothelial function [66,69].

Restoring sexual function, however, is not completely without risk. Sexual activity, like any form of physical activity, can precipitate cardiovascular events in those at risk. A large case-control

study reported the risk of a cardiovascular event in the 2 hours after intercourse was increased by 2.5 fold in healthy subjects and by 3 fold if there was a history of previous myocardial infarction [70]. Although the absolute risk remains very small, the issue of cardiovascular safety must be addressed in all men before treating ED. Jackson *et al.* [65] have suggested a classification scheme for assessing cardiovascular risk in men undergoing treatment for ED, those with the highest risk should be referred for specialist cardiac evaluation while the lowest risk group could be managed in primary care.

*Drug interactions with PDE 5 inhibitors.* PDE 5 inhibitors can be used safely in patients taking a wide range of other drugs but there are several potential important interactions. They are contraindicated in the presence of any nitrate therapy (including nicorandil) as the combination can cause profound hypotension. A patient taking nitrates seeking treatment for ED can be offered alternatives to PDE 5 inhibitors or the nitrates can be stopped or changed to an alternative therapy. Nitrates are a symptomatic treatment with no prognostic implications and so this is possible in most cases but should be done in consultation with a cardiologist in all but the most straightforward cases.

Nitrate therapy should not be given within 24 hours of taking sildenafil or vardenafil and at least 48 hours of taking tadalafil. If angina develops during or after sexual activity following the use of a PDE 5 inhibitor, the patient should be advised to discontinue any sexual activity and stand up as this reduces the work of the heart by reducing venous return.

PDE 5 inhibitors should be used with caution in patients who take alpha-blockers because the combination may lead to symptomatic hypotension in some patients. Patients should be stable on alpha-blocker therapy before initiating sildenafil which should be initiated at the lowest dose [66].

*Comparison of PDE 5 inhibitors.* The three currently available PDE 5 inhibitors, sildenafil, vardenafil and tadalafil, are all similar in efficacy and safety. Their side effect profiles differ slightly but the most notable difference is the longer half-life of tadalafil. Thus, a single dose of tadalafil offers the potential to restore erectile function to normal for 2 days and thereby remove the need for medication to be taken each time prior to sexual activity. The choice between this form of treatment and on-demand dosing is largely a matter of patient choice. Patient preference studies of agents with differing dosing instructions are difficult to perform in a blinded fashion. Several have been reported and have generally shown a preference for tadalafil over sildenafil [59,71–74].

*How to use PDE 5 inhibitors.* These agents should be taken orally about 1 hour before sexual activity. This period can be shortened if taken on an empty stomach. After the 1-hour period, there is a “window of opportunity” when sexual activity can take place. For sildenafil and vardenafil this is at least 4 hours but may be over 8 hours [75]. For tadalafil the window of opportunity may

last 48 hours. Men with diabetes usually require the maximum recommended dose. Patients should be warned that the drug only works in conjunction with sexual stimulation.

*Management of PDE 5 inhibitor non-responsiveness.* A large proportion of men with diabetes and ED will not respond to PDE 5 inhibitors and there are many potential reasons for this. PDE 5 inhibitors require a degree of NO tone to be effective, therefore severe endothelial dysfunction of autonomic neuropathy might be expected to reduce their efficacy; however, one study reported that neither autonomic neuropathy nor endothelial dysfunction predicted sildenafil responsiveness. The only significant factor that predicted the response to treatment was the initial degree of ED [29]. In practical terms, no single factor should preclude a trial of PDE 5 inhibitor therapy in a man without a contraindication.

Much has been written on the best approach for dealing with men who do not respond to a PDE 5 inhibitor but, unfortunately, mostly based on limited evidence. It has been suggested that if appropriate advice is given and sufficient attempts at intercourse made, many men previously labeled as non-responders can be treated successfully with PDE 5 inhibitors. One study reported that intercourse success rates reached a plateau after eight attempts so men with ED should try at least eight times with a PDE5 inhibitor at the maximum recommended dose before being considered a non-responder [76].

Hypogonadism should always be considered in dealing with men with ED who do not respond. Hypogonadism caused by confirmed pituitary or testicular disease usually responds well to treatment. The management of the borderline hypogonadism of the aging male is more controversial but there is some evidence that testosterone replacement in this situation can improve ED as a sole treatment [77] and enhance the response to PDE 5 inhibitors [78–80].

### **Other oral therapies**

#### *Apomorphine*

Apomorphine has been in use for many years. It is a centrally acting D1/D2 dopamine agonist that acts on the paraventricular nucleus of the thalamus early in the cascade that leads to erection. Among its several properties, it is a potent inducer of nausea, and this has previously limited its use as a therapeutic agent. A sublingual formulation is licensed in Europe as a treatment of ED. This preparation has no first-pass metabolism, and it rapidly produces therapeutic blood levels. Studies of the sublingual preparation have suggested that it is effective in inducing erections in about 50% of attempts and has acceptable levels of adverse effects [81]. To date, there have been no published trials of apomorphine in men with diabetes and it is not widely used in diabetic practice.

Various oral agents have been tried as treatments for ED in the past, including trazodone, yohimbine and phentolamine. The data on all of them are limited and none has stood the test of time. Testosterone should only be used to treat ED secondary to confirmed hypogonadism.

Figure 45.5 Alprostadil self-injection pen device.

Figure 45.6 A typical vacuum device with constriction rings.

**Table 45.7** Instructions to medical staff for treating prolonged erections caused by prostaglandin E1.

- Do not delay treatment beyond 6 hours
- Using aseptic technique, aspirate 20–25 mL blood from the corpus cavernosum (19 or 21 gauge butterfly needle)
- Repeat the above on the opposite side of the penis if detumescence does not occur
- If still unsuccessful, inject 0.5–1.0 mL of a 300- $\mu$ g/mL solution of phenylephrine every 5–10 minutes (maximum dosage 5 mL) into the corpus cavernosum. If necessary, this may be followed by further aspiration of blood through the same needle. Extreme caution is necessary in those patients taking monoamine oxidase inhibitors, as a hypertensive crisis may result. Use carefully in those with coronary heart disease, uncontrolled hypertension or cerebral ischemia. Monitor pulse rate and blood pressure throughout
- If the above are unsuccessful, refer for urgent surgical treatment, such as a shunt procedure

### Intracavernosal injection therapy

The technique of intracavernosal self-injection was first described in 1982 by Brindley [82], using phentolamine, although the French urologist, Virag [83], who used papaverine, was first to publish. Papaverine was more effective than phentolamine, but was an unlicensed treatment; it was superseded by alprostadil (prostaglandin E), which was licensed for the treatment of ED in 1996.

Alprostadil is supplied in a self-injection pen device, which is easy to use, and supplied with excellent instructions (Figure 45.5). In spite of this, most studies show that self-injection therapy has a disappointingly high long-term discontinuation rate [84–86]. Self-injection treatment carries a small risk of priapism (a sustained unwanted erection). Although an infrequent complication, priapism is an important one, as it must be treated within 6 hours by aspirating blood from the corpus cavernosum. Patients undertaking self-injection must be warned of this potential problem and given instructions on what to do should it occur (Table 45.7).

Local adverse reactions, such as penile pain, are relatively common with self-injection therapy. Prolonged papaverine use may lead to fibrosis in the penis, but this has only rarely been reported with alprostadil [87].

More recently the combination of vasoactive intestinal polypeptide and phentolamine has been licensed for use under the name of Invicorp. It appears to be a potentially useful treatment for ED [88,89].

### Transurethral alprostadil (MUSE)

Many men find injection therapy unacceptable because it requires injecting the penis. Transurethral administration of the vasoactive agent would appear largely to overcome this problem. The principle is simple. A slender applicator is inserted into the urethra to deposit a pellet containing alprostadil in polyethylene glycol. This gradually dissolves, allowing the prostaglandin to diffuse into the corpus cavernosum. In a placebo-controlled study of 1511 men with ED of mixed etiology, it was reported that 65% were able to have intercourse using this system [90]. The results in the 240 men with diabetes in the study were similar [91]. The most common side effect was penile pain, which occurred in 10.8% of applications. Hypotension was reported by 3.3% of the men receiving alprostadil. Priapism and penile fibrosis were not reported. A more recent study reported that most men found transurethral alprostadil less acceptable and efficacious than intracavernosal injection [92], and the long-term usage has been disappointing [93].

### Vacuum therapy

Vacuum devices became widely available in the 1970s. They consist of a translucent tube, which is placed over the penis, and an attached vacuum pump (Figure 45.6). The air is pumped out of the tube, and the negative pressure draws blood into the erectile tissue, producing tumescence. A constriction band (which has previously been placed over the base of the tube) is then slipped off to remain firmly around the base of the penis so as to maintain the erection, and the tube is then removed. The devices require a little practice and some dexterity, but most couples are able to

use them satisfactorily. Trials of vacuum therapy have reported success rates of approximately 70% in men with and without diabetes, suggesting it is an effective treatment, provided couples are prepared to use them [94–97].

Vacuum devices are safe and effective treatments, and inexpensive to use after an initial outlay (in the UK) of about £100–250. The side effects are discomfort from the constriction band, failure to ejaculate and a cold penis (reported by the female partner). Many couples find the use of vacuum devices unacceptable, and since the introduction of newer treatments their use has declined; however, they still have a role in men who do not respond or who cannot use other treatments.

### Surgery

In spite of recent advances in the management of ED, some men will not be able to use the available treatment options. There will therefore always be a limited role for surgery.

The surgical options available are:

- 1 The insertion of penile prostheses;
- 2 Corrective surgery for associated Peyronie disease or post-injection corporal fibrosis;
- 3 Venous and arterial surgery.

Discussion of vascular and corrective surgery of the penis is best left to a specialist urology textbook, but a general practitioner or diabetes physician needs to know which patients might benefit by referral for insertion of a penile prosthesis. This form of surgery is best reserved for men in whom conventional treatments have failed and who are keen to resume full sexual activity.

Counseling of the patient, and whenever possible his partner, is extremely important, particularly about the choice of prosthesis. The patient's or couple's wishes are very important factors in device selection, as is the cost of the prosthesis. In the UK, many hospital trusts will only pay for the malleable prostheses and not for the insertion of the considerably more expensive inflatable ones.

Patients must be warned regarding postoperative pain or discomfort and the potential for reoperation. Patients will need to restrict physical activity and refrain from intercourse for between 4 and 6 weeks after the operation. They should be warned about the possible complications of infection, erosion and prosthesis failure, and that these problems usually require device removal. It is also very important that the patient and his partner are aware that the erection produced by a prosthesis is different from a normal erection, depending very much on the type of prosthesis chosen. It is useful to show patients examples of the prostheses (Figure 45.7) and to describe how they are inserted and the mechanism of action.

There is uncertainty as to whether men with diabetes are at higher risk of infection than men without diabetes after insertion of a penile prosthesis, but there is a consensus that, should infection occur, it is more serious [98]. Good preoperative control of diabetes is important to minimize the risk. Most published series of well-selected groups of men who have undergone penile pros-

**Figure 45.7** Examples of penile prostheses.

thesis insertion have reported acceptable results, with good levels of patient satisfaction [99].

### Organization of the management of ED

Traditionally, ED has been managed in a dedicated ED clinic, often run by a urologist. The advent of effective oral therapies has made the management much simpler, so that ED in diabetes can usually be managed by any physician or general practitioner. A physician considering treating ED will have to decide whether to run a separate ED clinic or to see the patients in a routine diabetic clinic. Such a decision will depend on local resources and circumstances but it is certainly possible to manage ED in a diabetic clinic. If this is to be done, it is advisable to have patient information literature on ED available. There are several excellent pamphlets produced by pharmaceutical companies and national diabetes organizations such as Diabetes UK. It is often wise to let the patient take away the literature to read and to consider the matter, with treatment being started at a subsequent visit.

### Managing ED in primary care

There are considerable advantages for the treatment of ED in general practice. A general practitioner is more likely to know and understand a patient's particular circumstances. Men with ED may be less intimidated in seeking help from their family practitioner than from a hospital specialist or sexual therapist. Little specialized equipment is required, so there is no reason why interested general practitioners should not effectively treat the majority of men presenting with ED.

As with many disorders encountered in primary care, the general practitioner may choose to manage the problem in a standard consultation with the patient. Others may choose to refer their patients to a fellow partner or colleague with a particular interest in ED or to their practice nurse, who may have received appropriate training in the assessment of patients with ED.

When a man presents with ED, his general practitioner has an opportunity to consider other health issues and screen for under-

lying causes. ED is often associated with conditions that benefit from early detection such as diabetes, hypertension and hyperlipidemia. It is therefore important to consider general health issues and to address lifestyle factors.

### The specialist erectile dysfunction service

Although most men with ED will be managed in primary care, there is still a role for a specialist ED service. It is likely that these clinics will mainly treat men who have failed to respond to oral therapies and that they will maintain expertise in the use of other treatments, such as intracavernosal injection therapy and vacuum devices, referring patients when necessary to urologic surgeons for penile prosthesis insertion.

### Conclusions on male sexual dysfunction

NO-mediated relaxation of the smooth muscle of the corpus cavernosum is the key phenomenon leading to penile erection. In diabetes, there is impairment of NO production by autonomic nerve terminals (caused by autonomic neuropathy) and by endothelial cells (caused by endothelial cell dysfunction). Sildenafil and other PDE inhibitors work by inhibiting the breakdown of cGMP, the second messenger in the NO pathway, and hence enhance erections under conditions of sexual stimulation. These agents are safe and effective treatments and can be used to treat ED in a diabetic clinic or in general practice.

---

## Female sexual dysfunction

Male sexual dysfunction has been described as the most neglected complication of diabetes. However, there has been considerably more interest in, and research into, the sexual dysfunction of men as compared to women. There may be good reasons for this. In physiologic terms, the female equivalent of male ED is reduced vasocongestion of the vulva and vagina, leading to impaired arousal and reduced vaginal lubrication. Failure to achieve an erection makes sexual intercourse impossible, but reduced vaginal lubrication is easily overcome with simple treatments such as lubricating creams and may not even be considered to be abnormal by a postmenopausal woman.

In a review published in 1998, Enzlin *et al.* [100] undertook an analysis of 15 studies carried out in the area of female sexuality in diabetes since 1971. They reported that the prevalence of impaired sexual arousal and inadequate lubrication was between 14% and 45% in women with diabetes, which was significantly higher than in controls without diabetes [100]. In contrast, there was little evidence of an increased risk of dyspareunia or problems with orgasm in women with diabetes. Thus, it would appear that women with diabetes admit to specific sexual dysfunctions when they are asked, but it is the universal experience of diabetologists that women with diabetes rarely complain of sexual problems. That a problem is not often volunteered by patients does not mean it is not significant or worthy of research.

More recent studies in women with type 1 diabetes (T1DM) have shown similar findings. Enzlin *et al.* [101] reported that 27% of diabetic women had sexual dysfunction compared to 14% in controls but only reduced lubrication was significantly different between the groups. The same group found that in women with T1DM sexual dysfunction was more closely related to psychologic rather than somatic factors [102].

If vaginal lubrication is the female equivalent of tumescence, then vaginal dryness and impaired arousal may be related to failure of NO-mediated smooth muscle relaxation secondary to endothelial dysfunction and autonomic neuropathy. There has been very little research into the pathophysiology of sexual dysfunction in women, but several studies have reported, a little surprisingly, that there does not appear to be a strong relationship between neuropathy and female sexual dysfunction [103–106]. Anecdotally, women with severe autonomic neuropathy can have an excellent sex life, unlike men, so it is likely there are differences between men and women in the way the autonomic nervous system controls genital responses [107]. Little work has been carried out on the effect of other medical conditions or treatments on sexual function in women.

### Drug therapy and female sexual dysfunction

The mechanism of action of PDE 5 inhibitors would suggest they might improve arousal and vaginal lubrication; however, trials of sildenafil for this purpose in non-diabetic women have shown conflicting results. In a small cross-over study of 53 premenopausal women, it was reported that sildenafil significantly improved the frequency of intercourse and enjoyment compared with placebo [108]. In contrast, a much larger study of 583 women with female sexual arousal disorder reported no difference between the sildenafil or placebo-treated groups [109]. One of the few studies published to date on the effect of sildenafil on sexual dysfunction in women with diabetes reported that the treated group had improved arousal and sexual enjoyment as well as clitoral blood flow compared with controls [110].

Many women attending a diabetic clinic will be over 50 years of age and some will have problems associated with the menopause, including vaginal dryness and dyspareunia. It can be difficult to distinguish the effects of the menopause from those of diabetes, but in practical terms the treatment is the same. Topical estrogen or simple lubricant gels are usually effective. Managing loss of libido in women with diabetes is more complex and beyond the scope of this chapter. It is much more likely to be caused by psychosocial and relationship issues rather than somatic problems.

### Genitourinary infections in women with diabetes

Vaginal candidiasis is a common finding in women with diabetes, particularly if the blood glucose control is poor and probably because yeasts thrive in a glucose-rich environment. Severe infection can be very irritating and painful and can interfere with sexual intercourse. Infections usually respond to conventional antifungal creams and pessaries; resistant cases usually respond

to a single oral dose of fluconazole. To reduce the chances of reinfection, attempts should be made to improve diabetic control. The male partner may also need treatment for candidiasis for the same reason.

Other genital infections also occur in women with diabetes, but probably no more frequently than in the general population. These cases should be referred to the appropriate genitourinary service.

### Conclusions on female sexual dysfunction

There are differences in the ways in which men and women respond to sexual dysfunction. Traditionally, the view has been expressed that men focus on physiologic function, while the quality of the relationship is more important to women. Such generalizations are now considered a little dangerous, but there is no doubt that in women, psychologic factors are more important than the minor degrees of sexual dysfunction that occur in diabetes. When asked, women with diabetes admit to an increased prevalence of vaginal dryness and impaired arousal, but these are not common problems in the day-to-day management of diabetes. The treatment for these problems is the same for women either with or without diabetes. Other associated problems, such as vaginal candidiasis or estrogen deficiency, should be addressed. If there are relationship problems, referral to a counselor should be considered. The role of PDE 5 inhibitors remains uncertain in female sexual dysfunction, and further research is needed in this area.

---

## Contraception

Contraception and family planning are especially important in women with diabetes. Poor glycemic control during the first trimester of pregnancy is associated with an increased risk of fetal morbidity and mortality [111–113]. It is therefore essential that women with diabetes are advised to plan their pregnancies and achieve strict control of their diabetes prior to conception (see Chapter 53).

### Method of contraception

There is little consensus amongst diabetes professionals about the preferred method of contraception for women with diabetes. Neither the American Diabetes Association nor Diabetes UK has published recent guidance on the subject. Surveys of doctors in the UK [114] and Germany [115] have reported considerable variation among physicians for their recommended method of contraception for diabetic women. Most currently available methods of contraception are suitable for women with diabetes; however, certain factors should be taken into consideration before choosing any particular method.

### Contraindications to pregnancy

As medical and obstetric care has improved, the list of contraindications to pregnancy in women with diabetes has shrunk (see

Chapter 53). If pregnancy is contraindicated, sterilization should be considered.

### The oral contraceptive pill

In a survey of 938 women with T1DM undertaken in primary care in the UK, the oral contraceptive pill (OCP) was reported to be the most widely used method of contraception [114]. The combined OCP was used by 17%, and the progesterone-only pill (POP) by 8.6%; however, a more recent survey in general practice in the UK reported women with diabetes were significantly less likely to be prescribed the combined OCP than women without diabetes [116]. In contrast, progesterone-only and depot hormonal contraceptives were relatively more popular in women with diabetes. It seems there is a slight reluctance to prescribe the combined OCP in women with diabetes. The reasons for this are not clear and there are good reasons for using OCP. It is simple to use and, most importantly, very reliable. If properly used, it has the lowest failure rate for any contraceptive method, apart from sterilization [117]. Nevertheless, there have always been concerns about the safety of hormonal contraception in women with diabetes. Both the combined OCP and the POP carry an increased risk of thromboembolic disease and, in theory, can adversely affect glucose metabolism. These concerns are largely unfounded. A systematic review for the Cochrane database reported steroid contraceptive had limited effects of carbohydrate tolerance but strong statements could not be made because of the limited quality of trials [118]. Although a large definitive study examining the effects on cardiovascular morbidity and mortality in women with diabetes has not been performed, several smaller studies have suggested that OCPs with lower doses of estrogen have no greater effect on markers of cardiovascular risk in women with diabetes than women without diabetes [119,120]. Furthermore, there is no evidence that OCPs increase the risk of microvascular complications [121] or worsen metabolic control in women with T1DM [119].

Few studies, if any, have examined the safety of OCPs in T2DM. Two studies have reported that low-dose OCPs have no effect on glucose tolerance or plasma lipids in women with previous gestational diabetes [122,123].

On the available evidence, low-dose (<30 µg estradiol) combined OCPs can be safely used in women with T1DM or T2DM. Any woman taking the OCP should be reviewed regularly for assessment of blood pressure and serum lipids. Women with diabetes can also use the POP. It is not associated with adverse changes in serum lipids or clotting factors and is well tolerated; however, it is associated with menstrual irregularities, particularly intermenstrual bleeding.

Long-acting depot progestin preparations are also effective in women with diabetes. Several small studies have reported that progestins, particularly depot medroxyprogesterone acetate, can worsen carbohydrate tolerance in normal women [124–126], but there is no evidence they have a clinically significant effect on metabolic control in existing diabetes. Depot levonorgestrel (Norplant) appears to have minimal effect on carbohydrate tolerance [125].

### Intrauterine contraceptive device

The intrauterine contraceptive device (IUD) is a safe and effective form of contraception in women with diabetes. Early concerns about the risk of pelvic inflammatory disease (PID) in diabetes were largely unfounded; studies have suggested no increased risk of PID in women with T1DM [127] or T2DM [128]. Similarly, early suggestions of an increased failure rate for IUDs in women with diabetes have not been borne out [127].

### Barrier methods

Since the advent of AIDS, the condom has been widely advocated to reduce the risk of transmission of sexually transmitted diseases. It has a higher failure rate than OCPs and IUDs and for this reason is not recommended if pregnancy is contraindicated. For high-risk individuals, many genitourinary clinics recommend a combination of the OCP and condom to minimize the risk of pregnancy and sexually transmitted diseases – a technique known as “double-Dutch.”

### Emergency contraception

Three methods of emergency contraception are licensed in the UK and are available in many other countries: progestogen-only and combined estrogen–progesterone pills, and the copper IUD. The hormonal preparations can be taken up to 72 hours after unprotected intercourse, but are most effective if taken within 24 hours [129]. Nausea was reported in 23% and vomiting in about 6% of the women who used the progesterone-only regimen. Women with T1DM should be warned of these potential side effects. Little work on the use of these agents in women with diabetes has been published, but they may have a role in the prevention of unplanned pregnancies occurring at a time of poor metabolic control.

### Conclusions on contraception

All women with diabetes of reproductive age should receive good contraceptive advice, as unplanned pregnancies occurring while glycemic control is poor carry an increased risk of morbidity and fetal abnormalities. Most forms of contraception are safe and effective in women with diabetes, but the OCP remains the most popular as it is very reliable and well tolerated.

## Hormone replacement therapy

Attitudes to hormone replacement therapy (HRT) have changed considerably since the start of the new millennium. HRT is well established as an effective treatment for menopausal symptoms and as a treatment for osteoporosis. Until recently there was considerable interest from diabetologists in the potential role of HRT in reducing cardiovascular risk. A survey of general practitioners and hospital doctors in the UK as recently as 2001 suggested the majority would advise HRT for women with diabetes as prophylaxis for cardiovascular disease [130]. This belief was based upon a series of cross-sectional studies and effective marketing by drug companies. Since then the results of a large randomized controlled trials of combined HRT have been published and the results were surprising and interesting. Hulley *et al.* [131] reported that combined HRT did not reduce cardiovascular outcomes in women with established coronary heart disease. The Women’s Health Initiative (WHI) study enrolled over 160 000 healthy women and reported in 2002. It was stopped early because of an increase in the risk of breast cancer [132]. Furthermore, there was a significant increase of stroke, coronary heart disease and pulmonary embolus in the group given HRT compared with the control group. There was a reduction in the risk of colorectal cancer and hip fracture. The study also reported an increase in the risk of dementia in the group given HRT [133]. Interestingly, women who took HRT in the WHI had a lower risk of developing diabetes.

Not surprisingly, the WHI study has generated considerable debate and has had a significant impact on practice. Many new guidelines on HRT have been produced, but few in diabetes. A detailed discussion of the benefits of HRT is beyond the scope of this book. The current views of the risks and benefits of HRT are listed in Table 45.8. In brief, in women with diabetes, HRT should be considered for short-term relief of menopausal symptoms, such as hot flushes, but is not indicated for cardiovascular risk reduction.

There is reasonable evidence that HRT does not worsen glucose tolerance in women either with or without diabetes and may produce a slight amelioration. In women without diabetes,

### HRT and glucose tolerance

There is reasonable evidence that HRT does not worsen glucose tolerance in women either with or without diabetes and may produce a slight amelioration. In women without diabetes,

**Table 45.8** Risks and benefits of hormone replacement therapy (HRT).

#### Main benefits of HRT

HRT produces:

- Relief of hot flushes
- Relief of urogenital symptoms
- Reduction of risk of osteoporotic fractures
- Reduction of risk of colorectal cancer

#### Main risks of HRT

HRT increases the risk of:

- Thromboembolic disease
- Stroke
- Breast cancer (combined HRT)
- Endometrial cancer (estrogen-only HRT)
- Ovarian cancer (estrogen-only HRT)

#### No change in risk

- Weight gain, headache
- Migraine
- Breast cancer (estrogen-only HRT)
- Colorectal cancer (estrogen-only HRT)

#### Insufficient evidence

There is incomplete evidence but HRT may worsen:

- Coronary artery disease
- Dementia

estradiol [134] and low-dose conjugated estrogens [135] are associated with an improvement and no effect on insulin sensitivity, while higher doses of conjugated estrogens and alkylated estrogens may cause deterioration of glucose tolerance [134,136–138].

In postmenopausal women with diabetes, estradiol has been reported to improve the fasting blood glucose concentration and glycosylated hemoglobin percentage [139]. A larger prospective study of over 15 000 women with T2DM also reported HRT produced an improvement in HbA<sub>1c</sub> levels [140]. A recent small randomized trial reported HRT reduced serum fructosamine levels by 5% [141]. Any potential benefit to glucose tolerance is limited to oral HRT preparations: transdermal estradiol does not appear to have any effect on glucose tolerance [142,143].

### HRT and lipids

There is now evidence that the effect of HRT on lipid profiles, such as glucose tolerance, is at worst neutral and may be slightly beneficial. In women without diabetes, estrogens reduce total and low density lipoprotein (LDL) cholesterol and increase high density lipoprotein (HDL) cholesterol and triglyceride levels [131,143]. Progestins can reduce triglyceride levels and when given in combination can prevent the estrogen-induced increase. Transdermal estrogen preparations have a beneficial effect on plasma lipids, reducing LDL cholesterol and triglycerides and increasing HDL cholesterol [144].

The effect of HRT on lipid profiles in women with diabetes has been reported to be largely favorable in several studies. In a small randomized cross-over study of overweight women with T2DM, conjugated estrogen therapy reduced central obesity, HbA<sub>1c</sub> and total cholesterol, and improved physical functioning [145]. In a largest study, 61 postmenopausal women received combined HRT in a randomized cross-over design. HRT reduced total and LDL cholesterol, but there was no change in serum HDL or triglyceride levels [141].

### HRT and blood pressure

HRT can be prescribed to hypertensive postmenopausal women under careful supervision. One of the few studies of HRT and blood pressure in diabetes suggested that it can be prescribed without any adverse effect on ambulatory blood pressure measurements in hypertensive and normotensive women [146].

### HRT and osteoporosis

There is limited evidence to suggest women with T1DM have reduced bone mineral density at the time of diagnosis [147]. Although women with T2DM might be expected to be protected from osteoporosis because of their increased tendency to obesity, they would appear to be at increased risk of hip fracture (see Chapter 48). A very large prospective cohort study of postmenopausal women in Iowa reported that women with diabetes had a 1.7-fold higher risk of hip fracture than women without diabetes [148]. Thus, the benefits of HRT in reducing the risk of osteoporotic fractures would appear to be at least as great in women

with diabetes as women without diabetes. Although HRT can be considered in all postmenopausal women with diabetes and osteoporosis, there are several alternatives including bisphosphonates, raloxifen and strontium which do not have the risks of HRT.

### Conclusions on HRT

HRT is an established treatment for the symptoms of the menopause. It is also effective in preventing osteoporosis. It has no adverse effects on glycemic control or lipid profiles. The benefits of HRT do not justify the risks in asymptomatic women and it is not indicated for cardiovascular risk reduction. It can be considered for treating menopausal symptoms in women with diabetes on a short-term basis.

## Gastrointestinal Manifestations of Diabetes

**Adil E. Bharucha & Michael Camilleri**

Clinical Enteric Neuroscience Translational and Epidemiological Research Program, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA

### Keypoints

- Gastrointestinal manifestations are frequent in diabetes.
- Diabetes may not be the cause of gastrointestinal symptoms.
- Glycemia influences development of neuropathy and acutely changes gastric emptying.
- Extrinsic and enteric neuropathies are key mechanisms in diabetic gastroenteropathy.
- Motor dysfunctions may affect any region of the gastrointestinal tract in diabetes and cause fast or slow transit.
- Incontinence, a frequently unvoiced symptom, may reflect sphincter or sensation deficits.
- Assessments of hydration, nutrition and metabolic status are essential.
- Measurements of regional transit and anorectal motor and sensory functions are key to management of diabetic gastroenteropathy.
- For management of gastroparesis and dyspepsia, correct hydration, nutrition and metabolic status; exclude any iatrogenic factor, such as GLP-1 analog, and "gastroparesis"; and treat the pathophysiologic process.

### Introduction

Although most attention has traditionally focused on the stomach, diabetes can affect the entire gastrointestinal tract. The term diabetic enteropathy refers to all the gastrointestinal complications of diabetes. Gastrointestinal involvement may be asymptomatic or manifest as symptoms (i.e. dysphagia, heartburn, nausea and vomiting, abdominal pain, constipation, diarrhea and fecal incontinence). These manifestations may affect quality of life, impair nutrition, and affect glycemic control.

### Epidemiology

Studies in selected patient groups, often from tertiary referral centers, suggest that gastrointestinal symptoms are common in diabetes mellitus [1,2]; however, these studies are prone to selection and other biases, which are avoided by studies conducted among people with diabetes in the community, where the prevalence of gastrointestinal symptoms is either not different, or only slightly higher than people without diabetes. Thus, in the Rochester Diabetic Neuropathy Study, only 1% of patients had symptoms of gastroparesis and only 0.6% had nocturnal diarrhea

[3]. In another study from Olmsted County, Minnesota, the prevalence of gastrointestinal symptoms (i.e. nausea and/or vomiting, dyspepsia, heartburn, irritable bowel syndrome, constipation and fecal incontinence) was not significantly different between individuals with either type 1 (T1DM) or type 2 diabetes mellitus (T2DM) and age-matched controls [4]; however, people with T2DM and men with T1DM used laxatives more frequently than in controls. Moreover, that study and a Finnish population-based study reported that people with T1DM had a lower prevalence of heartburn [5].

In contrast to these studies, a study from Australia found that the prevalence of several upper and lower gastrointestinal symptoms was higher in 423 patients with predominantly (95%) T2DM than in controls [6]. Taken together, these data suggest that gastrointestinal manifestations are not uncommon among patients with diabetes presenting for care. In the general population, however, the prevalence of gastrointestinal manifestations is not substantially higher among people with diabetes and matched controls, perhaps partly because the prevalence of gastrointestinal symptoms, mostly attributable to functional gastrointestinal disorders (e.g. irritable bowel syndrome), among people without diabetes in the community is relatively high, and approaches 20%. In Olmsted County, Minnesota, the age-adjusted incidence per 100,000 person-years of definite gastroparesis for the years 1996–2006 was 2.4 (95% confidence interval [CI] 1.2–3.8) for men and 9.8 (95% CI 7.5–12.1) for women. The age-adjusted prevalence of definite gastroparesis per 100,000 persons on January 1, 2007, was 9.6 (95% CI 1.8–17.4) for men and 37.8 (95% CI 23.3–52.4) for women [7].

Diabetic gastroparesis may cause severe symptoms and result in nutritional compromise, impaired glucose control and a poor quality of life, independently of other factors such as age, tobacco use, alcohol use or type of diabetes [8]. Studies of the natural history of gastroparesis have been limited by relatively small numbers of patients, potential referral bias or short follow-up periods. The data suggest that gastric emptying and its symptoms are generally stable during 12 years of follow-up or more [9]. In a study of 86 patients with diabetes who were followed for at least 9 years, gastroparesis was not associated with mortality after adjustment for other disorders [10]. Among patients with gastroparesis, overall survival was significantly lower than the age- and sex-specific expected survival computed from the Minnesota white population [7]; the most common causes of death were cardiovascular disease (24.6%), respiratory failure (23.2%), malignancy (15.9%), chronic renal failure in 11 (15.9%), cerebrovascular accident (10.1%) and other causes (10.1%).

## Pathophysiology

Gastrointestinal dysmotility in diabetes is caused by extrinsic (i.e. sympathetic and parasympathetic) neural dysfunction, hyperglycemia and hormonal disturbances. More recently, a role for intrinsic (i.e. enteric) neuronal dysfunctions, resulting from loss of excitatory and inhibitory neurons and interstitial cells of Cajal, has also been implicated [11]. Neural dysfunction has been attributed to several mechanisms (e.g. oxidative stress) described below and detailed elsewhere [12].

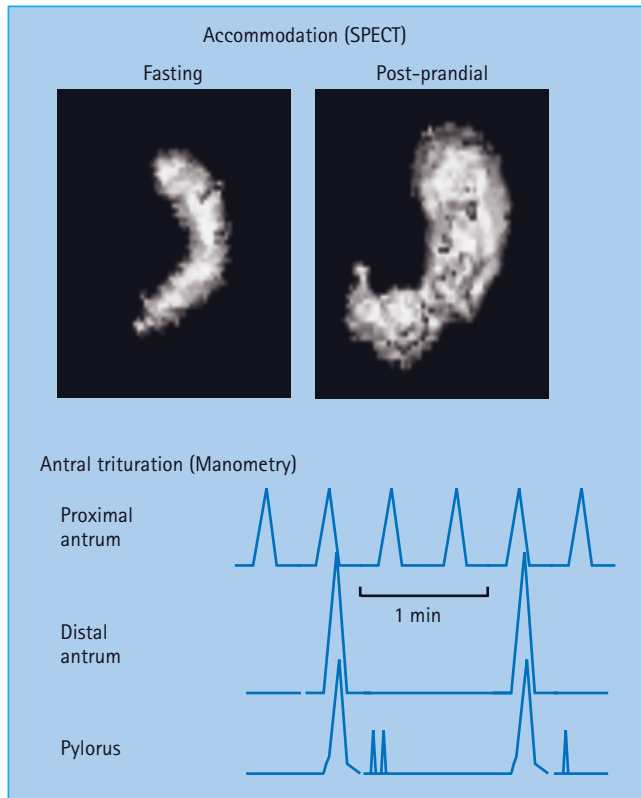

## Normal gastrointestinal motor functions

Gastrointestinal motor function is primarily controlled by the intrinsic or enteric nervous system (i.e. the “little brain” in the digestive tract) and modulated by the extrinsic (i.e. parasympathetic and sympathetic) nervous system (Figure 46.1) [13]. While intrinsic and extrinsic controls are independent, the prevertebral ganglia integrate afferent impulses between the gut and the central nervous system and provide additional reflex control of the abdominal viscera. The parasympathetic arm is excitatory to non-sphincteric muscle and inhibits sphincters. The sympathetic component has opposite effects. The enteric nervous system consists of 100 million neurons that are organized in distinct ganglionated plexi including the submucous plexus, which is primarily involved in absorption and secretion, and the myenteric plexus, which regulates motility. The interstitial cells of Cajal serve as pacemakers and also convey messages from nerve to smooth muscle. As with the somatic and autonomic nerves elsewhere, the gut’s autonomic and enteric nervous system can be affected in diabetes. Derangements of the extrinsic nerves at any level may alter gastrointestinal motility and secretion [14].

Gastrointestinal digestion and absorption require gastrointestinal motility, gastric and pancreatic secretion, and gastrointestinal hormonal release, which in turn, modulate motor, secretory and absorptive functions in the upper gut [15]. Traditionally, these processes are considered in three phases (cephalic, gastric and intestinal), which are integrated and overlap. Normally, liquids, particularly non-caloric liquids, empty rapidly from the stomach in a linear fashion. In contrast, gastric emptying of solids follows an exponential pattern. During the first 45 minute post-prandial period (i.e. the lag phase), the gastric antrum grinds

**Figure 46.1** Control of gastrointestinal motility. Note the extrinsic or autonomic nervous system modulates the function of the enteric nervous system, which controls smooth muscle cells through excitatory (i.e. acetylcholine [ACh], substance P [Sub P]) or inhibitory (nitric oxide [NO], vasoactive intestinal peptide [VIP], pituitary adenylate cyclase activating peptide [PACAP]) neurotransmitters. ICC, interstitial cells of Cajal; IPAN, intrinsic primary afferent neuron. Adapted from Camilleri M, Phillips SF. Disorders of small intestinal motility. *Gastroenterol Clin North Am* 1989; **18**:405–424.

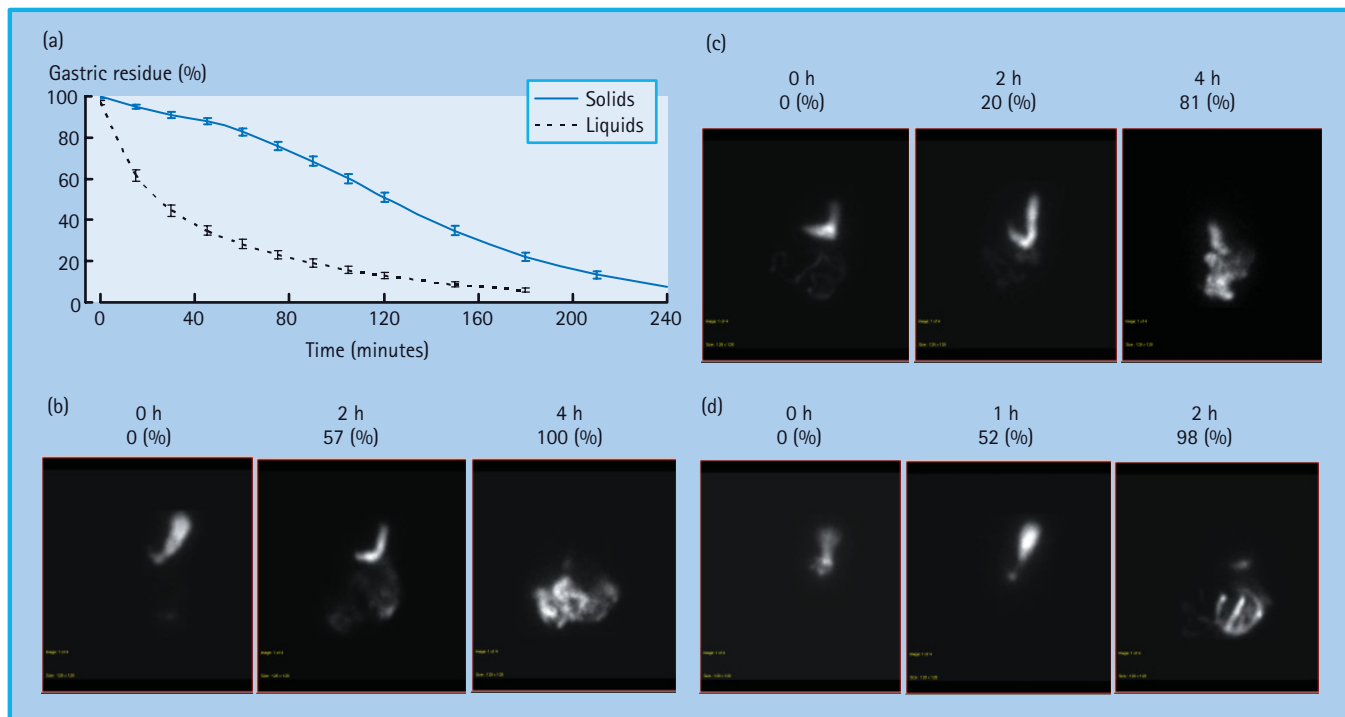

solids into particles smaller than 2mm in size, so they can be emptied through the pylorus. During the lag phase, the stomach relaxes or accommodates, providing room for digestion to occur (Figures 46.2 & 46.3). Thereafter, solids are emptied in a linear fashion, with approximately 50% emptying in 2 hours and 100% emptying in 4 hours.

Pancreatobiliary secretions and mechanical processes ensure small intestinal digestion, which precedes absorption. The small intestine transports solids and liquids at approximately the same rate; the head of the column of liquid chyme may reach the cecum as early as 30 minutes after ingestion. As a result of the lag phase for the transport of solids from the stomach, liquids typically arrive in the colon before solids. It takes about 150 minutes for half the solid and liquid chyme of similar caloric density (assuming solids are presented in a triturerated form to the small bowel) to traverse the small bowel. Complex carbohydrates or fat in the

**Figure 46.2** Assessment of gastric motor functions. Gastric accommodation can be assessed by measuring the post-prandial change in gastric volume using single photo emission computed tomography (SPECT). (top panel) The stomach wall is labeled with intravenous <sup>99m</sup>Tc pertechnetate. Food is subsequently transferred to the antrum. Manometry (bottom panel) demonstrates that the distal antrum and pylorus contract synchronously to grind food into smaller particles. Only particles 2mm or smaller can be emptied through the pylorus.

**Figure 46.3** Assessment of gastric emptying by scintigraphy. Normally liquids are emptied in a linear manner while solid emptying has an exponential profile, characterized by an initial lag phase, followed by a more rapid, linear emptying (a). The lag phase corresponds to the time required for antral trituration and gastric accommodation, during which approximately 10% of solids are emptied.

(b, c, and d) Representative examples of normal, delayed and accelerated gastric emptying respectively of an egg meal, labeled with <sup>99m</sup>Tc, in patients with diabetes. At time 0 (i.e. first image in each panel), the entire meal was in the stomach. Thereafter, the normal ranges for gastric emptying are 11–39% at 1 hour, 40–76% at 2 hours and 84–98% at 4 hours.

distal small intestine exert feedback control of proximal small intestinal motility, a process known as the small intestinal brake. Chyme is transferred from the ileum to colon in intermittent boluses. On average, it takes 36 hours, with an upper limit of 65 hours, to transfer contents from the cecum to the rectum. Compared to the stomach and small intestine, colonic transit is relatively prolonged, permitting digestion of fiber and absorption of water and electrolytes to be completed.

### Pathophysiology of diabetic enteropathy: insights from animal studies

In animal models, extrinsic neural dysfunction has been primarily implicated to a loss of myelinated and unmyelinated fibers without much neuronal loss [16,17]. The loss of nerve fibers is often multifocal, suggestive of ischemic injury. Within the enteric nervous system, reduced neuronal staining, and to a lesser extent neuronal loss, particularly inhibitory neurons expressing nitric oxide synthase (NOS) have been described in several animal models of diabetes [12]. In theory, this reduction in nitrergic inhibitory functions may contribute to impaired gastric accommodation and accelerated intestinal transit in diabetes. Reduced sympathetic inhibition may also contribute to accelerated intestinal transit. Because nitric oxide (NO) is a mediator of pyloric relaxation, loss of NOS may impair pyloric relaxation and thereby retard gastric emptying. Loss of intestinal cells of Cajal (ICC), documented in several animal models and case reports of diabetes, may also contribute to gut dysmotility [11,18].

Several mechanisms, including apoptosis, oxidative stress, advanced glycation end products and neuroimmune mechanisms may be responsible for neuronal loss and gut dysmotility [12]. The loss of ICC has been attributed to a reduction in hemoxygenase (HO-1) and other protective mechanisms against

hyperglycemia [11]. The effects of diabetes on neuronal morphology and functions are reversible. Insulin or pancreas transplantation improved glycemic control and the axonopathy affecting autonomic nerves in rats with diabetic autonomic neuropathy [19]. Insulin also restored expression of NOS and gastric emptying in animal models of diabetes while insulin and insulin-like growth factors prevented the loss of ICC in cultures [20,21]. Because ICC do not express receptors for either hormone, these effects are perhaps mediated by smooth muscle secretion of stem cell factor, which is the most important growth factor for ICC rather than directly by insulin and insulin-like growth factors [11]. Overexpression of glial cell line-derived neurotrophic factor, a trophic factor for enteric neurons, in transgenic mice reversed hyperglycemia-induced apoptosis of enteric neurons, improved gastric emptying and intestinal transit [22].

## Pathophysiology of diabetic enteropathy in humans

### Gastric dysfunctions

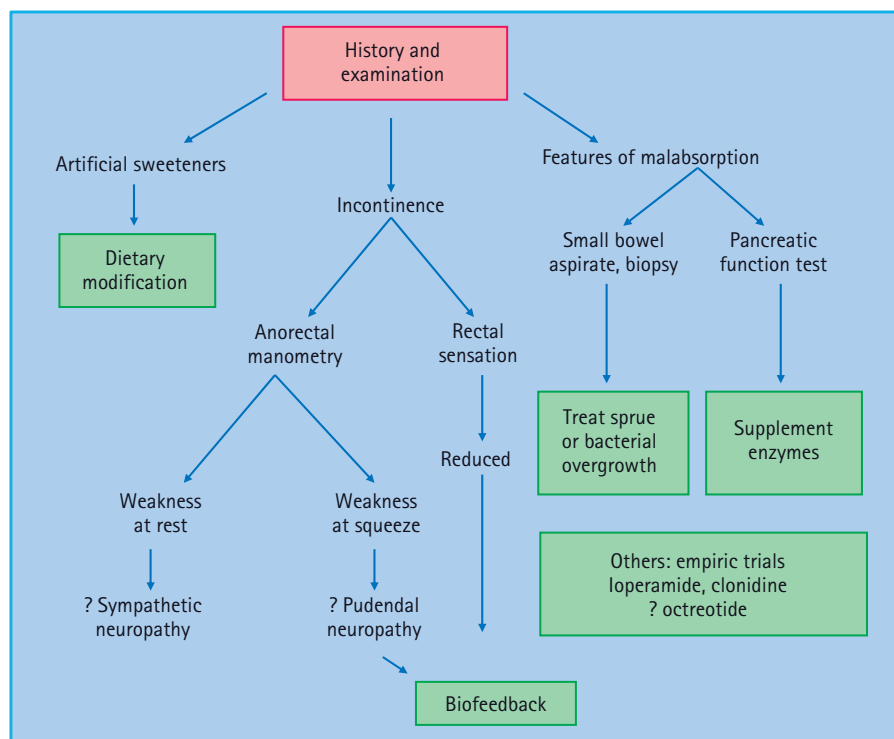

#### Neuropathy

Diabetes is associated with accelerated or delayed gastric emptying, increased and reduced gastric sensation, and impaired gastric accommodation (Figure 46.4). A vagal neuropathy can cause antral hypomotility and/or pylorospasm, which may delay gastric emptying [23]. The pathophysiology of rapid gastric emptying in diabetes is less well understood. Conceivably, impaired gastric accommodation resulting from a vagal neuropathy [24] may increase gastric pressure and thereby accelerate gastric emptying of liquids. However, the relationship between rapid gastric emptying and impaired gastric accommodation has not been substan-

GI manifestation of diabetes	Associated disease	Clinical presentation
↓ Gall bladder motility antral hypomotility pylorospasm		Gallstones Gastric stasis, bezoars
↓ Gastric accommodation		Dyspepsia
↓ $\alpha$ 2-adrenergic tone in enterocytes	Exocrine pancreatic insufficiency	Diarrhea, steatorrhea intestinal pseudo-obstruction
Small bowel (SB) dysmotility	Celiac sprue	Gastric or SB stasis or rapid SB transit
Colonic dysmotility	SB bacterial overgrowth	Constipation, or diarrhea
Anorectal dysfunction sensory neuropathy IAS-sympathetic EAS-pudendal neuropathy	Bile acid malabsorption	Disordered defecation or fecal incontinence

**Figure 46.4** Pathophysiology of diabetes enteropathy in humans. Adapted from Camilleri M. Gastrointestinal problems in diabetes. *Endocrinol Metab Clin North Am* 1996; **25**:361–378.

**Figure 46.5** Management of diarrhea in diabetes mellitus. Adapted from Camilleri M. Gastrointestinal problems in diabetes. *Endocrinol Metab Clin North Am* 1996; **25**:361–378.

tiated. The relationship between vagal neuropathy and impaired post-prandial accommodation is unclear because accommodation may be preserved even in people with diabetes and vagal neuropathy [25], perhaps reflecting non-vagal adaptive mechanisms involving enteric neurons [26]. Some patients with diabetes and gastroparesis also have small intestinal dysmotility, more frequently characterized by reduced than by increased motility [27]. Small bowel dysmotility may also contribute to gastric stasis.

### Hyperglycemia

Acute hyperglycemia delays gastric emptying in healthy subjects and in T1DM [28–31]. These effects may be explained by hyperglycemia-induced suppression of antral motility and migrating motor activity, the so-called intestinal “housekeeper” [32–34]. The effects of acute hyperglycemia on gastric emptying are modest. Indeed, even in T1DM, severe acute hyperglycemia (i.e. 16–20 mmol/L vs 4–8 mmol/L) prolonged the gastric emptying half-time by only 17 minutes from 124 to 141 minutes. Acute modulation of blood glucose within the physiologic post-prandial range (4–8 mmol/L) can also delay gastric emptying, to a lesser degree [31]. Cross-sectional studies suggest that higher glycated hemoglobin concentrations are associated with a higher prevalence of gastrointestinal symptoms and slower gastric emptying among people with diabetes in the community [6,35]. While strict glycemic control improves neural, renal and retinal functions in diabetes, the impact on gastric emptying is unclear [36]. Indeed, in the only study that assessed this question, improved glycemic control did not improve gastric emptying 1 week later in 10 patients with T2DM [37]. In addition to hyper-

glycemia, electrolyte imbalances caused by diabetic ketoacidosis (e.g. hypokalemia) and uremia may also aggravate impaired motor function in patients with diabetes. Iatrogenic gastroparesis may result from treatment with amylin or GLP-1 analogs.

### Diabetic diarrhea

It is useful to categorize the pathophysiology of diabetic diarrhea into conditions that are associated with malabsorption and those that are not (Figure 46.5). Involvement of sympathetic fibers, which normally inhibit motility and facilitate absorption via  $\alpha_2$ -adrenergic receptors, can result in accelerated small intestinal transit and cause diarrhea [38]. Artificial sweeteners such as sorbitol may also contribute to diarrhea. Patients with rapid ileal transit may have bile acid malabsorption [39,40] and deconjugated bile acids induce colonic secretion.

Features suggestive of malabsorption such as anemia, macrocytosis or steatorrhea should prompt consideration of bacterial overgrowth, small bowel mucosal disease or pancreatic insufficiency. Small intestinal dysmotility predisposes to bacterial overgrowth, which can cause bile salt deconjugation, fat malabsorption and diarrhea. Although T1DM is associated with celiac disease, most patients with celiac disease and T1DM in the community are asymptomatic [41]. Chronic pancreatic insufficiency may result from pancreatic atrophy, disruption of cholinergic enteropancreatic reflexes, or elevated serum hormonal levels of glucagon, somatostatin and pancreatic polypeptide, which reduce pancreatic enzyme secretion [42]. Nevertheless, the association between chronic pancreatic insufficiency and diabetes is uncommon. Moreover, because there is sufficient pancreatic reserve,

only 10% of pancreatic function is sufficient for normal digestion.

### Fecal incontinence

Loose stools and anorectal dysfunctions contribute to fecal incontinence in diabetic diarrhea. Compared to continent people with diabetes and healthy controls, patients with diabetes and fecal incontinence have a higher threshold for rectal perception of balloon distention, a marker of reduced sensation [43,44]. A sympathetic neuropathy may impair internal anal sphincter function and anal resting pressures while a pudendal neuropathy may result in reduced anal squeeze pressure.

### Constipation

The mechanisms of constipation in diabetes have not been carefully studied and are poorly understood. Clinical observations suggest that, similar to idiopathic chronic constipation, both colonic dysmotility and anorectal dysfunctions, such as impaired anal sphincteric relaxation during defecation, may contribute to constipation in diabetes [45]. Patients with colonic dysmotility have an impaired colonic contractile response to a meal and delayed colonic transit [46]. Patients with reduced rectal sensation may not perceive the desire to defecate. Compared to euglycemia, acute hyperglycemia inhibits the colonic contractile response to gastric distention and proximal colonic contraction elicited by colonic distention in healthy subjects [47]. By contrast, acute hyperglycemia did not significantly affect fasting or post-prandial colonic tone, motility, compliance and sensation, or rectal compliance and sensation in healthy people [48].

In addition to these factors, it is also important to consider the role of psychologic factors in the perception of gastrointestinal symptoms. Indeed, psychosomatic symptoms are significantly associated with the reporting of gastrointestinal tract symptoms [4]. Several medications have gastrointestinal side effects; for example, metformin can cause diarrhea while among other medications, verapamil and anticholinergic agents, can cause constipation.

---

## Clinical manifestations

### Dysphagia and heartburn

Esophageal dysmotility, typically characterized by impaired peristalsis with simultaneous contractions, is common, may cause dysphagia, and may be related to cardiovascular autonomic neuropathy in diabetic mellitus [49]. The amplitude of peristaltic contractions and basal lower esophageal sphincter pressures are generally normal. Symptoms of gastroesophageal reflux are also common, particularly in patients with impaired gastric emptying who have vomiting. Rarely, recurrent vomiting may lead to Mallory–Weiss tears and bleeding.

Dysphagia and heartburn should prompt upper gastrointestinal endoscopy to exclude reflux and other incidental mucosal diseases, such as candidiasis and neoplasms. While manometry

may reveal esophageal peristaltic disturbances in patients with significant dysphagia that is not explained by a structural lesion, it is unlikely to alter management, except for rare patients in whom another disorder, such as achalasia, is responsible for dysphagia. Because of the high prevalence of coronary atherosclerosis in diabetes, testing for coronary artery disease should be considered when necessary in patients with chest pain.

### Dyspepsia and gastroparesis

Although gastroparesis refers to a syndrome characterized by symptoms of nausea, vomiting, early satiation after meals and impaired nutrition and objective evidence of markedly delayed gastric emptying, gastric retention may be asymptomatic [50], perhaps because of the afferent dysfunction associated with vagal denervation [51]. Nausea and vomiting often occur in episodes lasting days to months or in cycles. Nausea and vomiting may be associated with impaired glycemic control and often cause hypoglycemia, perhaps because delivery of food into the small bowel for absorption is not sufficient to match the effects of exogenous insulin.

Consistent with the concept of a paralyzed stomach, the term gastroparesis should be restricted to patients with markedly delayed gastric emptying. When the delay in gastric emptying is not severe, the term diabetic dyspepsia is perhaps more appropriate. Dyspepsia is characterized by one or more, generally post-prandial, upper gastrointestinal symptoms, including bloating, post-prandial fullness and upper abdominal pain. Typically, vomiting is not severe but significant weight loss secondary to reduced caloric intake is not unusual. In addition to delayed gastric emptying, impaired gastric accommodation and abnormal, either increased or decreased, gastric sensation may also contribute to symptoms in diabetes [52,53]. Nonetheless, the distinction of dyspepsia from gastroparesis is challenging because there is no official distinction between moderately and severely delayed gastric emptying. Perhaps, gastric emptying of less than 65% at 4 hours reflects a significant delay as it is often associated with nutritional consequences, the need for nutritional supplementation, jejunal feeding or gastric decompression [54].

Patients with diabetic gastroparesis frequently have longstanding T1DM with other microvascular complications, including retinopathy, nephropathy, peripheral neuropathy and other forms of autonomic dysfunction. These can present as abnormal pupillary responses, anhidrosis, gustatory sweating, orthostatic hypotension, impotence, retrograde ejaculation and dysfunction of the urinary bladder) (Table 46.1). In contrast, it has been suggested that rapid gastric emptying of liquids is a relatively early manifestation of T2DM [55–59]. Clinicians have relied on these manifestations, and on certain symptoms, such as vomiting of undigested food eaten several hours previously and weight loss, and signs (e.g. a gastric succussion splash or features of an autonomic neuropathy) to predict delayed gastric emptying in patients with diabetes who present with upper and gastrointestinal symptoms. Several studies have shown, however, that symptoms are of limited utility for predicting delayed gastric emptying in diabetes

[60–66]. Similarly, the type and duration of diabetes, glycated hemoglobin levels and extraintestinal complications were, in general, not useful for discriminating normal from delayed or rapid gastric emptying; however, significant weight loss and a neuropathy were risk factors for delayed and rapid gastric emptying, respectively [67].

In patients with upper gastrointestinal symptoms, an upper gastrointestinal endoscopy is necessary to exclude peptic ulcer

disease and neoplasms, either of which can cause gastric outlet obstruction. Upper endoscopy may reveal gastric bezoars, which suggest antral hypomotility. Metabolic derangements, such as diabetic ketoacidosis or uremia, and medications, particularly opiates, calcium-channel blockers and anticholinergic agents, may contribute to dysmotility. Rarely, patients with gastroparesis present with retrosternal or epigastric pain and cardiac, biliary or pancreatic disease may be considered.

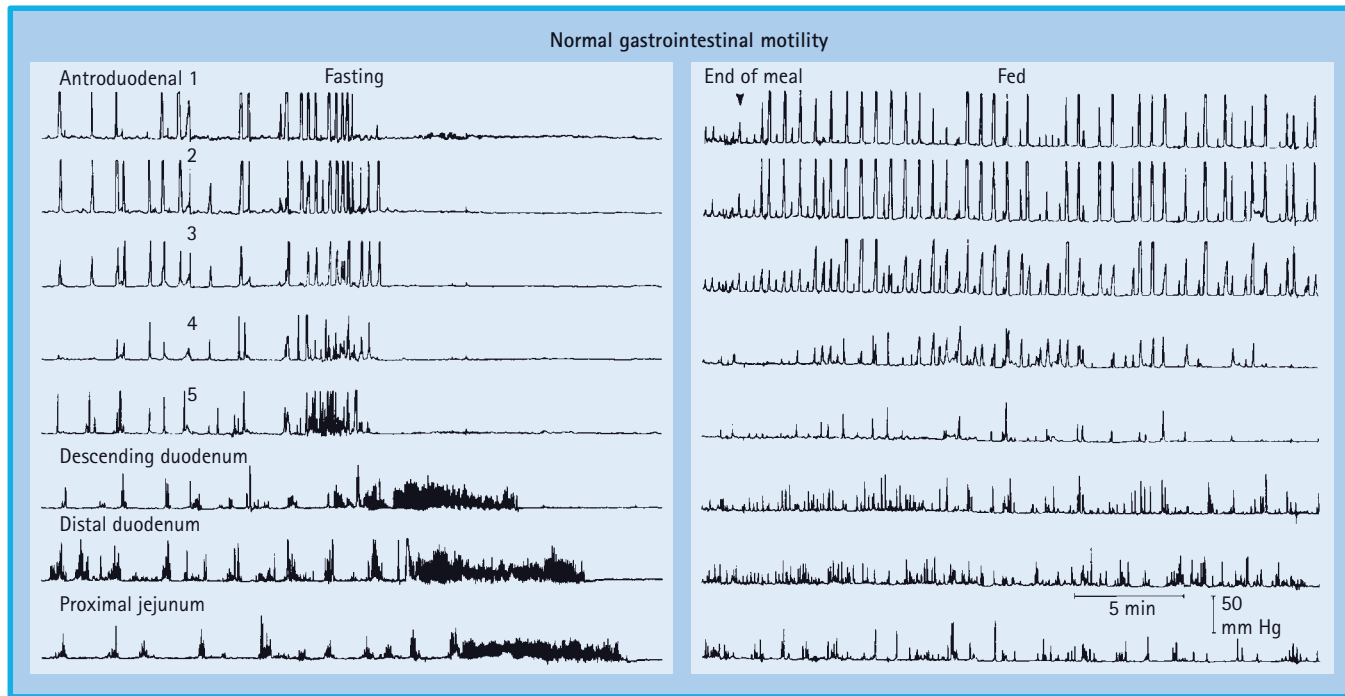

Barium X-rays of the small intestine or enterography with computed tomography should be considered only when the clinical features raise the possibility of small intestinal obstruction. Gastric emptying of solids should be quantified by scintigraphy and antroduodenal manometry should be considered in selected circumstances. Measurement of pressure profiles in the stomach and small bowel can confirm the motor disturbance and may facilitate the selection of patients for enteral feeding (Figure 46.6). Patients with selective antral hypomotility may tolerate feeding delivered directly into the small bowel while those with a more generalized motility disorder may not.

**Table 46.1** Symptoms and signs of autonomic dysfunction. Reproduced from Camilleri M. Disorders of gastrointestinal motility in neurologic disease. *Mayo Clin Proc* 1990; **65**:825–846, with permission.

Sympathetic	Parasympathetic
Failure of pupils to dilate in the dark	Fixed dilated pupils
Fainting, orthostatic dizziness	Lack of pupillary accommodation
Constant heart rate with orthostatic hypotension	Sweating during mastication of certain foods
Absent piloerection	Decreased gut motility
Absent sweating	Dry eyes and mouth
Impaired ejaculation	Dry vagina
Paralysis of dartos muscle	Impaired erection
	Difficulty emptying urinary bladder; recurrent urinary tract infections

**Diarrhea and constipation**

The term diabetic diarrhea was first coined in 1936 by Bergen at the Mayo Clinic to describe unexplained diarrhea associated with severe diabetes [68]. Diabetic diarrhea is typically chronic, may be episodic and can be severe. Diarrhea can occur at any time but is often nocturnal and may be associated with anal incontinence,

**Figure 46.6** Normal manometric profile (fasting and post-prandial). The migrating motor complex characteristic of fasting state is demonstrated by the presence of quiescence (phase I), intermittent activity (phase II) and an activity front (phase III). Post-prandial profile shows high amplitude, irregular but persistent phasic pressure activity at all levels. Reproduced from Malagelada J-R, Camilleri M, Stanghellini V. *Manometric Diagnosis of Gastrointestinal Motility Disorders*. New York: Thieme Publishers, 1986, by permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

which may indicate internal anal sphincter dysfunction. Patients with diarrhea often have symptoms of delayed gastric emptying such as early satiety, nausea and vomiting.

Constipation may occur in isolation or alternate with episodes of diarrhea. Many physicians regard constipation to be synonymous with infrequent bowel movements. It is important to characterize symptoms because many people have misconceptions about normal bowel habits. For example, it is not necessary to have a bowel movement daily – the normal range varies from three bowel movements every week to three every day. Moreover, by constipation, patients refer to one or more of a variety of symptoms including infrequent stools, hard stools, excessive straining during defecation, a sense of anorectal blockage during defecation, the need for anal digitation during defecation and a sense of incomplete evacuation after defecation [69]. Some of these symptoms, such as a sense of anorectal blockage during defecation, may suggest disordered evacuation. A careful rectal examination during relaxation and straining is needed to exclude rectal mucosal lesions and to detect the presence of rectal prolapse, rectocele and disordered defecation. Normally, voluntary contraction is accompanied by upward and anterior motion of the palpating finger toward the umbilicus as the puborectalis contracts. Conversely, the puborectalis should relax and the perineum should descend (by 2–4 cm) during simulated evacuation. The rectal examination may suggest features or defecatory disorders such as reduced or increased perineal descent and paradoxical contraction of puborectalis.

### Abdominal pain

Patients with diabetes are obviously susceptible to the usual causes of abdominal pain seen in the general population. There is an increased prevalence of gallstones because of altered gallbladder contractility and of mesenteric ischemia caused by generalized atherosclerosis; however, there is little evidence that altered gallbladder contractility per se (i.e. in the absence of gallstones) causes symptoms. Thoracolumbar radiculopathy may result in pain in a girdle-like distribution which does not cross the midline. Specific tests are indicated in the clinical features of pain suggest these disorders. It is essential to elicit a careful history.

---

### Diagnostic tests

Typically, diagnostic testing is primarily guided by symptom pattern and severity; however, because patients with delayed gastric emptying are often asymptomatic, gastric emptying assessments should also be considered in patients with unexplained hypoglycemia. After initial testing to identify disturbances of transit, more detailed testing with intraluminal techniques, such as manometry and/or a barostat, may be useful for characterizing motor dysfunctions and guiding therapy (Table 46.2). Autonomic function testing is also useful [70]. Delayed gastric emptying can be documented by scintigraphy or the presence of a large amount of retained food in the stomach. Barium studies and scintigraphy

using labeled liquid meals are of limited value for identifying dysmotility because the gastric emptying of liquids and semisolids (e.g. mashed potatoes) frequently is normal, even in the presence of moderately severe symptoms. Assessment of solid emptying by means of a radiolabel that tags the solid phase of the meal is a more sensitive test with a well-defined normal range. The proportion of radioisotope retained in the stomach at 2 and 4 hours distinguishes normal function from delayed gastric emptying with a sensitivity of 90% and a specificity of 70% [71]. The importance of obtaining scans for 4 hours after a meal cannot be over-emphasized. Because gastric emptying is slow initially, it is not accurate to extrapolate emptying from scans taken for a shorter duration. Another useful test for measuring solid phase gastric emptying utilizes a standardized meal with biscuit enriched with  $^{13}\text{C}$ , a substrate containing the stable isotope. When metabolized, the proteins, carbohydrates and lipids of the *S. platensis* or the medium chain triglyceride octanoate give rise to respiratory  $\text{CO}_2$  that is enriched in  $^{13}\text{C}$ . Measurement of  $^{13}\text{CO}_2$  breath content (a reflection of the amount of biscuit remaining in the stomach) by isotope ratio mass spectrometry allows an estimation of gastric emptying  $t_{1/2}$  [72]. Further validation of this technique is necessary in patients with bacterial overgrowth and small bowel mucosal disease.

For patients with severe upper gastrointestinal symptoms, antro-pyloro-duodenal manometry is a specialized technique that assesses pressure profiles in the stomach and small bowel and also guides management. Manometry may also reveal hypomotility of the gastric antrum and/or an intestinal neuropathy (Figures 46.6 & 46.7). Patients with selective abnormalities of gastric function may be able to tolerate enteral feeding (delivered directly into the small bowel) whereas patients with a more generalized motility disorder may not.

Gastric accommodation in response to meal ingestion may be impaired in diabetes [73]. This may contribute to the gastrointestinal symptoms of nausea, bloating and early satiety. Imaging of the stomach wall using  $^{99\text{m}}\text{Tc}$  pertechnetate allows measurement of gastric volume after meal ingestion.

For patients with constipation, colonic transit, anorectal manometry and rectal balloon expulsion tests provide a useful start. Anorectal manometry and the rectal balloon expulsion test generally suffice to diagnose or exclude defecation disorders; magnetic resonance imaging (MRI) or barium proctography are only required in selected patients. Colonic transit is often delayed in patients with defecatory disorders. Therefore, in patients with slow colonic transit, slow transit constipation can only be diagnosed after excluding defecatory disorders. Intraluminal assessments of colonic phasic motility (by manometry) and tone (by barostat) often reveal other dysfunctions (e.g. impaired contractile responses to a meal and/or pharmacologic stimuli (e.g. bisacodyl or neostigmine) in patient with slow transit constipation. Colonic transit can be characterized by radiopaque markers, which, depending on the technique, takes 5–7 days, or by scintigraphy, which takes 24–48 hours. Both techniques are equally accurate for identifying slow or rapid colonic transit.

**Table 46.2** Commonly performed autonomic tests. Reproduced from Camilleri M, Ford MJ. Functional gastrointestinal disease and the autonomic nervous system: a way ahead? *Gastroenterology* 1994; **106**:1114–1118, with permission.

Test	Physiologic functions tested	Rationale	Comments/pitfalls
<b>Sympathetic Function</b>			
1. Thermoregulatory sweat test (% surface area of anhidrosis)	Preganglionic and postganglionic cholinergic	Stimulation of hypothalamic temp. control centers	Cumbersome, whole body test
2. Quantitative sudomotor axon reflex test (sweat output, latency)	Postganglionic cholinergic	Antidromic stimulation of peripheral fiber by axonal reflex	Needs specialized facilities
3. Heart rate and blood pressure responses			
Orthostatic tilt test	Adrenergic	Baroreceptor reflex	Impaired responses if intra-vascular volume is reduced
Postural adjustment ratio	Adrenergic	Baroreceptor reflex	Impaired responses if intra-vascular volume is reduced
Cold pressor test	Adrenergic	Baroreceptor reflex	Impaired responses if intra-vascular volume is reduced
Sustained hand grip	Adrenergic	Baroreceptor reflex	Impaired responses if intra-vascular volume is reduced
4. Plasma norepinephrine response to: Postural changes	Postganglionic adrenergic	Baroreceptor stimulation	Moderate sensitivity, impaired response if intravascular volume is reduced
Intravenous edrophonium	Postganglionic adrenergic	Anticholinesterase "stimulates" postganglionic fiber at prevertebral ganglia	False-negatives caused by contributions to plasma norepinephrine from many organs
<b>Parasympathetic Function</b>			
1. Heart rate (RR) variation with deep breathing	Parasympathetic	Vagal afferents stimulated by lung stretch	Best cardiovagal test available, but not a test of abdominal vagus
2. Supine/erect heart rate	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
3. Valsalva ratio (heart rate, max./min.)	Parasympathetic	Vagal stimulation by change in central blood volume	Cardiovagal test
4. Gastric acid secretory or plasma pancreatic polypeptide response to modified sham feeding or hypoglycemia	Parasympathetic	Stimulation of vagal nuclei by sham feeding or hypoglycaemia	Abdominal vagal test, critically dependent on avoidance of swallowing food during test
5. Nocturnal penile tumescence	Pelvic parasympathetic	Integrity of S2-4	Plethysmographic technique requiring special facilities
6. Cystometrographic response to bethanechol	Pelvic parasympathetic	Increase in intra-vesical pressure suggests denervation supersensitivity	Tests parasympathetic supply to bladder, not bowel

Small intestinal dysmotility may manifest as one or more of the following features: abnormal migrating motor complexes; failure to convert from fasting to post-prandial motor pattern and/or features of a vagal neuropathy such as excessive number of fasting migrating motor complexes or persistent post-prandial migrating motor complexes). Assessment of stool fat provides a useful differentiation point for diabetic diarrhea, as it indicates malabsorption as the pathophysiology leading to diarrhea. An upper endoscopy provides an opportunity to obtain duodenal aspirates for bacterial overgrowth and small bowel biopsy to exclude celiac disease. Lactose or glucose hydrogen breath tests rely on substrate metabolism by bacterial overgrowth in the small intestine with hydrogen release and breath excretion; however, studies have shown that the early peak is frequently caused by rapid delivery of the substrate to the colon with bacterial metabolism by normal colonic flora rather than small bowel bacterial

overgrowth [74]. To reduce the potential impact of this confounding factor (i.e. rapid intestinal transit), a more restricted definition to diagnose small intestinal overgrowth may be preferable. An early hydrogen peak (20 ppm), caused by small intestinal bacteria, may be seen at least 15 minutes before the later prolonged peak, which corresponds to the passage of the remaining lactulose into the colon. Even with more restricted definitions, the sensitivity and specificity of the lactulose hydrogen breath test in detecting small bowel bacterial overgrowth have been reported to be only 68% and 44% and for the glucose breath test 62% and 83%, respectively [73].

### Management

The principles of management are to address fluid and nutritional requirements, improve glycemic control and treat symptoms.

**Figure 46.7** Manometric profile in 26-year-old woman with diabetes and autonomic neuropathy, showing abnormal propagation of phase III of interdigestive motor complex and lack of a well-developed antral component in fasting tracing. Post-prandially, note antral hypomotility, pylorospasm, and failure of meal to induce a fed pattern. Reproduced from Colemont LJ, Camilleri M. Chronic intestinal pseudo-obstruction: diagnosis and treatment. *Mayo Clin Proc* 1989; **64**:60–70, with permission.

### Gastroparesis and dyspepsia

While nutritional requirements and symptoms can be addressed to a variable extent in patients with mild and compensated gastroparesis, patients with severe gastroparesis often require hospitalization for one or more of the following measures: intravenous hydration and correction of metabolic derangements (ketoacidosis, uremia, hypo-/hyperglycemia), nasoenteric decompression, and/or enteral nutrition to manage vomiting and nutritional requirements [54]. Parenteral nutrition may become necessary in cases of malnutrition. Bezoars may be mechanically disrupted during endoscopy, followed by gastric decompression to drain residual non-digestible particles. Erythromycin at a dose of 3 mg/kg body weight intravenously every 8 hours can accelerate gastric emptying [75,76]. When oral intake is resumed, treatment with oral 250 mg erythromycin t.i.d. for 1–2 weeks is worthwhile. Thereafter, the prokinetic effects of erythromycin are limited by tachyphylaxis. Anecdotal findings suggest that erythromycin may be effective if courses are separated by a drug-free period (e.g. lasting 2 weeks). Hyperglycemia interferes with the prokinetic effect of intravenous erythromycin on gastric emptying in healthy subjects and patients with diabetes [34]. Because both liquids and homogenized solids are more readily emptied from the stomach than solids, liquid or blenderized food will be better tolerated. Frequent monitoring of blood glucose levels is essential during this phase.

For patients with severe gastroparesis who do not respond to the measures outlined above, it may be necessary to bypass the stomach with a jejunal feeding tube. This procedure should be preceded by a trial of nasojejunal feeding for a few days of with infusion rates of at least 60 mL iso-osmolar nutrient per hour. It

is preferable to place jejunal feeding tubes directly into the jejunum either by endoscopy, or if necessary by laparoscopy or mini laparotomy, rather than via percutaneous endoscopic gastrostomy tubes. Such tubes allow restoration of normal nutritional status but they are not without adverse effects. There is no evidence to suggest that gastrectomy relieves symptoms or enhances quality of life. Patients with gastroparesis often have concomitant small intestinal denervation which is likely to cause persistent symptoms after gastrectomy [27,77].

If the patient remains symptomatic, other prokinetic agents may be considered as adjuncts. In the USA, the only available medication is metoclopramide, a peripheral cholinergic and antidopaminergic agent. During acute administration, it initially enhances gastric emptying of liquids in patients with diabetic gastroparesis, but its symptomatic efficacy is probably related to its central antiemetic effects. Its long-term use is restricted by a decline in efficacy and by a troubling incidence of central nervous system side effects. Therefore, the authors prefer to prescribe a dose of 10 mg t.i.d., administered 30 minutes before meals, for a short duration; the higher dose is 20 mg t.i.d. A systematic review of trials concluded there was limited evidence to support the use of domperidone, which is another dopaminergic antagonist not approved for use in the USA [78]. Endoscopic injection of botulinum toxin into the pylorus was not effective in controlled studies primarily of patients with idiopathic gastroparesis [79,80].

Although the Food and Drug Administration (FDA) recognizes gastric electrical stimulation as a humanitarian use device for refractory gastroparesis, its use for this indication is controversial. While published data suggest that the device reduces

vomiting frequency only when the device is on, data submitted to the FDA concluded that electrical stimulation reduced vomiting frequency to a similar extent with the device turned off or on, suggesting a placebo response [81,82]. Moreover, the device is expensive and does not accelerate gastric emptying. Between 10 and 20% of patients have device-related complications.

### Diabetic diarrhea

Diabetic diarrhea is treated symptomatically with loperamide, preferably administered 30 minutes before meals, in the dose range of 2–16 mg/day. Consumption of artificial sweeteners that contain the osmotically active sugar substitute sorbitol should be reduced. Second-line approaches are clonidine, 0.1 mg orally or by patch, in patients who do not experience significant postural hypotension [83]. Amitriptyline, which has anticholinergic effects, may reduce intestinal cramping and transit. Octreotide (25–50 µg subcutaneously 5–10 minutes before meals) delays small intestinal transit [84] and may also reduce secretory diarrhea associated with rapid intestinal transit [85]. While it has been suggested that octreotide reduces small bowel bacterial overgrowth in chronic intestinal pseudo-obstruction [86], this study assessed for bacterial overgrowth by breath testing. Indeed, by delaying small intestinal transit, octreotide may predispose to bacterial overgrowth. Regulating stool consistency may also improve fecal continence. In addition, pelvic floor retraining with biofeedback therapy can improve rectal sensation, and enhance coordination between perception of rectal distention and contraction of the external anal sphincter [44]; however, biofeedback therapy is less effective in patients with markedly reduced rectal sensation. A descending colostomy may be required and may improve the quality of life in patients with severe diarrhea associated with fecal incontinence.

### Constipation

For patients without pelvic floor dysfunction, chronic constipation can be generally managed with pharmacologic agents such as osmotic and stimulant laxatives [87]. Pelvic floor retraining by biofeedback therapy is the cornerstone for managing defecatory disorders; laxatives are used as an adjunct to pelvic floor retraining [88]. Fiber supplementation, either with dietary supplementation or with fiber products (e.g. psyllium 15–18 g/day), should be considered in patients with inadequate fiber intake. Of the osmotic laxatives, polyethylene glycol (up to 17 g in 8 ounces of water once or twice per day) is a widely used and safe over-the-counter agent. While lactulose is a poorly absorbed disaccharide, lactulose syrup contains small amounts of absorbable sugars and may increase hyperglycemia. Magnesium compounds are safe but patients with impaired renal function may develop magnesium retention. Bisacodyl or glycerin suppositories are useful rescue agents in patients who do not have a bowel movement for 2 days. If possible, suppositories should be administered 30 minutes after a meal to synergize pharmacologic therapy with the physiologic response to a meal. By activating chloride channels and inducing colonic secretion, lubiprostone accelerates colonic transit in

healthy subjects and improves symptoms in functional constipation [89–91]. While there are no studies in patients with diabetes and constipation, lubiprostone should be considered in patients who have not responded to osmotic agents.

## The Skin in Diabetes

**Graham R. Sharpe & Paul D. Yesudian**

Department of Dermatology, Broadgreen Hospital, Liverpool, UK

### Keypoints

- Various skin conditions are associated with diabetes, either type 1 or type 2, the specific chronic complications of the disease, the use of antidiabetic drugs and certain endocrine and metabolic disorders that cause diabetes.
- *Necrobiosis lipoidica diabetorum* is unrelated to glycemic control. Treatment is difficult, but in the early stages topical steroids may be beneficial.
- Diabetic dermopathy (“shin spots”) is the most common skin disorder in patients with diabetes, usually in the pre-tibial region in long-standing diabetes, and tends to resolve within 1–2 years.
- The skin is thickened in diabetes, and irreversible glycation of skin collagen and other proteins may lead ultimately to yellowish skin discoloration especially in the palmar creases.
- *Acanthosis nigricans* is the presence of hyperpigmented velvety hyperkeratotic plaques in the flexural regions, particularly the axillae or posterior neck. It is associated with various causes of insulin resistance.
- Erythema occurs on the face, around the nail margins and on the lower limbs.
- Calciphylaxis implies advanced vascular damage with a poor prognosis.
- Large vessel injury can lead to recalcitrant leg ulcers.
- Candidal overgrowth is frequently observed in people with poorly controlled diabetes.
- Bacterial infections such as “malignant” otitis externa can be potentially lethal.
- Erythrasma, caused by corynebacteria, is seen more frequently in obese people with diabetes.
- Dermatophytosis is *not* found more frequently in those with diabetes than in those without the disease.
- Vitiligo shares an autoimmune pathogenesis, like type 1 diabetes.
- There is no scientific basis for the assumption that pruritus occurs more commonly in those with diabetes.
- Necrolytic migratory erythema is an unusual rash that is diagnostic of the glucagonoma syndrome.
- Insulin injections can cause both lipoatrophy and lipohypertrophy.
- Allergic insulin reactions, which are now rare because of purer insulin availability, can be subdivided into immediate-local, general, delayed or biphasic responses.
- Sulfonyleureas are well-recognized causes of multiple cutaneous drug reactions.

### Introduction

Various skin disorders are associated with diabetes. Some are relatively specific “markers” of the condition, usually caused by the metabolic changes in diabetes or associated with endocrine disorders that cause diabetes. Other skin conditions develop as manifestations of chronic diabetic complications, particularly vascular changes and peripheral neuropathy. Skin infections are more common in people with poorly controlled diabetes, but not specific for the condition. Cutaneous side effects of drug treatments for diabetes may occur, although these are less common with current therapies.

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

### Cutaneous metabolic manifestations

This group includes a number of conditions that appear specific to diabetes (e.g. diabetic thick skin) or are much more common in people with diabetes than the general population (e.g. *necrobiosis lipoidica*). The cause of many of these conditions remain obscure, although some may be related to the process of non-enzymatic glycation of cutaneous structural proteins, particularly collagens or changes in microvascular structural proteins. A number of cutaneous conditions were previously thought to have an increased incidence in diabetes, but subsequent studies have not substantiated these links (e.g. generalized pruritus) [1]. Likewise, the evidence that granuloma annulare is associated with diabetes is inconclusive [2]. The metabolic manifestations currently regarded as being genuinely associated with diabetes are shown in Table 47.1.

### Necrobiosis lipoidica diabetorum

This is a rare condition with a prevalence of 0.3% in diabetic populations [3]. Although it is much more common in those with diabetes than individuals without diabetes, the relationship to diabetes and the etiology of necrobiosis lipoidica diabetorum (NLD) remains unclear. An early and much quoted study of 171 patients suggested that about two-thirds of patients with NLD

had diabetes, usually type 1 (T1DM) [3], with a further 12–15% having an abnormal glucose tolerance test [4]; however, patient selection may have given an overestimate of the incidence. A more recent retrospective study of 65 patients with NLD in a dermatology clinic found that 11% were known to have diabetes and a further 11% had an abnormal glucose tolerance test [5]. NLD usually develops in young adult or early middle life, but has occasionally been reported in childhood [6]. Women are three times more commonly affected than men.

There is no proven association with glycemic control, but patients with diabetes and NLD do appear to have a higher incidence of chronic diabetic complications such as retinopathy, neuropathy and microalbuminuria [7,8]. This suggests that microangiopathy may have an etiologic role. The presence of immunologic deposits in lesional vessel walls also implicates immune factors in the pathogenesis [9]. Nevertheless, the cause remains unknown.

NLD has a distinctive appearance (Figure 47.1). Early lesions may be rounded, dull red, symptomless papules or plaques which

slowly progress to the typical chronic lesion – an oval or irregularly shaped, indurated plaque with central atrophy [3,8]. NLD often has a shiny surface, with prominent telangiectatic vessels crossing over a waxy yellowish central area. The margin of lesions may be brownish or red and sometimes with comedo-like plugs, where necrotic material is extruded through the surface. The shin is the most commonly affected site, but the thighs, ankles and feet may also be affected; lesions rarely occur on the trunk, upper limbs or scalp [10]. Ulceration occurs in 25% of cases and may be very slow to heal. NLD lesions are usually partially or completely anesthetic and alopecia is frequently present [11]. They are variable in number but usually few and most extend slowly over several years, sometimes coalescing with adjacent areas. Long periods of quiescence may occur or occasionally NLD lesions may heal with scarring. The condition can lead to significant morbidity and cosmetic disfigurement. The diagnosis is usually clinical; a diagnostic skin biopsy is not normally required and may heal slowly or risk ulceration in atrophic lesions. The differential diagnosis of early lesions includes granuloma annulare, cutaneous sarcoid, necrobiotic xanthogranuloma and diabetic dermopathy.

Histologically, NLD lesions consist of foci of degenerate collagen bundles with a hyalinized appearance (necrobiosis), surrounded by fibrosis, a diffuse infiltrate of histiocytes and frequently a palisading granulomatous reaction with giant cells similar to those seen in sarcoidosis (Figure 47.2). There is a superficial and deep perivascular infiltrate that is composed of lymphocytes and plasma cells [12,13]. Capillary wall thickening and microvascular occlusion are present, but do not appear central to the pathologic process. These abnormalities occur throughout the dermis. There is considerable overlap between these features and those of granuloma annulare [13], and this similarity undoubtedly contributes to the suggestion that granuloma annulare is associated with diabetes. Despite histologic similarities in the earlier stages of the two conditions they run a very different

**Figure 47.2** Histologic feature of necrobiosis lipoidica diabeticorum showing degeneration of the collagen (necrobiosis), associated with fibrosis and a granulomatous histiocytic infiltrate. A giant cell is indicated by an asterisk. Hematoxylin and eosin stain  $\times 40$ .

clinical course and the association has now been discounted [12,14].

No treatment for NLD has proved effective in double-blind placebo controlled trials and treatment remains unsatisfactory. Spontaneous remission is unusual [3] and good diabetic control does not usually have a significant effect on the course of the condition. Patients should be encouraged not to smoke and to avoid trauma to the area which may result in a painful and recalcitrant ulcer. For early NLD lesions corticosteroids either applied topically (perhaps under occlusion) or by intralesional injection may be beneficial [15,16]. There is evidence that the inflammatory process extends beyond the clinical margins and topical steroids may halt or slow progression if applied to the periphery of lesions [8]. Once atrophy has developed this is irreversible and topical steroids should not be used in chronic lesions because they may worsen skin atrophy. There is a suggestion that topical retinoids may be beneficial in atrophic cases [17]. Oral steroids may be of benefit in a short course of 5 weeks with reduction of disease activity, but not atrophy [18]. Benefit was maintained in a 7-month follow-up but careful monitoring of blood glucose control is essential. The thiazolidinediones or glitazones have been reported to benefit NLD but more experience is required [19]. Various anticoagulants and antiplatelet agents have been tried; including aspirin, dipyridamole, heparin and oxpentifylline, but controlled trials has not shown any of these to be effective [20,21]. Pentoxifylline, ticlopidine, nicotinamide and clofazamine have all been tried [22–24]. There are several reports in small open studies of approximately 50% of the patients responding to topical PUVA (application of 8-methoxypsoralens [methoxsalen] to the skin prior to treatment with ultraviolet A light) [25–27]. Non-steroidal systemic immunosuppression with cyclosporine, mycophenolate mofetil or the tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) antagonist infliximab have been reported to be beneficial in a few cases [28–31]. Pulsed dye laser treatment may improve telangiectasia and erythema but there is a risk of skin breakdown [32]. There are reports of good results following excision and grafting [33], although the disease may recur locally. In most cases, cosmetic camouflage is the preferred option.

### Diabetic dermopathy (shin spots)

This is the most common dermatologic condition associated with diabetes, occurring in up to 50% of patients with diabetes but also in up to 3% of adults without diabetes; subjects without diabetes usually have only one or two lesions whereas most patients with diabetes have four or more [34,35]. Men are more commonly affected and it is also more prevalent in patients over 50 years of age and in long-standing diabetes. The condition is associated with the three most common microangiopathic complications of diabetes: neuropathy, nephropathy and retinopathy [36]. There is also an association with coronary artery disease and diabetic dermopathy is a subtle sign that suggests more serious complications [37]. The presence of microvascular changes, notably thickening of arterioles and capillaries, led to the term “diabetic dermopathy” [38].

**Figure 47.3** Diabetic dermopathy, “shin spots.” Courtesy of Professor Julian Verbov, Royal Liverpool University Hospital.

The lesions are well-circumscribed atrophic brownish scars often on the shins, giving the alternative name “diabetic shin spots” (Figure 47.3) [34,35]. The forearms, thighs and bony prominences may also be affected [39]. The lesions are usually bilateral and may appear in crops. Early lesions are oval red papules measuring up to 1 cm in diameter, which slowly develop scaling and a brown color because of the presence of hemosiderin-laden histiocytes and extravasated erythrocytes in the superficial dermis [34]. There is no effective treatment, but the lesions tend to resolve over 1–2 years.

#### Diabetic bullae (bullous diabeticorum)

Various forms of bullae have been described in subjects with diabetes, but all are relatively rare [40,41]. Diabetic bullae affect men more than women and are more common in older patients and those with peripheral neuropathy [42]. The conditions usually present as tense blisters, from a few millimeters up to several centimeters in size, on a non-inflammatory base, appearing rapidly and healing over a few weeks without scarring (Figure

**Figure 47.4** Diabetic bullae.

47.4). The feet and lower legs are the most common sites, followed by the hands. Electron microscopy studies demonstrate a subepithelial split at the level of the lamina lucida and immunofluorescence studies are negative [43]. Other causes of subepithelial blisters, including the autoimmune blistering diseases porphyria cutanea tarda, pseudoporphyria and infections such as bullous impetigo.

#### Diabetic thick skin

The thickness of the skin is largely attributable to the filamentous proteins of the dermis, of which collagen is by far the most abundant. Compared with normal subjects, the collagen bundles in the dermis of patients with diabetes are thickened and disorganized, as a result of irreversible non-enzymatic glycation, cross-linking and “browning” of protein. Collagen normally turns over slowly; the formation of advanced glycation end-products (AGEs) damages the protein thereby reducing the ability of enzymes such as collagenase to remodel the collagen fibers [44]. Gradual and irreversible modification of collagen, elastin and other structural dermal proteins is part of the physiologic aging process, but is accelerated in diabetes, especially if poorly controlled.

Browning of collagen results in yellow skin discoloration, best seen on the palms and soles of patients with diabetes. The skin of patients with diabetes is measurably thicker than in subjects without diabetes [45] and shows loss of elasticity [46]. In some studies, skin thickness relates to duration of diabetes [47] and in others to the presence of complications such as neuropathy [48]. Skin thickness is usually clinically insignificant, but may, if advanced, lead to the specific complications of “diabetic hand syndrome” and diabetic scleredema [49]. The combination of thick tight waxy skin and limited joint mobility has been called cheiroarthropathy and is present in 30–40% of patients with T1DM [50].

#### Diabetic hand syndrome

Up to 75% of subjects with diabetes over 60 years of age are affected, although the incidence is not closely related to the duration of disease or metabolic control [51,52]. Milder skin thicken-

ing may develop in up to 20% of individuals without diabetes, but occurs at an older age. The early changes include thickening of the skin over the dorsum of the hands and digits, especially the proximal interphalangeal joints (sclerodactyly). The interphalangeal joints are particularly susceptible and may present as painful stiff fingers. In a minority of patients, the condition progresses to cause a fixed flexion deformity of the fingers and Dupuytren contracture, while soft tissue thickening of the wrist may cause carpal tunnel syndrome by compression of the median nerve. More extreme cases present with a tight waxy appearance together with pebbly pads over the knuckles and distal fingers (Garrod's knuckle pads).

### Scleredema of diabetes

This is marked dermal thickening, commonly involving the posterior aspect of the neck and upper parts of the back, and extending to the face, arms and abdomen with more severe involvement. It has a prevalence of 2.5% in type 2 diabetes mellitus (T2DM), and is found particularly in those who are overweight and with poorly controlled diabetes [53]. Histology of the condition shows

dermal thickening which contains large collagen bundles and an increased number of mast cells [49]. Scleredema, with similar morphologic changes, may follow chronic streptococcal infection of the skin, often involving the lower legs. Scleredema is reported to respond to ultraviolet light [54].

### Acanthosis nigricans

This rare condition is characterized by a velvety papillomatous overgrowth of the epidermis, which is usually hyperpigmented. The flexural areas, particularly the axilla, inguinal region, inframammary region and neck, are most frequently affected (Figure 47.5). Rarely, more generalized changes involve the knuckles and other extensor surfaces, with verrucous patches and hyperkeratosis of the palms and soles. Histologic features include extensive folding and thickening of the epidermis, with increased numbers of melanocytes, which accounts for the dark color.

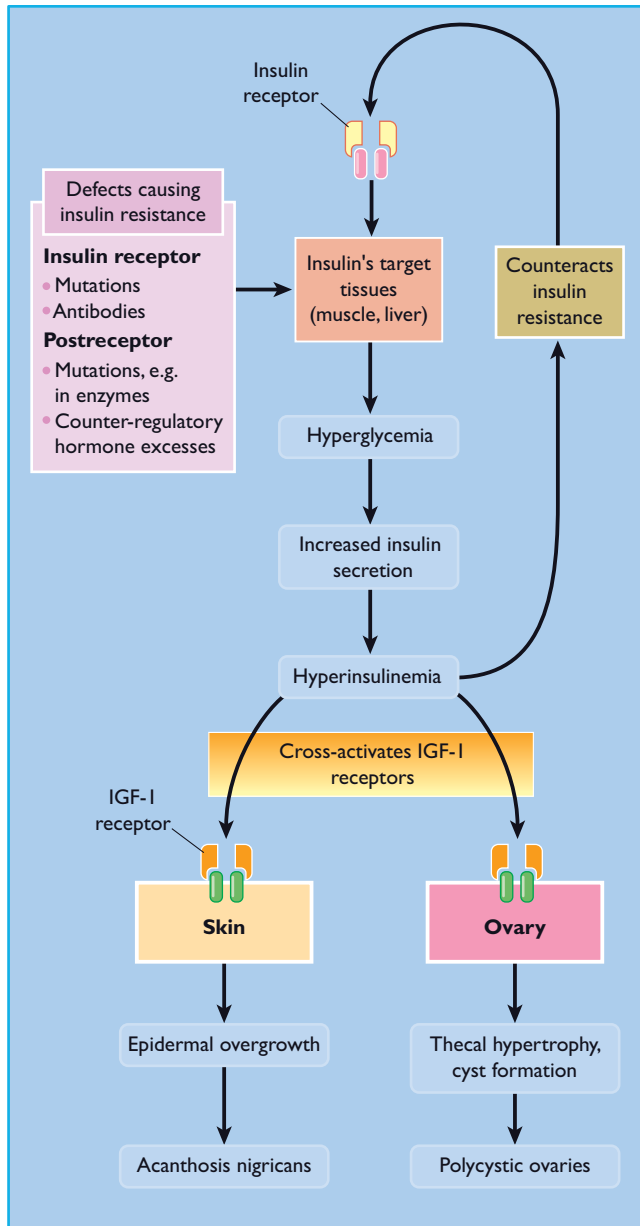

Severe and widespread acanthosis nigricans is usually a manifestation of internal malignancy, often of the gastrointestinal tract. The more limited presentation is associated with various endocrine disorders, which share the common features of insulin

**Figure 47.5** Acanthosis nigricans, showing typical dark velvety appearance: (a) in the axilla; (b) in the groin. Figure 47.5(b) courtesy of Dr. S. Mendelsohn, Countess of Chester Hospital, Chester.

resistance and hyperinsulinemia: these include diabetes mellitus, acromegaly, Cushing disease and polycystic ovarian disease, obesity, genetic and autoimmune insulin receptor defects and lipoatrophic diabetes [55–57]. It is presumed that hyperinsulinemia induced by insulin resistance activates insulin-like growth factor I (IGF-I) receptors, which are closely related to insulin receptors, on various tissues [58]. In the skin, stimulation of IGF-I receptors on keratinocytes could lead to excessive epidermal growth (Figure 47.6).

**Figure 47.6** Suggested relationship of insulin resistance and hyperinsulinemia to acanthosis nigricans. Raised insulin levels may act on insulin-like growth factor I (IGF-I) receptors in the skin to cause epidermal overgrowth. Similar events in the ovary could lead to polycystic ovary disease which is also associated with insulin-resistant states.

Acanthosis nigricans can be disfiguring and upsetting for the patient. Mild peeling agents such as 5% salicylic acid in a bland cream may be helpful. The condition usually partially regresses if the hyperinsulinemia can be successfully reduced.

**Eruptive xanthomas and hypertriglyceridemia**

Eruptive xanthomas are caused by hypertriglyceridemia with elevated serum levels of chylomicrons or very low density lipoproteins. This can occur in diabetes, especially if poorly controlled. The lesions are caused by triglyceride deposition in the skin and present as small red or yellow nodules measuring up to 0.5 cm diameter. They occur predominantly on the extensor surfaces of the limbs and buttocks; the onset is usually rapid and lesions frequently occur in groups or crops (Figure 47.7). Men are more commonly affected. Although xanthomas may itch initially, they are usually asymptomatic. Lesions usually regress slowly within months after hypertriglyceridemia has been corrected by lipid lowering drugs or improved glycemic control.

**Figure 47.7** Eruptive xanthoma: (a) buttocks; (b) knees.

**Table 47.2** Vascular changes.

Diabetic erythema and rubeosis
Periungual telangiectasia
Calciphylaxis
Acral dry gangrene

## Vascular changes

Skin conditions develop as manifestations of chronic diabetic complications affecting both small and large vessels. A number of these changes, particularly those causing erythema, are associated with longstanding diabetes (Table 47.2).

### Rubeosis faciei

Facial erythema can occur in people with diabetes, with the intensity of coloration dependent on the vascular engorgement in the superficial venous plexus [59]. The changes occur as a result of altered vascular tone or diabetic microangiopathy. Capillary microscopy has demonstrated venular dilatation people with diabetes with this condition. It appears more obvious in fair-skinned individuals and can be difficult to distinguish from normal facial redness in the general population [60]. Hypertension is common in these patients and may exacerbate the capillary damage.

### Periungual telangiectasia

Erythema of the skin surrounding the nail bed resulting from the dilatation of proximal nailfold capillaries is an excellent marker of functional microangiopathy [61]. It can occur in up to 49% of those with diabetes. Even though connective tissue diseases can exhibit periungual telangiectases, the lesions are morphologically different. In patients with diabetes, isolated homogenous engorgement of venular limbs is seen; whereas mega-capillaries or irregularly enlarged loops are observed in those with connective tissue disease [62]. Different capillary changes can be observed in those with recently diagnosed diabetes than those with long-standing disease. In patients with advanced microvascular disease or following prolonged periods of poor control, small hemorrhages or vascular occlusion (leading to localized areas of non-perfusion) may occur. Nailfold capillaries are thought to reflect the general status of the microcirculation and have been used in detailed studies of functional changes of diabetic microangiopathy.

### Erysipelas-like erythema

This manifests as well-demarcated patches of cutaneous reddening, occurring on the legs and feet of patients with diabetes and microcirculatory compromise. It can be mistaken for erysipelas, but is differentiated by the lack of associated fever, leukocytosis or elevated erythrocyte sedimentation rate. This finding can correlate, in some cases, with destructive lesions of the underlying bone [63]. The pathogenesis of erysipelas-like erythema may be small vessel occlusive disease with compensatory hyperemia.

**Table 47.3** Cutaneous infections associated with diabetes.

Yeast infections (candidiasis)
Bacterial infection (boils and sepsis)
Erythrasma
Malignant otitis externa
Necrotizing fasciitis
<i>Phycomyces</i> infections

## Calciphylaxis

Calciphylaxis is a small-vessel vasculopathy occurring in patients with renal failure and sometimes in those with diabetes. It is characterized by mural calcification, intimal proliferation, fibrosis and thrombosis [64]. The lesions start as small red tender areas of skin which become ischemic leading to the development of subcutaneous nodules and poorly healing, necrotizing skin ulcers. They can serve as a portal of entry for infectious agents. The prognosis in those with calciphylaxis is poor because of impaired wound healing and infection leading to sepsis. Aggressive analgesic treatment may be required for ischemic pain, along with optimal blood glucose control and weight reduction [65].

## Macrovascular changes

Cutaneous signs of ischemia in the lower limbs include cold or cyanosed feet, erythema, hair loss and atrophy. Patients with diabetes and both venous insufficiency of the lower legs and arterial disease are particularly prone to developing non-healing ulcers; these frequently become superinfected and can be very troublesome to manage. Patients with diabetes have a higher incidence of large-vessel disease than the non-diabetic population. A sign of large-vessel disease is dependent rubor with delayed return of color (>15 seconds) after pressure has been applied to the skin. Patients with diabetes are also prone to venous stasis ulcers as many of them are obese and this in turn leads to increased lower extremity venous pressure. Venous hypertension and skin breakdown at sites of increased venous pressure ensues, leading to venous ulcers. Neuropathy, with lack of pain sensation, also contributes to foot ulceration. Repeated trauma and increased shear forces affect the skin without the usual protective mechanisms which are impaired by peripheral neuropathy, leading to further skin breakdown [62].

## Infections

Studies have shown that no significant increase in the prevalence of cutaneous infections occurs in most subjects with diabetes and the strength of previously assumed associations have been questioned [66]; however, poor glycemic control can increase the risk of infection by causing abnormal microcirculation, decreased phagocytosis, impaired leukocyte adherence and delayed chemotaxis [67]. Infections occurring at presentation or with poor glycemic control are shown in Table 47.3.

(a)

(b)

**Figure 47.8** *Candida* infections in patients with diabetes. (a) Flexural infection showing satellite lesions. (b) Chronic paronychia caused by *Candida albicans*. Note swollen and erythematous nailfolds.

### Candida infection

Infection with *Candida albicans* may be a presenting feature of diabetes or manifest as a complication of poorly controlled diabetes. The infection appears as erythematous papules with satellite pustules and can affect the flexural areas in the body (Figure 47.8a), the vulva and penis, and also the nail margins, causing paronychia (Figure 47.8b). In women, vulvovaginitis is the most common manifestation and presents with pruritus vulvae that can be intense and distressing. The vulva appears erythematous and fissured, with peripheral pustulation in severe cases. It may be particularly troublesome while a patient is hyperglycemic and glycosuric [68]. Candidal balanitis, balanoposthitis and phimosis occur less commonly in men, but could be a presenting feature [69]. Candidal angular stomatitis and an atrophic tongue resembling median rhomboid glossitis are oral manifestations of diabetes. Oral candidiasis occurs more commonly in patients with diabetes who smoke or wear dentures [70]. Candidal intertrigo occurs on opposing surfaces under the breast, in the groins and axillae, or in the folds of the abdominal skin. Scratching of the areas involved with *Candida* infection can result in bacterial superinfection.

*Candida* infection of the hands and feet are probably equally seen in those with diabetes and the non-diabetic population, but tends to be more severe in the former. Chronic paronychia presents as swelling and erythema around the lateral nailfold, with more severe involvement leading to onycholysis (Figure 47.8b). Microscopic examination and culture of the extruded material will confirm the presence of *Candida*. Less common than paronychia is infection of the web space between the middle and fourth finger (erosion interdigitale blastomycetica) [71]. Exclusion of moisture is an essential aspect to the treatment, and systemic antifungal drugs (e.g. oral fluconazole or itraconazole) rather than topical preparations may be required. Inappropriate treatment with steroids or antibiotics can worsen *Candida* infection at any site.

### Bacterial infections

Furuncles, carbuncles, styes and erythrasma were particularly frequent before the introduction of insulin and antibiotics, and skin infections from *Staphylococcus aureus* are still probably more common in the patient with diabetes than in the non-diabetic population. Increased rates of colonization with staphylococci has been reported in those with poorly controlled diabetes [72]. Severe (“malignant”) otitis externa is an uncommon but potentially lethal infection caused by invasive *Pseudomonas* spp. The condition occurs in elderly patients with diabetes and manifests as purulent discharge with severe pain in the external ear. It progresses from cellulitis to osteomyelitis, meningitis and cerebritis with a high mortality [73].

Erythrasma, caused by *Corynebacterium minutissimum*, is rare but occurs with increased frequency in obese patients with diabetes. It presents as a red shiny or scaly patch in the intertriginous areas and with ultraviolet light exhibits a characteristic coral-red fluorescence. Topical or systemic erythromycin is curative. Unusual infections with coliforms or anaerobes occur in those with diabetes as can *Pseudomonas* infections of the toe web spaces or nailfold (paronychia) and secondary infection of venous ulcers [74]. Anaerobic cellulitis with *Clostridium* species can occur in patients with diabetic ketoacidosis, requiring treatment with metabolic control, aggressive débridement of devitalized tissue and intravenous antimicrobial therapy [64]. Necrotizing fasciitis is a potentially lethal skin and soft tissue infection that is more common in those with diabetes [68]. *Streptococcus pyogenes*, anaerobic streptococci, *Bacteroides* and *Staphylococcus aureus* are some of the organisms associated with necrotizing fasciitis. This infection can extend from trivial wounds such as furuncles, insect bites and injection sites, or sometimes begin from decubitus ulcers. Rapid progression ensues, with extensive tissue destruction and severe systemic toxicity, leading to death [75]. This condition should be considered in patients with diabetes and cellulitis who have associated systemic features such as tachycar-

dia, leukocytosis, marked hyperglycemia or acidosis. This potentially fatal infection should be treated with urgent surgical débridement of necrotic tissue and intravenous antibiotics, after obtaining blood and tissue culture. The mortality remains high (about 25%) in spite of optimal treatment [76].

**Dermatophytosis**

Dermatophyte infections are probably not more common in the diabetic population than in their normal counterparts [66]; however, they could serve as a portal of entry for other infectious agents, particularly in those with neurovascular complications. *Trichophyton rubrum* is the most common pathogen, causing erythematous lesions which are often annular with scaly edges. Intertrigo or interdigital infection presents as maceration and superficial scaling. The diagnosis is confirmed by finding fungal hyphae in the superficial scale, ideally taken from the edge of the lesion. Treatment of choice is with the newer topical imidazole antifungal agents, but if extensive, systemic terbinafine, itraconazole or griseofulvin may be required.

**Phycomyces infections**

Poor metabolic control, resulting in hyperglycemia and ketoacidosis may permit organisms that are normally non-pathogenic to establish infections in traumatized skin. Leg ulcers or non-healing surgical wounds may have super-added phycomycete infections. Deep *Phycomyces* infection such as rhinocerebral mucormycosis is a rare but life-threatening complication of diabetes. It can be a presenting manifestation of diabetes in the elderly and manifests as fever, facial cellulitis, periorbital edema, proptosis and, rarely, blindness [77]. The infection spreads along the turbinates, septum, palate, maxillary and ethmoid sinuses and can extend into the frontal lobe, cavernous sinus or carotid artery. It should be suspected in any patient with diabetes presenting with sinusitis, purulent nasal discharge, altered mental state and infarcted tissue in the nose or palate. Treatment involves correction of acid–base imbalance, aggressive débridement of devitalized tissue and intravenous antifungal therapy.

**Associated conditions**

These are a group of dermatoses that are reported more commonly in those with diabetes than in the non-diabetic population (Table 47.4). A number of endocrine conditions are associated with diabetes and also cause specific skin changes (Table 47.5).

**Vitiligo**

Vitiligo is an autoimmune condition seen more commonly in patients with T1DM, but can also occur in T2DM. Polyglandular autoimmune syndrome type 2 is characterized by adrenal failure, autoimmune thyroid disease and T1DM, and can be associated with vitiligo [78]. There is no evidence that vitiligo occurs specifically in patients with circulating antibodies, and is not associated with any specific human leukocyte antigen type. It manifests as

**Table 47.4** Associated conditions.

Vitiligo
Lichen planus
Yellow nails
Clear cell syringoma
Cutaneous neuropathy (pain, neurotrophic ulcers)
Autonomic neuropathy (decreased sweating)
Perforating skin disorders (e.g. folliculitis, Kyrle’s disease)

Acanthosis nigricans
Hirsutism
<b>Partial and total lipodystrophy</b>
Absence of subcutaneous fat

patchy symmetrical depigmented areas of skin and, although asymptomatic, can cause significant emotional distress. Treatment is unsatisfactory but topical steroids and calcineurin inhibitors such as tacrolimus ointment can be used. Patients should be advised on photoprotection and use a high factor sunscreen or cover the area.

**Lichen planus**

Lichen planus is an inflammatory disorder of the skin recognized by the presence of violaceous flat-topped polygonal papules, distributed in the flexural aspects of the limbs. An increased incidence of diabetes has been reported in patients with lichen planus, particularly the erosive oral lichen planus variant [79,80]; however, most studies have examined the presence of diabetes in patients with lichen planus rather than the reverse. The link between diabetes and lichen planus is therefore still unproven, especially because both are relatively common conditions.

### Pruritus

Even though there is a common assumption that itching is a symptom of diabetes, this is highly questionable. Studies have failed to link the presence of generalized pruritus with diabetes [81,82]. Localized itching, particularly in the genital area, can be associated with *Candida* infections which are more common in patients with diabetes. The presence of xerotic skin, a feature present both in those with and without diabetes, can also predispose to pruritus. There is no direct relationship between ichthyosis or xerosis (dry skin) and diabetes [83].

### Yellow nails

Yellow nails have frequently been noted in patients with diabetes, particularly the distal hallux [84]. An early sign of diabetes is the presence of a yellowish or brownish discoloration in the distal part of the hallux nail plate. These later change to a canary yellowish color that can affect both the toe and finger nails. Even though yellowish nails are seen in association with onychomycosis, psoriasis and in the elderly, it appears to be a diabetic marker not associated with these causes. A study of finger nails has shown patients with diabetes to have high levels of furosine lysine, another marker of non-enzymatic glycosylation [85].

### Clear cell syringomas

Syringomas are adnexal non-neoplastic lesions that are derived from intra-epidermal parts of the sweat duct. Clear cell syringoma is an unusual variant and is clinically undistinguishable from the typical syringomas. They present as yellowish papules distributed around the eyes and are asymptomatic. The clear cell variety has two features of note: the histologic preponderance of clear cell and the frequent coexistence with diabetes [86,87]. It has been postulated that in these patients, there may be a phosphorylase deficiency secondary to elevated glucose levels that in turn results in the formation of clear cells.

### Glucagonoma

The glucagonoma syndrome is caused by tumors of the  $\alpha$  cells of the pancreas which secrete glucagon (see Chapter 17). Even though the syndrome is extremely rare, it needs to be considered in patients with diabetes who present with diffuse atypical rashes. Most tumors are malignant and have usually metastasized at the time of diagnosis, but tumors grow slowly and patients frequently present with a long history. The syndrome consists of four major components: increased glucagon levels, diabetes (usually mild), weight loss and the pathognomonic rash of necrolytic migratory erythema.

Necrolytic migratory erythema occurs in 70% of patients, manifesting as an annular erythematous and figurate rash. Initial features are a non-specific itchy eczematous rash with a migrating active edge that develops vesicles, superficial blisters, erosions and scaling (Figure 47.9). The eruption waxes and wanes in cycles of up to 2 weeks and occurs particularly on the lower abdomen, buttocks, legs, perineum and intertriginous areas. The rash can be a presenting sign, occurring 1–6 years before the diagnosis of

**Figure 47.9** Necrolytic migratory erythema in a patient with the glucagonoma syndrome. Courtesy of S. Bloom, Royal Postgraduate Medical School, London, UK.

glucagonoma is made [88]. It can be associated with other physical findings, including glossitis, stomatitis, brittle dystrophic nails and alopecia. A skin biopsy can be contributory, showing suprabasal acantholysis, and psoriasiform hyperplasia with pallor, ballooning and necrosis of the upper spinous layer of the epidermis [89].

The role of hyperglucagonemia and the cause of the skin eruption is unclear. Deficiency of essential fatty acids, zinc and amino acids may be important in the pathogenesis. The rash may respond to resection of the pancreatic islet cell tumor, sometimes within 48 hours. Management may also involve chemotherapy, essential amino acid and fatty acid supplementation, and the use of somatostatin or its analog octreotide, which suppresses glucagon levels and may also have an independent action on the skin lesions [90,91].

### Perforating dermatoses

Acquired reactive perforating folliculitis, also called Kyrle's disease, is a condition characterized by transepidermal elimina-

**Figure 47.10** Perforating skin disease (Kyrle's disease).

tion of degenerative collagen and is seen in end-stage renal disease caused not only by diabetes but by other conditions as well [92]. Perforating dermatoses have also been associated with T1DM and T2DM, affecting mainly African-American patients on dialysis. It presents with pruritic hyperkeratotic papules on the extensor surfaces of the lower limbs, but can occur on the trunk and face (Figure 47.10). The lesions can occur at sites of trauma (Koebner or isomorphic phenomenon). Histology reveals an atrophic epidermis surrounding a plug of degenerate material consisting of elastin and collagen [62]. It is thought to be a disorder of keratinization which engenders a proliferation of epidermis to eliminate abnormal tissue. Although it appears to be an inflammatory condition, microvasculopathy has been noted in the underlying dermis of biopsy specimens [93]. The lesions can be exacerbated by injury or excoriation. It is notoriously difficult to treat but can be helped by topical steroids or retinoids, failing which phototherapy is a useful option.

## Iatrogenic conditions

Both insulin and oral antidiabetic treatments can cause a variety of skin manifestations (Table 47.6).

### Reactions to insulin

#### Lipoatrophy

Lipoatrophy occurs at sites of insulin injections and is particularly prominent with the longer-acting preparations [94]. It is characterized by a loss of subcutaneous fat and can be a cosmetic concern. This complication is less common with the advent of purer insulins. Circumscribed depressed areas of skin are seen at sites of insulin injections 6–24 months after the start of treatment. It is more common in young female subjects with diabetes. The pathogenesis is secondary to an immunologic reaction as biopsies from affected sites show immunoglobulin M and complement. Other theories include mechanical trauma from the angle of injection, surface alcohol contamination or local production of

**Table 47.6** Cutaneous complications of antidiabetic treatment.

<b>Insulin</b> (especially impure animal preparations)
Localized allergic (urticaria, granuloma)
Systemic allergic (pruritus, urticaria, anaphylactoid)
Lipoatrophy
Lipohypertrophy
Idiosyncratic reactions (pigmentation, keloid formation)
<b>Sulfonylureas</b>
Maculopapular eruptions
Erythema multiforme
Eczematous or lichenoid eruptions
Photosensitivity
Chlorpropamide alcohol-induced flushing

tumor necrosis factor from macrophages induced by injected insulin. Repeated injections to the same site may predispose to this problem [95].

#### Lipohypertrophy

Lipohypertrophy presents as soft subcutaneous nodules or thickening at sites of repeated injections [96]. It occurs because of the lipogenic action of insulin, with repeated local stimulation of adipocytes being causative. Insulin absorption may be delayed at such sites, potentially resulting in disruption of glycemic control [97]. It resolves spontaneously by changing the site of insulin injections. Hyperkeratotic verrucous variants of lipohypertrophy have also been described [98].

#### Insulin allergy

Reactions to insulin were previously common because of the presence of impurities such as cow or pig proteins, and preservatives or additives. The use of recombinant human and analog insulin has decreased the incidence of insulin allergy which is now less than 1% of insulin-treated patients [64]. Allergic reactions to insulin can be classified as immediate-local, general, delayed or biphasic. Immediate-local reactions occur within a few minutes of injection and subside within an hour. Erythema with urtication can occur and is possibly immunoglobulin E (IgE) mediated. Treatment of the immediate-local reaction is to change the insulin to a more purified product. Systemic reactions include generalized urticaria and, rarely, anaphylaxis. Generalized urticarial reactions to purified insulins are rare [99], but a few patients sensitized to animal insulins have experienced anaphylaxis with human insulin [100]. Delayed hypersensitivity reactions are the most common, appearing about 2 weeks after the start of insulin therapy. Itchy nodules are evident at the sites of injections, 4–24 hours after injection. Biphasic responses have been reported in some individuals, with immediate urticaria followed by a delayed reaction several hours later. They are considered IgG-mediated immune complex reactions. The hypersensitivity may be to insulin itself, or to preservatives such

as aminobenzoic acid or to zinc [101]. Insulin allergic reactions may be managed by antihistamines, addition of glucocorticoids, discontinuation of therapy or a change in the insulin delivery system.

#### Other cutaneous complications of insulin

Occasionally, lack of simple hygiene leads to infection with abscess formation. Granulomatous lesions that have a furuncular or pustular appearance can occur following insulin injections [102]. Keloids, hyperkeratotic papules, purpura and localized pigmentation can also occur. Patients using insulin pumps for subcutaneous insulin delivery can experience local infections at the site of needle insertion, contact allergy to the associated tape and tubing material and, rarely, subcutaneous nodules [103]. Retention of fluid can occur when insulin therapy is first commenced. This is manifested as edema of the legs and is probably caused by temporary inhibition of sodium excretion.

#### Reaction to oral hypoglycemic agents

##### Sulfonylureas

Sulfonylureas are the most common oral hypoglycemic agents that cause skin reactions. About 1–5% of patients taking first-generation sulfonylureas develop cutaneous reactions within 2 months of treatment [64]. Maculopapular, morbilliform, urticarial or generalized erythematous reactions are common and resolve with discontinuation of the medication. Photosensitive reactions, usually of the photoallergic type, as well as lichenoid eruptions have also been reported (Figure 47.11) [104]. Erythema multiforme, characterized by erythematous and hemorrhagic skin lesions associated with “target” lesions, can be a severe manifestation of drug reactions (Figure 47.12). Extensive blistering which includes the mucosal surfaces can occur and if the conjunctiva are involved, urgent ophthalmologic opinion is mandatory. Rarer reactions include erythema nodosum and exacerbation of porphyria cutanea tarda [105].

The chlorpropamide alcohol flush is a disulfiram-like effect occurring in 10–30% of patients taking this drug. Patients experience facial erythema, headache and palpitations about 15 minutes after drinking alcohol and it subsides in about an hour.

Figure 47.11 Drug rash with chlorpropamide.

Figure 47.12 Erythema multiforme. (a) Showing the varied appearance of the condition: annular, arcuate and blistering lesions and confluent erythema on the ears. (b) Mouth ulceration in Stevens-Johnson syndrome, the severe form of erythema multiforme.

Endogenous opioids may be important as the flush is blocked by naloxone [106]. Second-generation sulfonylureas such as glipizide and glimepiride are less likely to cause cutaneous side effects. Glipizide has rarely been associated with photosensitivity, rash, urticaria and pruritus. Glimepiride can similarly cause lichenoid skin reactions [107].

### Other oral hypoglycemic agents

Rashes with other oral antidiabetic agents are much less common than sulfonylureas. Transient erythema or urticaria may occur with the biguanide metformin. It is also reported to cause a psoriasiform drug eruption, erythema multiforme, photosensitivity and leukocytoclastic vasculitis [108,109]. Acarbose can cause a generalized erythema multiforme, although it is minimally absorbed from the gut. It may be the degradation products of acarbose that causes the allergic reaction [110]. Thiazolidinediones such as rosiglitazone and pioglitazone can cause edema, transient erythema and urticaria, as can the glinides such as repaglinide, but such reactions are uncommon.

## Bone and Rheumatic Disorders in Diabetes

**Andrew Grey & Nicola Dalbeth**

Department of Medicine, University of Auckland, Auckland, New Zealand

### Keypoints

- Musculoskeletal disorders may cause pain and functional impairment, and adversely affect management of diabetes.
- Fibroproliferative disorders of soft tissue such as limited joint mobility, frozen shoulder, Dupuytren contracture, trigger finger and carpal tunnel syndrome occur more commonly in diabetes and can lead to upper limb disability.
- Charcot joint is an infrequent but serious complication of diabetic peripheral neuropathy, and is characterized by disordered osteoclastogenesis. Bisphosphonate therapy may be a useful adjunct to standard treatment.
- Patients with diabetes are at high risk of developing gout, particularly in the presence of renal impairment and diuretic use.
- The prevalence of diffuse idiopathic skeletal hyperostosis is increased in patients with type 2 diabetes (T2DM).
- Fracture risk is increased in both type 1 (T1DM) and T2DM.
- Bone mineral density is decreased in T1DM, and increased in T2DM.
- Disease complications increase fracture risk by increasing risk of falls and causing regional osteopenia.
- Thiazolidinediones decrease bone formation and bone mineral density, and increase fracture risk in T2DM.
- Fracture healing may be impaired in diabetes.

### Musculoskeletal disease in diabetes

#### Background

A variety of musculoskeletal disorders are associated with diabetes. These disorders may cause pain and functional impairment, and influence the ability of patients to adhere to other aspects of diabetes treatment, particularly exercise and weight management. Therapies commonly used in the treatment of rheumatic disease, particularly corticosteroids and non-steroidal anti-inflammatory drugs (NSAIDs), may be particularly problematic in patients with diabetes. The important bone and joint disorders associated with diabetes discussed in this chapter are outlined in Table 48.1.

#### Fibroproliferative disorders of soft tissue

##### Limited joint mobility (cheiroarthropathy)

Limited joint mobility refers to a syndrome of joint contractures resulting in decreased passive mobility of the joints in patients with diabetes [1]. Flexion contractures of the proximal interphalangeal (PIP) joints and metacarpophalangeal (MCP) joints of the hands are characteristic, with the fifth PIP joint affected

first (Figure 48.1). The skin on the dorsum of the hands typically appears tight and waxy [2]. Large joints such as the wrists, elbows, ankle and cervical spine can also be affected, and reduced lung volumes have been reported in severe cases [3,4]. Pain is usually mild or absent early in disease, and features of synovitis such as joint swelling, effusion, warmth and tenderness are typically absent. The disorder can be readily differentiated from systemic sclerosis by lack of Raynaud phenomenon and other systemic features, normal nailfold capillary examination and negative autoantibodies [5,6].

The presence of limited joint mobility of the hands is detected clinically by assessing for the prayer sign or the table-top sign. The prayer sign is positive if patients are unable to oppose the palmar surfaces at any interphalangeal or MCP joints when the hands are placed in the prayer position. For assessment of the table-top sign, the patient places both hands on a table top with the palms down and the fingers fanned out. The fingers are then viewed at table level. In stage 0, the entire palmar surface of the fingers makes contact with the table. In stage 1, one finger is affected (usually the fifth PIP joint of one or both hands). In stage 2, two or more fingers of both hands are affected (usually the fourth and fifth PIP joints). In stage 3, there is involvement of all the fingers and also restricted movement in a larger joint, usually the wrist or elbow [7]. Passive joint movement should also be assessed to confirm limitation of joint mobility [8].

Prevalence estimates for limited joint mobility in type 1 diabetes mellitus (T1DM) range 9–58%, and 25–75% in type 2 diabetes

mellitus (T2DM) [1,9–11]. There is some evidence that prevalence rates have declined in patients with T1DM in the last 20 years because of improvements in glycemic control [12].

Limited joint mobility is an important entity primarily because of its clinical associations. It is one of the earliest complications of diabetes and is strongly associated with the presence of microvascular complications such as retinopathy and nephropathy in T1DM, [1,12–15], and macrovascular complications in T2DM [10]. It is also associated with other fibroproliferative disorders affecting the upper limb such as frozen shoulder, Dupuytren contracture and carpal tunnel syndrome [15–18]. In general, limited joint mobility does not severely impact on hand function, but combinations of these upper limb disorders may cause upper limb disability [19–21]. In addition to microvascular complications, risk factors for the development of limited joint mobility in patients with diabetes include older age, puberty (in T1DM), disease duration and cigarette smoking [10,22–24].

Advanced imaging techniques have demonstrated thickening of skin, tendons and tendon sheaths in patients with limited joint mobility [25,26]. Histologic examination of the skin shows altered mucopolysaccharide distribution, elastin and collagen, and reduced vascular lumen [27]. Non-enzymatic glycosylation and accumulation of collagen have been implicated in the pathogenesis [28]. Disordered glycosaminoglycan (GAG) metabolism is also a feature; skin biopsies from patients with severe limited joint mobility show pronounced hyaluronan expression in the epidermis and diminished expression in the dermis and basement membrane compared with skin from controls without diabetes and controls with diabetes but without limited joint mobility [29]. In addition, increased urinary GAG excretion has been reported in patients with limited joint mobility [30]. Reduced circulating insulin-like growth factor I (IGF-I) is associated with

**Figure 48.1** Limited joint mobility with flexion contractures affecting the finger proximal interphalangeal joints. Courtesy of Dr. Tim Cundy.

limited joint mobility, implicating the growth hormone–IGF-I axis in the pathogenesis of this complication [31]. Microvascular abnormalities also contribute to disease, with reports of disordered palmar microvascular flow in response to thermal challenge [32].

The mainstay of therapy remains obtaining excellent glycemic control, and reduced prevalence of this disorder has been reported with such interventions [12,33]. Physiotherapy, particularly hand therapy, may be of benefit to improve joint contractures and function. Corticosteroid injection of flexor tendon sheaths has been reported to lead to resolution of finger contractures in almost two-thirds of cases related to limited joint mobility, and should also be considered [34].

**Frozen shoulder**

This disorder is characterized by shoulder pain, stiffness and severely restricted range of motion in all planes [35]. Three phases of the disorder are well-recognized: first, the painful freezing stage with associated nocturnal pain (lasting 4–8 months), followed by the adhesive phase with improvement in pain but

severely restricted range of motion (lasting 8–24 months), and finally the resolution phase [36]. The mean time to resolution is 30 months [36]. Plain radiographs of the shoulder are typically normal. Although the condition is usually self-limiting, some patients have persistent shoulder pain and restricted range of motion many years after assessment [37,38].

Imaging and histologic studies have demonstrated that the pathologic features of frozen shoulder are thickening of the capsule and synovium with contracted joint volume. Affected tissue is characterized by dense type I and type III collagen deposition with proliferating fibroblasts and a chronic inflammatory infiltrate comprising T cells, macrophages and mast cells [39,40]. Disordered collagen synthesis and vascular endothelial growth factor 1 (VEGF-1) mediated angiogenesis have also been implicated [41,42].

Treatment is tailored to the stage of the disorder [35]. In the painful freezing stage, analgesics, including NSAIDs if tolerated, are indicated. Early use of intra-articular corticosteroids is associated with improved outcomes, and physiotherapy with exercise within the limits of pain is of greater benefit than more intensive physiotherapy such as stretching and mobilization [43,44]. Although oral corticosteroids provide short-term relief in the painful freezing stage, they are not routinely recommended because of lack of long-term benefit and risk of adverse events [45]. In the adhesive phase, more intensive physiotherapy is indicated. For those who fail to respond to physiotherapy and have persistent shoulder restriction, interventions such as radiographic-guided hydrodilatation, manipulation under anesthesia or arthroscopic release should be considered [46,47].

Diabetes is a major risk factor for frozen shoulder. The prevalence of frozen shoulder is 11–19% of patients with diabetes, compared with 2–3% of age-matched controls [16,19,48,49]. Patients with diabetes are also more likely to have bilateral disease. Key risk factors for frozen shoulder in patients with diabetes are older age, duration of diabetes, previous myocardial infarction, retinopathy and peripheral neuropathy [50]. The presence of other fibroproliferative musculoskeletal disorders such as limited joint mobility and Dupuytren contracture is strongly associated with frozen shoulder in patients with diabetes [50]. Furthermore, frozen shoulder in patients with diabetes is more difficult to treat because of persistent disease and worse outcomes following surgical interventions [47,51,52].

### **Dupuytren contracture**

Dupuytren contracture is a fibroproliferative disorder of the palmar fascia leading to formation of palmar nodules, development of a palmar aponeurosis cord with tethering of the overlying skin and eventually flexion contractures, particularly affecting the ring and little fingers [53]. Elderly men of northern European ancestry are most frequently affected. Disordered fibroblast and myofibroblast function has been described, with deposition of type III collagen, potentially mediated by growth factors such as transforming growth factor  $\beta$  (TGF- $\beta$ ) and basic fibroblast growth factor [54–56].

Surgical treatment is the mainstay of therapy, although non-surgical options, particularly local injection of collagenase, are promising [57]. Splinting and intralesional corticosteroids may be considered, but are frequently ineffective [58]. Surgical referral should be considered in the presence of contracture. Various surgical approaches are available, including fasciotomy (division of the affected palmar fascia) or fasciectomy (excision of the affected palmar fascia). Percutaneous needle fasciotomy is a minimally invasive technique with good short-term outcomes, although recurrence is a frequent problem [59,60].

Risk factors for Dupuytren contracture include advanced age, male sex, cigarette smoking, manual labor and alcohol consumption. Diabetes is also an important risk factor for Dupuytren contracture, which is present in up to 26% of patients with diabetes [19,20,61]. Age and disease duration are the major risk factors for development of Dupuytren contracture in patients with diabetes [62]. Dupuytren contractures are also associated with microvascular complications in T1DM and macroalbuminuria in T2DM [63,64]. Rapidly progressive contractures are less frequently seen in patients with diabetes [62]. Coexistent fibroproliferative disease is frequent in patients with diabetes-associated Dupuytren contracture, with higher rates of limited joint mobility [64].

### **Stenosing tenosynovitis (trigger finger)**

Trigger finger is “a condition in which the flexor tendon is prohibited from gliding through the tendon sheath because of thickening of the synovial sheath over the tendon” [65]. This disorder most frequently affects the ring finger, but can also affect the other fingers and the thumb. The patient may report a clicking sensation when moving the finger, discomfort over the palm or overt triggering when the finger is locked in flexion [66]. Nodular or diffuse flexor tendon sheath swelling may be palpable.

The syndrome occurs as a result of a discrepancy between the flexor tendon and its sheath in the A1 pulley at the level of the metacarpal head [66]. The pulley becomes thickened with increased extracellular matrix and fibrocartilage metaplasia [67]. These pathologic changes may be induced by repetitive trauma.

Corticosteroid injection into the tendon sheath is an effective therapy for the majority of patients, particularly in the presence of nodular disease. For patients with nodular disease of less than 6 months' duration, local injection has a reported success rate of 90% [68]. Splinting and hand therapy are useful adjuncts to local injection. If conservative therapy fails, release using a percutaneous needle approach or open surgery is indicated [69].

Patients with diabetes are at higher risk of trigger finger, with a lifetime risk of 10% compared to 2.6% of the general population [66]. Patient age, diabetes duration and presence of microvascular complications are associated with increased risk of trigger finger in diabetes [62,70]. Outcomes are typically worse when trigger finger is associated with diabetes, with lower responses to corticosteroid injection and greater need for surgery [71–73]. Furthermore, T1DM is associated with higher prevalence of disease, more affected digits, greater need for surgery and higher risk of recurrence [62,71,73].

### Carpal tunnel syndrome

Carpal tunnel syndrome is a common compressive neuropathy affecting the median nerve as it traverses with the flexor tendons through the carpal tunnel, an anatomical space comprised of the carpal bones and the transverse carpal ligament [74]. The most common histologic appearance is non-inflammatory tenosynovial fibrosis, with increased fibroblast number and type III collagen deposition, most likely mediated by TGF- $\beta$  [75]. Compression within the carpal tunnel leads to disordered microvascular supply of the nerve, causing demyelination and axonal degeneration. The typical presentation is hand paresthesia, particularly affecting the thumb, index finger and middle finger. Paresthesia is often more frequent at night, and may wake the patient from sleep. Wrist and hand pain may also occur, and patients frequently report hand clumsiness.

Clinical examination may be normal, but in the presence of severe and prolonged disease there may be features of median nerve denervation, including thenar wasting, weakness of thumb abduction and sensory loss over the median nerve distribution. Provocative tests including Phalen and Tinel tests may be positive, and if present have relatively high specificity for carpal tunnel syndrome. The Phalen test is positive if paresthesia in the median nerve distribution is reported following flexion of the wrist at 90° for 60 seconds. The Tinel test is positive if paresthesia is reported after tapping the volar wrist over the carpal tunnel. The diagnosis is confirmed by nerve conduction testing, with the typical findings of prolonged latencies and delayed conduction velocities affecting the median nerve across the wrist [76].

Treatment consists of maintaining the wrist in a neutral position using a removable wrist splint. Splinting is particularly useful for nocturnal symptoms, and may be sufficient to treat mild disease [77]. Although oral corticosteroids have short-term efficacy, side effects are usually unacceptable [78]. Local corticosteroid injection provides good short-term relief [79]. Surgical release under local anesthesia is a well-tolerated and effective therapy, which should be considered in patients who have failed conservative therapy or have severe symptoms and signs of nerve compression [80]. Open release and endoscopic approaches have similar clinical outcomes [81].

Carpal tunnel syndrome may be caused by a number of factors including non-specific flexor tenosynovitis affecting the wrist, rheumatoid arthritis and other inflammatory synovial arthropathies, obesity, pregnancy and disordered wrist anatomy [74]. Diabetes is one of the most common metabolic disorders associated with carpal tunnel syndrome, being present in 16% of affected patients [82]. Most studies have shown increased risk of carpal tunnel syndrome in patients with both T1DM and T2DM [62,83,84]. A recent survey using clinical and neurophysiologic assessment reported a prevalence of carpal tunnel syndrome of 2% in a reference population without diabetes, 14% in patients with diabetes but no diabetic polyneuropathy, and 30% in patients with diabetic polyneuropathy [85]. Carpal tunnel syndrome is associated with duration of diabetes, and is more frequently present in patients with microvascular complications

such as retinopathy, nephropathy and polyneuropathy [62,86]. Carpal tunnel syndrome is also more common in patients with limited joint mobility, and it has been postulated that this disorder occurs at higher frequency in diabetes because of accelerated thickening and fibrosis of the flexor tendon sheaths within the carpal tunnel [18]. Glycosylation of collagen may also reduce compliance of connective tissue within the carpal tunnel [84]. In addition, the presence of existing microvascular disease may further increase the risk of endoneural ischemia as the median nerve travels through the carpal tunnel. Carpal tunnel syndrome may be more difficult to assess in patients with coexistent diabetic neuropathy, because of atypical presentation and neurophysiologic assessment [85,87]. Treatment options for patients with diabetes and carpal tunnel syndrome are similar to those for patients without diabetes, and responses to surgery are usually good [88,89]. One study reported positive results in symptoms scores and neurophysiologic testing using local insulin injections in women with T2DM and carpal tunnel syndrome, in combination with corticosteroid injection [90].

### Disorders of joints

#### Charcot joint

Charcot joint is a destructive arthropathy, most commonly affecting patients with diabetes in the presence of severe peripheral neuropathy. This disorder affects 0.1–0.4% of patients with diabetes and may lead to severe foot deformity and disability, ulceration and limb amputation [91].

Several stages of disease are described [92,93]. The developmental stage presents as acute inflammation with swelling, warmth and erythema of the foot. Pain may be a feature, despite the presence of peripheral sensory neuropathy. Peripheral pulses are usually easily palpable. Gradually worsening deformity occurs, with bone resorption, fracture and dislocation, leading to instability of the foot and the classic rocker-bottom dislocation of the midfoot. Plain radiographs may appear normal early in the acute phase of disease (Stage 0), but magnetic resonance imaging (MRI) scans show florid bone marrow edema, subchondral cysts and microfractures, and bone scintiscan shows increased uptake on the bony phase [93]. As deformity develops, radiographs show severe osteolysis, bone fragmentation and disordered architecture (Stage 1). In the coalescence phase (Stage 2), hyperemia resolves, swelling reduces and skin temperature normalizes. Bone debris is resorbed and bone sclerosis may occur. The reconstructive stage (Stage 3) is characterized by remodeling of bone, ankylosis and proliferation of bone, and formation of a stable foot. The acute phase (Stages 0 and 1) typically lasts 2–6 months, and the reparative phase (Stages 2 and 3) lasts up to 24 months. During both the acute and the reparative phases of disease, bony deformity may lead to abnormal load bearing, with ulceration of overlying skin and secondary osteomyelitis.

Five separate patterns of foot involvement are identified in patients with diabetes [94]: I, affecting the forefoot with osteolysis of the MTP and IP joints of the feet, leading to the “sucked candy” appearance on plain radiography; II, affecting the tarsometatarsal

**Figure 48.2** Plain radiograph of Charcot foot. Note the osteolysis, bone fragments, subluxation and fracture affecting the tarsometatarsal joints of the foot. Courtesy of Dr. Tim Cundy.

(Lisfranc) joint leading to instability, subluxation and fracture (Figure 48.2); III, dislocation and fracture affecting the midtarsal and naviculocuneiform joints; IV, affecting the ankle and subtalar joints, often with severe osteolysis; V, affecting the calcaneus. The most common patterns are II and III, and combinations of patterns may be present. Bilateral disease is present in one-quarter of patients. Rarely, other joints such as the knees, elbows and shoulders are affected.

The etiology of the disease remains controversial [95]. Minor trauma frequently precipitates onset of disease, and may lead to subclinical bone injury that triggers an aberrant inflammatory response [96]. It is likely that disordered weight-bearing in joints affected by peripheral neuropathy leads to repetitive injury and instability (the neurotraumatic hypothesis). Additionally, autonomic dysfunction causing vasodilatation, arteriovenous shunting and hyperemic bone resorption has been implicated (the neurovascular hypothesis). Development of osteopenia and osteolysis increases risk of fractures in the presence of abnormal load-bearing with a cycle of joint instability and fracture development, causing further abnormal load-bearing [97]. Recent work has focused on the role of local inflammation in disease pathogenesis. Advanced imaging and histologic analysis have demonstrated that inflammation of synovium and bone is evident in Charcot joint, and is characterized by increased expression of the pro-inflammatory cytokines tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and interleukin 1 [98–101]. Large numbers of osteoclasts are present within affected bone, and patients with Charcot joint have increased ability to form peripheral blood derived osteoclasts *in vitro* compared with diabetic and non-diabetic controls [101,102]. Markers of bone resorption are increased in patients with acute Charcot joint [103]. Interestingly, acute phase markers are not significantly elevated, indicating an apparent dissociation between local and systemic inflammatory disease [104]. These

data implicate receptor activator of nuclear factor  $\kappa$ B ligand (RANKL) mediated osteoclastogenesis, driven locally by pro-inflammatory cytokines, and provide a rationale for the use of agents that target the osteoclast in treatment of the disease.

Management of Charcot joint depends on the stage of disease. Treatment during the acute phase consists of immobilization which reduces inflammation, prevents abnormal load-bearing and stabilizes the foot in a position of least deformity. The standard immobilization method during the acute phase is a non-weightbearing total contact cast. This treatment requires close monitoring and regular adjustment, and should be maintained until swelling and temperature normalize, and radiographs show no further bony destruction [105]. Some recent uncontrolled reports have indicated that use of a weightbearing total contact cast may be an acceptable alternative to the non-weightbearing option, but controlled trials are not yet available [106,107].

The recognition that the acute phase of Charcot joint is associated with excessive osteoclast activity has led to the testing of agents targeting bone turnover for treatment of this condition. Two randomized controlled trials of bisphosphonates have been reported, and both show efficacy. A single intravenous infusion of 90 mg pamidronate in a study of 39 patients with acute Charcot joint led to significant improvements in symptoms and bone turnover markers [108]. In a study of 20 patients with acute Charcot joint, weekly oral administration of 70 mg alendronate for 6 months was associated with significant improvements in pain scores, bone turnover markers and foot bone density [109]. A randomized trial of intranasal calcitonin demonstrated efficacy with respect to bone turnover markers, but no differences in clinical variables were reported [110]. The efficacy of TNF-inhibitors and other antiresorptive agents such as the RANKL inhibitor denosumab has not yet been studied in Charcot joint, although the potential use of these agents has been recently highlighted [96].

Surgery is generally not considered first-line therapy, although one study has reported good surgical outcomes following débridement, open reduction and internal fixation with autologous bone grafting in the acute phase of disease [111]. In general, surgical management is currently recommended for patients in the reparative (rather than the acute) phase of disease, and particularly for patients with deformities associated with chronic foot ulcers and joint instability. Various surgical approaches to arthrodesis may be used, including open reduction with both internal and external fixation, depending on the presence of local infection and other anatomic variables [112]. Other surgery includes exostotomy, osteotomy, intramedullary rodding and amputation. Infection, non-union and triggering of an acute Charcot reaction are important postoperative complications, and careful postoperative management is essential.

Outcomes in patients with Charcot foot are frequently poor. A recent analysis of 115 patients reported that non-operative management was associated with a 2.7% annual rate of amputation, a 23% risk of requiring bracing for more than 18 months and a 49% risk of recurrent ulceration. The presence of open ulcers at

**Figure 48.3** Chronic tophaceous gout of the hands in a patient with type 2 diabetes.

initial presentation or chronically recurrent ulcers is associated with increased risk for amputation [113].

### Gout

Gout is an inflammatory arthritis caused by intra-articular deposition of monosodium urate (MSU) crystals [114]. This disorder is the most common form of inflammatory arthritis affecting men, and affects 1–2% of the Caucasian adult population [115]. In early disease, gout presents as recurrent episodes of self-limiting acute inflammatory attacks (“flares”) of arthritis. These attacks most often affect the first MTP joint, midfoot and ankle. In the presence of prolonged hyperuricemia, some patients develop recurrent polyarticular attacks, chronic tophaceous disease and erosive arthritis (Figure 48.3).

The key risk factors for gout are hyperuricemia, male sex, chronic renal impairment, hypertension, obesity, diuretic use, coronary heart disease, and seafood, meat and alcohol intake [116–118]. The relationship between gout and metabolic syndrome is well-recognized. Serum urate concentrations and gout are strongly associated with abdominal adiposity, and have been shown to predict the development of T2DM [119–121]. Patients with gout have high rates of the metabolic syndrome and T2DM compared to individuals without gout [122]. Promotion of renal tubular reabsorption of uric acid by insulin is thought to mediate this relationship [123]. Recent identification of the glucose and fructose transporter SLC2A9 as a key regulator of serum urate concentrations suggests a further etiologic link between hyperuricemia and hyperglycemia [124]. A recent study reported a prevalence of gout of 22% in patients with T2DM treated in secondary care [125]. Key risk factors for gout in this population were male sex, renal impairment and diuretic use. Fewer than half of the patients with gout and diabetes in this study were pre-

scribed urate-lowering therapy, and only 8% had a serum urate of  $<0.36$  mmol/L. Interestingly, severe hyperglycemia may reduce urate concentrations, as glycosuria has a uricosuric effect. Thus, as glycemic control improves in patients initiating treatment for diabetes, there is a potential risk of worsening gout attacks [126].

Options for treatment of acute gout flares include NSAIDs, corticosteroids and/or colchicine [127]. Long-term urate-lowering therapy is indicated for patients with gout who have recurrent flares, gouty arthropathy, tophi or radiographic damage. Serum urate lowering to a concentration of  $<0.36$  mmol/L (6 mg/dL) is needed to dissolve MSU crystals, prevent flares and achieve tophus regression. Allopurinol is the mainstay of urate-lowering therapy, but may be ineffective at recommended doses. If the serum urate target is not achieved with allopurinol alone, further options include dose escalation of allopurinol, addition of a uricosuric agent such as probenecid or benzbromarone, or consideration of the new xanthine oxidase inhibitor febuxostat [128]. Initiation of urate-lowering therapy is frequently associated with exacerbation of gout flares; this side effect can be avoided by commencement of urate-lowering therapy once the acute flare has resolved, gradual introduction of the urate-lowering drug, and co-prescription of low dose colchicine.

The presence of coexistent gout has several implications for individuals with T2DM. Poorly controlled gout may hinder attempts at exercise and weight loss. In addition to the dietary restrictions required for glycemic control, these patients also need to avoid alcohol and purine-rich foods. Diuretic therapy may exacerbate hyperuricemia and should be avoided in patients with gout unless absolutely required. Drugs such as losartan and fenofibrate have weak urate-lowering effects and may be of particular benefit in patients with diabetes and gout if antihypertensive or lipid-lowering therapy is required [129,130].

**Osteoarthritis**

Increased load-bearing of articular cartilage is an important risk factor for development of osteoarthritis, and a strong positive relationship has been reported between obesity and the risk of developing osteoarthritis [131–134]. Although some studies have reported an association between T2DM and osteoarthritis, most have not adequately controlled for body mass index (BMI). In most (but not all) studies that have adjusted for BMI, T2DM has not been shown to be an independent risk factor for development of osteoarthritis [131,133,135,136]. Overall, current data indicate that increased BMI, rather than T2DM, is a risk factor for development of osteoarthritis.

**Rheumatoid arthritis**

Rheumatoid arthritis and T1DM share several genetic associations such as *PTPN22*, *HLA-DR9*, the chromosome 4q27 region, the *IDDM5* region and the *IDDM8* region [137–141]. Furthermore, there is evidence of familial clustering of these disorders; 2.8% of first-degree relatives of probands with rheumatoid arthritis have T1DM, compared with 0.35% of the general population [142]. Despite these observations, there is little evidence that the prevalence of rheumatoid arthritis is increased in patients with T1DM [143].

**Skeletal disease in diabetes****Diffuse idiopathic skeletal hyperostosis**

Diffuse idiopathic skeletal hyperostosis (DISH) is a disorder characterized by increased bone formation, particularly at the entheses (the insertions of ligaments and tendons into bone) [144]. Ossification of the anterior longitudinal ligament of the spine occurs, most commonly in the thoracic spine (Figure 48.4). Extraspinal ossification may also be identified. The prevalence has been reported to be as high as 15% in women and 25% in men over the age of 50 [145].

Patients may present with back pain and stiffness, although it remains controversial whether DISH is associated with increased

back pain, and the disorder is frequently detected as an incidental finding on chest radiographs [146,147]. Rare complications such as dysphagia, vocal cord paralysis, compression of the inferior vena cava and neurologic compression syndromes have been described in patients with florid hyperostosis [148]. Spinal fracture may occur after relatively minor injury and cause significant neurologic compromise [149]. The diagnosis is made radiographically, according to the Resnick criteria, which in brief are:

- 1 Presence of flowing calcification and ossification along the anterolateral aspects of at least four contiguous vertebral bodies;
- 2 Relative preservation of intervertebral disc height and the absence of extensive degenerative disc disease;
- 3 Absence of features of spondyloarthropathy [150].

There have been no controlled trials of therapies in patients with DISH. For symptomatic patients, analgesics and physiotherapy are standard therapy. A small uncontrolled study of patients reported that a physiotherapy program focusing on spinal mobility, stretching and strengthening had some benefits in improving lumbar spinal mobility after 24 weeks, with no significant benefits in pain or functional outcomes [151]. Surgery is rarely required, but may be indicated for compressive syndromes caused by florid hyperostosis.

Most case series have identified both obesity and T2DM as risk factors for DISH [152–154]. The presence of additional metabolic disorders such as dyslipidemia or hyperuricemia further increases the risk of DISH associated with diabetes [155]. Patients with DISH have higher rates of hyperglycemia and higher circulating insulin levels particularly after a glucose load [153,156]. It is likely that obesity has direct biomechanical effects, because of increased load at the entheses. Additionally, systemic factors may contribute to the development of DISH, as patients with this disorder have evidence of increased bone mineral density (BMD) elsewhere in the skeleton [157,158]. Insulin, growth hormone and IGF-I have been implicated in the pathogenesis of DISH, and high circulating concentrations of these hormones may contrib-

**Figure 48.4** Plain radiographs of diffuse idiopathic skeletal hyperostosis (DISH) affecting the thoracic spine. Courtesy of Dr. Anthony Doyle.

ute to the development of hyperostosis [156,159,160]. High expression of nuclear factor  $\kappa$ B (NF $\kappa$ B), platelet-derived growth factor BB and TGF- $\beta$ 1 has also been reported in affected tissue in patients with DISH, implicating these factors in osteoblast activation and new bone formation [161].

## Osteoporosis and fractures

### Background

Fragility fractures are a major cause of morbidity and public health expenditure. The most devastating fracture, that of the proximal femur, is associated with a 20% risk of dying within 6 months of the event, and a substantial risk of loss of independence [162]. Individual fractures are associated with considerable periods of disability and loss of productivity [163]. The number of fractures occurring annually is rising steadily, as a result both of aging of the world population, and of an age-specific increase in some countries [162].

Important risk factors for fragility fracture include low BMD, older age, female gender, light body weight, previous fracture, cigarette smoking and glucocorticoid use [162]. Dual-energy X-ray absorptiometry (DEXA) is currently the preferred modality for measurement of BMD. Recently, absolute fracture risk algorithms have been developed, using these risk factors, to provide 5–10 year estimates of the risk of any osteoporotic fracture, or of hip fracture [164,165].

Insight into the mechanism(s) by which bone loss occurs can be gained by measurement of biochemical markers of bone turnover, which reflect either osteoblast function/bone formation or osteoclast function/bone resorption. At present, bone markers are important tools in evaluating the pathogenesis and treatment of osteoporosis in clinical studies, but their utility in the management of individual patients is limited by assay variability, low predictive value for skeletal events and high cost [166].

In recent years, evidence has accrued that suggests the risk of fragility fractures is increased in both types of diabetes, albeit by different mechanisms. In addition, attention has focused recently on the skeletal effects of treatments for T2DM, in particular the thiazolidinediones.

### Fracture epidemiology in diabetes

#### Type 1 diabetes

Two recent meta-analyses of observational studies have examined the relationship between T1DM and risk of fracture [167,168]. Hip fracture is the only fracture type evaluable in these analyses, because of the paucity of studies of other fracture types. Both meta-analyses demonstrated a substantially increased (six- to ninefold) relative risk of hip fracture in T1DM (Figure 48.5) [167,168]. Studies of other fracture types in T1DM are few in number and many include only a small number of events, but they generally support the notion that non-vertebral fracture risk is increased, with relative risk estimates of 1.3–3 for any fracture [169,170] and of 2.4 for foot fractures [171]. The only study to date to assess vertebral fracture risk in T1DM found no increase [172].

#### Type 2 diabetes

Until quite recently, little information was available as to the skeletal consequences of T2DM; however, recent epidemiologic studies have suggested that fracture risk is increased in that disease. Meta-analyses of these observational studies report increased risk of all fractures, and also those of the hip, forearm and foot (Figure 48.5) [167,168]. Relative risk estimates for hip fracture are lower in T2DM (1.4–1.7) than in T1DM, and estimates of fracture risk at other sites in T2DM range 1.2–1.4. Since the meta-analyses were published, the Women's Health Initiative (WHI) Observational Study, which included >5000 postmenopausal women with T2DM, reported increased risks of any fracture and of fractures at several specific sites, including the hip, spine, foot and upper arm [173]. Risk estimates ranged 1.2–1.5 across the skeletal sites. The WHI study was one of the few with the capacity to evaluate vertebral fractures. Although there was an increased risk of spine fractures in the WHI study, it remains uncertain whether risk of this fracture type is higher in T2DM, as other studies have not found an association [174].

### Mechanisms of skeletal fragility in diabetes

Although fracture risk appears to be increased in both T1DM and T2DM, it is likely that there are important differences in the mechanisms by which skeletal fragility is increased in the two diseases (Table 48.2). At least two mechanisms underlie the increased skeletal fragility in T1DM. The majority of cross-sectional studies of T1DM have reported decreased BMD throughout the skeleton, although there is no consistent association between age of participants or duration of disease and magnitude of BMD deficit [175,176]. Interestingly, studies performed in children and young adults demonstrate lower than normal BMD at hip and spine at the time of diagnosis [177,178]. Taken together with the observations from longitudinal studies that BMD does not progressively decline in T1DM [179–182], and cross-sectional studies of middle-aged subjects with T1DM that report normal levels of markers of bone turnover [183–185], these data suggest that the observed deficit in BMD in T1DM occurs early in the course of the disease, and perhaps prior to its clinical presentation. It is likely that deficiency of insulin and other pancreatic  $\beta$ -cell hormones such as amylin and preptin, each of which has been implicated in skeletal homeostasis [186–189], contributes to the decreased BMD observed in T1DM. Recent data also implicate low levels of IGF-I in the pathogenesis of cortical bone loss in T1DM [190]. Insulin deficiency alone is probably not sufficient to explain the lower BMD, because insulin therapy does not normalize BMD. Lower body weight may also be a factor, as there is a strong positive relationship between weight and BMD [191,192].

The magnitude of the reduction in BMD (3–8%) is probably not sufficient to explain the higher rates of fracture in T1DM [176]. A second mechanism by which skeletal fragility is likely to be increased is via an increased propensity to falls as a result of disease complications. Neuropathy, visual impairment, cerebrovascular disease and hypoglycemia in particular are likely to increase falls risk. In the only study to date that has evaluated this

**Figure 48.5** Association of (a) type 1 diabetes and (b) type 2 diabetes with hip fracture risk in meta-analyses of case–control and cohort studies. Each square shows the study-specific relative risk (RR) estimate (the size of the square reflects the study-specific statistical weight, i.e. the inverse of the variance), and the horizontal line shows the related 95% confidence interval (CI). The diamond shows the summary RR estimate, and its width represents the corresponding 95% CI. Reproduced from Janghorbani *et al.* [168], with permission from Oxford University Press.

possibility, substantially higher risks of hip fracture were observed in T1DM with a range of disease complications than in those without complications [193]. Neuropathy may also impact adversely on BMD in the distal limbs, as patients with T1DM and neuropathy have lower cortical bone mass in the distal limbs than

those without neuropathy [194]. Animal studies suggest that interruption of nerve supply to bone decreases regional bone mass independent of changes in mechanical loading [195]. The presence of regional osteopenia likely contributes to the increased risk of distal limb and foot fractures in T1DM.

**Table 48.2** Mechanisms of increased skeletal fragility in diabetes.

	<p><b>Disease treatment</b> Thiazolidinediones</p>

BMD, bone mineral density; IGF, insulin-like growth factor.

The mechanism(s) by which skeletal fragility is increased in T2DM is uncertain (Table 48.2). The observation that fracture risk is increased is in some ways surprising, because the higher body weight that commonly accompanies T2DM might be expected to preserve bone mass and protect patients from adverse skeletal outcomes. In fact, BMD in the axial skeleton is higher in subjects with T2DM than in subjects without diabetes [167,173,174]; however, BMD remains an important risk factor for fracture in T2DM, because incident fractures occur more frequently in subjects with T2DM and decreased BMD than in those with normal BMD [196]. The limited available evidence suggests that T2DM patients with neuropathy and nephropathy have lower BMD than those free of these complications [167,197].

As in T1DM, it is likely that complications of T2DM, such as neuropathy, vascular disease and impaired vision, increase the risk of falling, and thereby of fracture. In the Study of Osteoporotic Fractures, a prospective study of fracture epidemiology in older American women, participants with T2DM had a 22% higher risk of non-spine fractures than participants without diabetes [174]. Participants with T2DM who were treated with insulin had both a higher prevalence of disease complications and a higher risk of fracture than those with T2DM who were not treated with insulin. In the Health ABC study, a prospective study of older (>70 years) American men and women, there were strikingly higher prevalences of neuropathy, cerebrovascular disease and falls in participants with T2DM who developed a fracture than in those with T2DM who did not fracture [196]. Many risk factors for falls, including use of medications associated with increased falls risk, are more commonly present in those with T2DM than in the population without diabetes [198]. Low-impact falls are more frequent in insulin-treated patients with diabetes than healthy controls [199]. Curiously, adjusting for diabetes complications

**Figure 48.6** Fracture rates, captured as adverse events, in randomized controlled trials of thiazolidinediones (TZDs). \*\*,  $P < 0.01$  vs comparator; Φ, significantly higher than comparators. Reproduced from Grey [208], with permission from Wiley-Blackwell Publishing Ltd.

and/or falls risk did not attenuate the increased fracture risks observed in T2DM [174,196].

It is possible that aspects of bone strength and/or quality that are not captured by DEXA assessment are abnormal in patients with either type of diabetes, and contribute to increased bone fragility. At present, there is no validated methodology for assessing these aspects of bone quality. Potentially relevant to this hypothesis is a growing body of evidence that advanced glycation end-products (AGE), products of non-enzymatic glycation, are present in greater amounts in the skeletons of diabetic animals than those of non-diabetic animals [200]. The glycation of matrix proteins in bone may alter biomechanical properties in such a way as to decrease bone strength [201,202]. *In vitro* studies suggest that AGEs inhibit differentiation of osteoblasts [200,203] and increase differentiation of osteoclasts [204], thereby potentially altering bone remodeling and/or strength in a detrimental fashion. There may be AGE-specific effects on bone remodeling, as pentosidine decreases osteoclast development *in vitro* [205]; however, mice deficient in the receptor for AGE exhibit increased bone mass and decreased osteoclast function, suggesting that the overall effect of increased AGE signaling in bone is likely to be detrimental [206].

Finally, in T2DM, there is clear evidence that treatment with either of the currently available thiazolidinediones (TZDs), rosiglitazone and pioglitazone, increases fracture risk, at least in women [207,208]. Data collected as adverse events during the conduct of randomized controlled trials of each TZD in middle-aged populations of those with T2DM demonstrated a twofold increase in risk of distal limb fractures in women, although not in men (Figure 48.6) [209–211]. Observational data from an older cohort of patients with T2DM suggest that fracture risk is also increased in men exposed to TZDs, and that the incidence of “classic” osteoporotic fractures (hip, forearm, humerus) is also higher in TZD users [212].

**Figure 48.7** Mechanisms by which peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) regulates bone metabolism. Within the bone microenvironment [black arrows], activation of PPAR $\gamma$  signaling promotes differentiation of mesenchymal stem cells (MSC) into adipocytes (A) at the expense of osteoblasts (Ob), decreases stromal cell production of IGF-I, and promotes differentiation of osteoclast precursors (OcP) into mature bone-resorbing osteoclasts (Oc). The net effect is to decrease bone formation and increase bone resorption. Activation of PPAR $\gamma$  signaling at extraskeletal sites such as adipose tissue and the liver, and the ensuing effects of insulin sensitization on the  $\beta$ -cells of the pancreas [regular arrows] may indirectly impact on the skeleton [interrupted arrows] by altering circulating levels of several hormones and cytokines, as indicated. RANK, receptor activator of NF $\kappa$ B; RANKL, receptor activator of NF $\kappa$ B ligand. Reproduced from Grey [208], with permission from Wiley-Blackwell Publishing Ltd.

The mechanisms underlying the adverse skeletal effects of TZDs are complex, and likely to involve both direct and indirect pathways (Figure 48.7). Of primary importance is the effect of the TZDs to inhibit bone formation directly, by diverting mesenchymal stem cell precursors from the osteoblast to the adipocyte lineage [207]. A substantial body of preclinical studies in rodents, and data accruing from studies in humans, demonstrates that TZDs decrease bone formation and BMD *in vivo* [207]. In addition, TZDs increase or maintain bone resorption at inappropriately elevated levels, via direct actions on osteoclast development [207,213]. Indirect actions of TZDs that potentially contribute to their detrimental skeletal effects include decreasing systemic and skeletal production of IGF-I, modulating production of skeletally active adipokines and decreasing levels of pancreatic  $\beta$ -cell hormones with known skeletal activity [208].

The skeletal toxicity of TZDs has prompted interest in the effects of other oral hypoglycemic agents on bone health. At present, the available data suggest that metformin and sulfonylureas are neutral in regard to the skeleton [214].

#### *Investigation and management of osteoporosis in diabetes*

Diabetes of either type should be regarded as a risk factor for fragility fracture, and included in clinical fracture risk assessment, along with recognized risk factors such as age, gender, body weight, previous fracture, cigarette smoking, glucocorticoid use and BMD. Recently developed fracture risk algorithms may be helpful in determining an individual patient's short to medium-term absolute fracture risk [164,165]. Although BMD is on average increased in T2DM, measurement of BMD in patients with T2DM is still helpful in defining that person's fracture risk. Prescription of TZDs to patients with T2DM who are found to be at high risk of fracture should be avoided unless there are

compelling reasons to do so. Minimizing falls risk is an important component of skeletal management in diabetes – this can be achieved by targeting both macrovascular and microvascular disease complications, minimizing the risk of hypoglycemia, optimizing visual acuity and minimizing use of other medications known to be associated with falls. Although there are no data from interventional studies on the effects of pharmacologic treatments of osteoporosis in diabetes, it is reasonable to assume that agents known to prevent fractures in non-diabetic osteoporotic populations, such as bisphosphonates, will also be effective in those with diabetes [162].

#### **Fracture healing in diabetes**

A growing body of evidence suggests that fracture healing is abnormal in those with diabetes. In rat models of T1DM, the mechanical and structural properties of the healing bone are inferior in the diabetic rats when compared with control animals, findings that are accompanied by evidence of both decreased callus size and collagen content [215,216]. Interventional studies demonstrate that therapy with insulin to achieve normoglycemia is associated with fracture healing that is indistinguishable from that observed in non-diabetic animals [217,218]. Subsequently, administration of insulin at the site of skeletal injury was also shown to promote fracture healing, without altering serum glucose, implying a role for insulin in directly mediating bone repair [219]. Few data are available from human studies, but increased rates of fracture non-union in both T1DM and T2DM have been reported [220], as have higher than expected rates of serious complications in patients with diabetes and open ankle fractures [221]. Further investigation of the influence of diabetes and its treatment on fracture repair in humans is needed.
