## Psychologic Factors and Diabetes

**Christopher M. Ryan**

University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

### Keypoints

- Both type 1 (T1DM) and type 2 diabetes mellitus (T2DM) can affect the psychologic and neuropsychologic status of children and adults. In most instances, these effects are modest in magnitude and are most likely to be associated with certain events that occur during the course of diabetes or its management.
- Children show remarkable psychologic resilience to the diagnosis of diabetes. About one-third report some psychologic distress shortly after diagnosis but this generally subsides within 6 months. This “adjustment disorder” is characterized by increased depressive symptomatology, more anxiety, social withdrawal and sleep disturbances. A similar adjustment reaction is often seen in parents, particularly mothers, of newly diagnosed children. Diagnoses of post-traumatic stress disorder are also more common in parents, occurring at rates comparable with that reported in children diagnosed with cancer. Increased rates of depression are also found in adults newly diagnosed with T1DM, whereas diagnosis of T2DM does not appear to increase the risk of depression unless accompanied by multiple medical co-morbidities.
- During the first 5–10 years of their diabetes, most children and adolescents show adequate psychologic functioning; however, after 10 years of diabetes, their rates of anxiety, depression or eating disorders are markedly increased, with as many as one-third of adolescents with diabetes meeting criteria for one or more psychiatric disorders. Adults with diabetes also show elevated rates of depression which are twice as high as those reported in the general population. At greatest risk are people who have been hospitalized, are older with multiple medical problems, have a history of past psychopathology or are female. Metabolic control is only weakly associated with the occurrence of a mood disorder.
- Macrovascular disease, chronic foot ulceration and proliferative retinopathy increase the risk of psychopathology, an understandable reaction to serious complications; however, lifetime psychiatric disorders such as depression may also increase the risk of later development of complications such as retinopathy. Recurrent diabetic ketoacidosis, particularly in females, is also predicted by poor psychologic functioning, and by high rates of family dysfunction.
- Phobic disorders are more common in adults with diabetes than in the general population. Fear of blood and injury may lead to less blood glucose self-monitoring and poorer control. Fear of hypoglycemia is common and may also lead to premature treatment as blood glucose levels begin to fall, resulting in persisting hyperglycemia.
- Quality of life for those with diabetes does not differ from patients with other chronic conditions, such as arthritis. Poor health-related quality of life is associated with biomedical complications, being female, physical inactivity, low income and recurrently hypoglycemia. Intensive diabetes management is not associated with a deterioration in quality of life.
- Interventions to reduce psychologic distress include individual psychotherapy or counseling, and group therapy; however, the efficacy of either – in terms of affecting mood or metabolic control – has not been studied extensively in clinical trials, but data from smaller studies suggests effects may be weak, at best. A promising technique for depressive symptoms is cognitive–behavior therapy, which teaches patients problem-solving strategies for stressful situations and “thinking away” distorted beliefs. Pharmacotherapy, including selective serotonin reuptake inhibitors and tricyclic antidepressants, has been found to reduce symptom severity but specific drugs may differentially influence glycated hemoglobin values.
- Cognitive dysfunction in diabetes is generally mild, but children diagnosed in the first 5 to 7 years of life have an elevated risk of manifesting clinically significant impairments in all cognitive domains. Those with a later onset of diabetes show modest effects, most evident on measures of intelligence, academic achievement and psychomotor efficiency. Deficits appear early in the course of the disease, and are evident within 2–3 years after diagnosis. Hypoglycemia was long considered to be the cause of this neurocognitive dysfunction but more recent research suggests that adverse effects on cognition may only occur when blood glucose levels are very low for an extended period of time. Although the etiology of neurocognitive changes in children remains poorly understood, a growing body of evidence implicates chronic hyperglycemia and, in particular, the development of microvascular and macrovascular complications.
- In adults with T1DM, neurocognitive deficits are quite modest and are most apparent on measures of intelligence, psychomotor speed and executive function. Older adults with T2DM also manifest marked reductions in memory function and, in both groups, the strongest

predictor of cognitive dysfunction is chronic hyperglycemia and the presence of biomedical complications, particularly retinopathy and peripheral neuropathy.

- Structural damage to the brain is also common in both children and adults with either T1DM or T2DM. Not only is there a reduction in cortical gray matter density, but white matter structures may be disrupted. Cerebral atrophy is often present, neural slowing is evident on electroencephalography and regional cerebral blood flow is altered.
- Diabetes management and health outcomes are influenced by reciprocal relationships between metabolic control and psychologic variables. The latter include enduring psychologic traits such as locus of control, coping style, temperament and transitory psychologic states

(stress, anxiety, depression). Diabetes is also strongly related to family functioning, especially in children and adolescents: low family conflict, good communication, cohesion and marital satisfaction relate to better diabetes control.

- Adherence or self-care behaviors (taking medicine, complying with diet, glucose monitoring, exercise regimens) are only weakly related to diabetic control, but this may reflect the inaccuracy of self-reported behavior. For those who are most seriously non-compliant, psychologic interventions include psychotherapy, family therapy and patient empowerment programs to improve goal-setting, problem-solving, coping, managing stress and self-motivation.
- A psychologist or other mental health care professional should be part of the diabetes care team.

---

## Introduction

Diabetes and psychology have long been linked. More than 50 years ago, the psychosomatic model of medical illness postulated that psychosocial factors could trigger or maintain various disorders, including diabetes. This notion was subsequently abandoned by most scientists, yet the person living with diabetes and managing this behaviorally complex condition may nevertheless identify numerous points where diabetes and psychology interact. This chapter examines three major points of intersection: psychologic reactions to the development of diabetes and the appearance of complications, the neuropsychologic or cognitive consequences of diabetes, and psychologic factors that influence, or are influenced by, the everyday management of diabetes.

---

## Psychologic impact of diabetes

Patients with diabetes ought to manifest significant psychologic distress, or so goes conventional clinical wisdom. After all, they have a disorder that shortens their lifespan, leads to debilitating biomedical complications such as blindness or neuropathy, and requires them to take complete daily responsibility for managing their health with drugs or insulin injections and careful monitoring of diet, exercise and blood glucose levels, for the remainder of their lives. Chronic illnesses like diabetes also mark individuals, particularly children, as different from their healthy peers, and burden families with demanding health care responsibilities that they may be unwilling or unable to meet. Given all of these factors, one should not be surprised to find that many people with diabetes, and their families, have elevated rates of emotional disturbances and behavioral problems.

### Psychologic distress shortly after diagnosis

#### Observations in children and their parents

Children and adults show remarkable psychologic resilience in response to a diagnosis of diabetes. In what may be the most

comprehensive prospective psychologic study of children with diabetes and their families, Kovacs *et al.* [1] assessed 95 children, 8–13 years of age, shortly after discharge from their initial hospitalization, and followed them for 6–10 years. Within 3 months of diagnosis, 36% of the children experienced sufficient psychologic distress to meet criteria for a diagnosable psychiatric disorder [2]. Most had “adjustment disorder,” defined as a transient reaction that exceeds the normal and expectable response to a stressor, develops within 3 months of onset of the stressor and lasts no more than 6 months. The occurrence of such a disorder signals that the child is beginning to come to terms with the diagnosis of diabetes, and can be considered to be a component of the “mourning process” that often accompanies the development of any chronic illness [3]. As one would expect with an adjustment disorder, recovery was rapid, with 93% showing complete remission of these psychiatric symptoms within 9 months. Other investigators, using different outcome measures, have also demonstrated rapid psychologic adaptation to the diagnosis of diabetes [4–6].

Parents of children newly diagnosed with diabetes also manifest psychologic responses that are analogous to an adjustment disorder. For mothers, the strain associated with caring for a school-aged child with diabetes elicited mild levels of depressive symptomatology, anxiety and generalized distress, but this dissipated within 6 months [7]. Less symptomatology was evident in fathers, both shortly after diagnosis and approximately 1 year later; however, if fathers do report experiencing high rates of emotional dysfunction in the first 2 years following their child’s diagnosis, their child is more likely to manifest poorer metabolic control and greater blood glucose variability during the first 5 years of diagnosis [8]. Greatly elevated rates of post-traumatic stress disorder (PTSD) have also been reported in a prospective study of parents evaluated at 6 weeks and 6 and 12 months after their child’s diagnosis. Depending on time point, 16–22% of mothers met DSM-IV criteria for a PTSD diagnosis, as did 8–14% of fathers [9]. These rates were significantly higher than those reported in the general population but are comparable with those seen in mothers of children diagnosed with cancer. The best predictor of PTSD severity at 12 months was PTSD severity at

6 months. Poorer disease outcomes, particularly episodes of hypoglycemia, were associated with an increased level of PTSD severity.

Elevated rates of worry and concern are also present in parents, but these differ by gender: 46% of mothers reported worry all or almost all of the time, whereas only 13% of the fathers reported similarly high levels of concern [10]. Mourning was the primary coping process engaged in by mothers, whose responses most commonly included feeling sad, worried and/or tired, and who manifested bouts of crying and irritability. As duration of illness increased, levels of psychologic distress, particularly depression, showed slight increments, with the greatest increases occurring in those mothers who were most distressed at the time of their child's diagnosis and in those mothers of higher socioeconomic status. The latter finding may reflect the possibility that these women were more knowledgeable about diabetes, and hence may have been more discouraged about its management and long-term outcomes. Despite the stresses and strains that the diagnosis of diabetes exerts on both the child and the family, there is little evidence of major family disruption in the first 2–3 years following diagnosis. Measures of parental perception of overall quality of family life as well as estimates of the quality of parents' marriage show essentially no change during that period [11].

### Diagnosis in adulthood

The onset of diabetes during adulthood ought to produce similar adjustment disorders within several months of diagnosis in both the patient as well as the spouse or other family member. A German sample of newly diagnosed, adult patients (aged 17–40 years of age) with type 1 diabetes mellitus (T1DM) had a rate of major depressive episodes that was twice that of a reference group drawn from a representative national population (5.8% vs 2.7%), although more careful analysis shows that these differences were statistically significant only for women with diabetes (9.3% vs 3.2% in reference group) [12]. There were no differences in rates of major depression between men with diabetes and the reference group (3.6% vs 2.2%), nor for other psychiatric disorders. Because this is a cross-sectional study, it is impossible to determine whether this is truly a "classic" depression or whether it is a transient adjustment disorder, as is typically seen in children and adolescents with diabetes. In contrast, several studies of adults with type 2 diabetes mellitus (T2DM) have found little psychologic morbidity in the first year following diagnosis. One smaller clinical study reported that of the 71 subjects studied, more than 50% expressed no emotional reaction to the diagnosis and felt that they could cope with diabetes [13]. Negative emotional reactions, along with feelings of being incapable of coping with this disorder, were expressed by only 26% of the sample, and this may reflect the fact that these individuals had significantly less social support than the others. A larger, more recent study assessing symptoms of depression, similarly found little evidence of a psychologic reaction in 824 patients newly diagnosed with T2DM [14]. Although there were marked gender differences, with women with diabetes reporting higher rates of significant

depressive symptomatology than men with diabetes (16.1% and 8.2%, respectively), those values were comparable to UK normative data for women and men (13% and 8%, respectively). Greater depressive symptomatology was associated with more medical co-morbidities: newly diagnosed patients with diabetes taking both lipid-lowering and antihypertensive medications reported more symptoms of depression than those on only one, or on no concurrent medication.

### Psychologic reactions emerging in the course of diabetes

#### Depressive symptomatology in children and adolescents

After resolution of their adjustment disorder, are children able to get on with their lives, or is there an increased likelihood of subsequent psychologic distress in the individual with diabetes? As duration of diabetes continues, it now appears that most children and adolescents with diabetes function well psychologically, although small increases may be evident in depressive symptomatology and internalizing behaviors, such as somatic complaints, social withdrawal, sleep disturbance and symptoms of depression and anxiety. In both school-aged [6,15,16] and pre-school children [17], this was evident after 2–3 years of diabetes, yet the magnitude of these changes was not so large as to be indicative of clinically significant psychopathology. Somewhat higher rates of externalizing, or aggressive, behaviors have also been reported, with this phenomenon especially pronounced in boys with diabetes [15], and strongly associated with consistently elevated blood glucose levels [18]. High levels of family conflict and the occurrence of multiple stressful life events appear to be particularly potent predictors of more aggressive behavior in children and adolescents with diabetes [19].

After 6 years of follow-up, Kovacs *et al.* [16] found trivially small increases in symptoms of depression for all subjects, and increased symptoms of anxiety for girls but not boys. Children who reported more difficulties in managing their diabetes also showed more symptoms of psychologic distress. Level of psychologic distress shortly after diabetes onset was the best predictor of symptomatology 6 years later, whereas the degree of metabolic control, as indexed by glycated hemoglobin (HbA<sub>1c</sub>) values, was not a viable predictor in this or in most other studies [20,21]. Neither age nor age at onset predicted increased psychologic distress in Kovacs *et al.*'s cohort, although others have found an association between developmental stage and emotional or behavioral problems in so far as adolescents manifested more problems than pre-adolescents [21].

Even after 10 years of diabetes, older adolescents and young adults with childhood onset of diabetes may report little psychologic distress, although they tend to have lower levels of self-esteem and express concerns about their sociability and their physical appearance [22]. What is remarkable, however, is that when patients are formally evaluated with structured psychiatric interviews to assess for clinically significant psychopathology over this extended time period, marked elevations are found in rates of psychiatric disorder. Not only were females more often affected

than males [23,24], but their risk of subsequently experiencing a recurrence of depression was nine times greater than males [25]. Kovacs *et al.* [1] reported that 40% of their sample had experienced at least one episode of a psychiatric disorder during the first 10 years of living with diabetes, and 26% had two different psychiatric disorders. Major depression was the most common diagnosis (26% of sample), followed by some form of anxiety disorder (20%). By comparison, similarly aged, subjects without diabetes drawn from the community had rates of depression that ranged from 9–16%, and rates of anxiety that ranged from 11–25% [26].

Remarkably similar rates of clinically significant DSM-IV disorders have been reported more recently by Northam *et al.* [23], who followed a cohort of newly diagnosed Australian children over a 10-year period. By year 10, 37% of those with diabetes received at least one diagnosis; of those, 60% met criteria for two or more disorders and 55% met criteria for three or more disorders [23]. In that study, mood, anxiety and eating disorders were each present in 17% of the sample; nearly 20% of the sample manifested a behavior disorder. Of note is their observation that those adolescents who met criteria for a DSM-IV psychiatric disorder were also more likely to have manifested significant externalizing problems shortly after diagnosis. Although not evaluated by Northam *et al.*, other investigators have identified maternal psychopathology as a potent predictor of subsequent psychiatric disorder [1] and increased depressive symptomatology in children and adults with diabetes [27].

Significantly elevated rates of suicidal ideation have also been reported for adolescents with diabetes, with lifetime prevalence rates noted to be 26%, compared to rates for adolescents without diabetes ranging from 9–12% [28]. Although the rate of actual suicide attempts is low amongst youth with diabetes (4%), suicidal ideation was associated with greatly increased rates of non-compliance with medical treatment.

### Clinically significant mood disorders in adults

The process of psychologic adaptation to the diagnosis of diabetes in adulthood remains incompletely understood, largely because few longitudinal studies have been conducted with adults [29]. In what remains the largest follow-up study of adults with T1DM, the Diabetes Control and Complications Trial (DCCT) Research Group [30] found no change in self-reported psychologic symptomatology over a follow-up period of 6–9 years, and found no relationship between type of treatment (conventional or intensive insulin therapy) and levels of psychologic distress [31]. Rates of clinically significant distress were higher in both treatment groups (25%) compared with rates of depression measured by self-report in the general population (14.4%) [32]. A smaller study that followed adults for 2 years from the diagnosis of T1DM also reported either no changes in psychologic state over time, or a significant improvement in functioning (e.g. reduced depressive symptomatology) [33].

Cross-sectional studies of adults with either T1DM or T2DM have demonstrated repeatedly that rates of psychologic distress, particularly depression and anxiety, tend to be higher than the

general population, but are usually comparable to those reported in individuals with other chronic diseases [34–38]. Using self-report measures of psychologic symptoms, Peyrot & Rubin [39] found greatly elevated rates of both depressive (41%) and anxiety symptomatology (49%), with 38% of their entire sample showing elevations in both domains; however, repeated reassessment of these patients over a 6-month period indicated that these effects are quite unstable. Across all three assessments, only 13% of the sample was consistently disturbed. The strongest predictors of persisting distress included being female, having less than a high school education, being middle-aged and having more than two diabetes-associated biomedical complications [40]. Prevalence rates for any depressive disturbance were nearly twice as high in this study [39] than DCCT reports (41% vs 25%, respectively), but this is likely to be because of sampling differences. The DCCT study group was comprised of highly motivated patients with minimal diabetes-associated complications who were vigorously followed by a treatment team that included a psychologist or psychiatrist [41], whereas those patients studied by Peyrot & Rubin included a mix of patients with T1DM and T2DM who were recruited during a 1-week diabetes management outpatient program.

Numerous other studies have also demonstrated high rates of anxiety disorder [42] and depressive symptomatology in adults with either T1DM or T2DM [35,43]. An early analysis of 42 studies indicated that the risk of depression was doubled in people with diabetes, as compared to people without diabetes, and this occurred regardless of type of diabetes (Figure 49.1) [32]. Similar results have been reported in a more recent meta-analysis of 10 studies that included 9028 patients with T2DM and 42 272 adults without diabetes; again, rates of self-reported depression were significantly elevated in patients with diabetes (17.6% vs 9.8%) [44].

**Figure 49.1** The increased prevalence of depression in people with diabetes compared with subjects without diabetes. The data are from a meta-analysis of 42 studies; figures for subjects with diabetes are the aggregate of both controlled and non-controlled studies. Adapted from Anderson *et al.* [32].

Variations in prevalence rates are common across individual studies, and appear to be related to the method used to ascertain depression. Those studies using self-report symptom scales yielded prevalence rates that were nearly three times higher than rates obtained using formal structured interviews with clinically established diagnostic criteria (31% vs 11%) [32]. Discrepancies amongst studies have also been found to be caused by differences in subject characteristics, particularly age and medical history [45,46]. The highest rates of current psychiatric distress tend to be found in hospitalized patients [47] or in older adults with multiple medical co-morbidities [48,49]. Frequently [50,51], but not invariably [45,52], adults with diabetes and more emotional problems also have poorer metabolic control. A review of more than 30 studies indicates that although depression is associated with higher HbA<sub>1c</sub> values, the magnitude of this effect is extremely small, with the exact value being a function of how depression is ascertained. In studies using symptom self-reports, less than 3% of the variance in HbA<sub>1c</sub> was explained by depression; when standardized diagnostic interviews are used, approximately 8% of the variance in HbA<sub>1c</sub> was accounted for by depression [53].

Studies of children with diabetes have indicated that the best predictor of future psychopathology is past psychopathology [16], and the same principle applies to adults. Lustman *et al.* [29] reassessed a group of adults with diabetes 5 years after they had first met criteria for current depression, and found that 67% were depressed at follow-up, whereas only 15% of the initially non-depressed adults met criteria for psychiatric disorder at follow-up. Repeated episodes of depression were common in the initially depressed group, with subjects having an average of 4.2 episodes during the 5-year follow-up period. Recurrence of depression was apparently unrelated to duration of disease, type of diabetes or development of diabetes-associated complications, but it was associated with a family history of psychiatric disorder. A subsequent study found that the severity of recurrent depressive episodes was related to the presence of neuropathy, but no other biomedical complication, at study entry and it has been suggested that the discomfort associated with this complication may serve as a stressor capable of provoking an episode of depression in vulnerable individuals [54]. The generally weak relationship between diabetes-related variables and reoccurrence of a mood disorder suggests that depression is not merely a psychologic reaction to the development of diabetes or its complications, but may be influenced significantly by underlying genetic or constitutional factors [25,55,56].

### **Depression as a risk factor for subsequent development of type 2 diabetes**

Most readers would assume from this literature that the emergence of depression is a direct consequence of coping with its demanding burden of care [48] and/or its associated co-morbid medical conditions [57], but there is growing evidence, at least from studies of older adults with T2DM, that the reverse may be true, and that being depressed greatly increases the risk of subsequently developing diabetes. In a meta-analysis that included 13

comparative prospective studies of depression and T2DM, a robust relationship was noted between depression and the subsequent incidence of T2DM (60% increase in risk), whereas the relationship between having T2DM and subsequently developing depression was modest at best (15% increase in risk) [58]. Although the exact pathologic mechanisms have not yet been established, it is certainly plausible that depression could greatly increase the likelihood of developing diabetes, in so far as depressive symptomatology is associated with a variety of behavioral (e.g. poorer compliance with dietary and weight loss recommendations; less physical activity) [59] and physiologic (e.g. increased activation of the hypothalamic-pituitary-adrenal axis, and increased inflammation) [60] risk factors for T2DM.

The diagnosis and treatment of depression and other psychiatric disorders in patients with diabetes is described in detail in Chapter 55.

### **Psychologic reactions to biomedical complications**

#### **Microvascular and macrovascular complications as triggers for psychologic distress**

Diabetic complications may not only disrupt the individual's usual lifestyle and interfere with self-care activities, but may also serve as a reminder that despite their best efforts, patients have failed to manage their disease adequately. In the same way that the child recently diagnosed with diabetes manifests an anxious or depressed mood as part of an adjustment disorder, older patients might be expected to show psychologic distress soon after a complication appears. This conjecture has not been tested empirically: it is not known how adults with diabetes react psychologically shortly after a complication appears, although as a group, adults with complications usually [61], but not invariably [62], have greater levels of psychologic distress.

Three types of diabetic complications are known to increase the risk of psychopathology: macrovascular disorders, chronic foot ulceration and sight-threatening proliferative retinopathy. Adults with diabetes and macrovascular disease often have elevated rates of depression [52] and poorer quality of life [55], although this is not always the case [46,63]. Similarly, patients with chronic unilateral foot ulceration secondary to diabetic neuropathy have higher rates of depression and report greater dissatisfaction with their lives than age-matched adults with diabetes but no history of foot ulceration [64]. Results from a prospective cohort study noted that 24% of adults with diabetes presenting with their first diabetic foot ulcer had clinically significant major depression, and this was associated with a threefold risk of death during an 18-month follow-up period [65]. Other studies have also demonstrated marked increases in depressive symptomatology and peripheral neuropathy, and have attributed this psychologic distress to the physical distress associated with reduced feeling in the feet and unsteadiness, as well as its unpredictability [66,67].

Increased psychiatric symptomatology is also seen in patients with proliferative diabetic retinopathy, compared with those without retinopathy [68]. Both level of visual acuity and duration

of visual problems affect mental health. Wulsin *et al.* [69] followed patients with diabetic retinopathy for 8 months, beginning shortly after a vitreous hemorrhage, and found that greater impairment of visual acuity was associated with increased psychological distress and poorer coping efforts. Unlike a classic adjustment disorder, these relationships grew stronger, rather than weaker, over time. Fluctuations in visual impairment may also increase psychological distress [70], although that is not inevitable [71], and it is important to keep in mind that the degree of psychological distress secondary to visual loss is not unique to patients with diabetes; at least one study of older adults has reported no significant difference in psychological adjustment between those with and without diabetes, either at the onset of visual loss or when re-evaluated 12 months later [72].

### Depression exacerbates the development and course of complications

Distress and depression are usually assumed to be a direct response to the occurrence of a complication, but there is growing evidence for the alternative possibility; that depression, at least under certain circumstances, may increase the likelihood that an individual will subsequently develop complications. The most compelling support for this view remains Kovacs' sophisticated statistical analysis of 10-year follow-up data from their childhood-onset cohort study which demonstrated that severity of retinopathy could be predicted from three antecedent variables [73]. These variables had an additive effect in so far as the likelihood of retinopathy increased with increasing duration of diabetes, with length of time spent in poor control and with overall proportion of time depressed. Depression was not a reaction to retinopathy in this cohort but predated the diagnosis of retinopathy by several years.

An analogous pattern of results has been reported more recently in a study of 483 African-Americans with T2DM who were followed over a 6-year period. Patients with high depression scores at both baseline and 6-year follow-up had significantly higher baseline HbA<sub>1c</sub> values and were more likely to show progression of diabetic retinopathy (odds ratio 2.44) and progression to proliferative diabetic retinopathy (odds ratio 3.19), compared with patients with low depression scores at both visits [74]. Baseline HbA<sub>1c</sub> values accounted for 21% of the progression to diabetic retinopathy, while being depressed at both visits accounted for an additional 6% in the regression model.

These intriguing findings suggest that depression may be a risk factor, not only for the development of subsequent psychopathology, but also for the development of subsequent diabetes complications, at least in certain individuals. The physiologic basis for this relationship remains unknown but, as discussed below, depression could interfere with patients' ability to manage their diabetes [75], and so contribute to poor metabolic control. It follows that early treatment of depression may not only improve the individual's mental health, but may improve metabolic control and delay the appearance of diabetic complications [76]. Support for that possibility comes from one small placebo-

controlled medication trial clinical study that used a selective serotonin reuptake inhibitor (SSRI) in a group of older adults with T2DM [77], but several other studies, taking a "collaborative care" approach have had no impact on metabolic control or other diabetes-related variables despite marked success in reducing depression in people with diabetes [78,79].

### Interactions between acute metabolic complications and psychological distress

Acute complications of diabetes, particularly recurrent diabetic ketoacidosis (DKA), may also be predicted in children from indicators of poor psychological functioning in the first year following diagnosis [80]. This is particularly true in girls, for whom more behavior problems and lower levels of social competence were associated with higher rates of DKA. Family dysfunction in the first year following diagnosis was also predictive, with higher levels of family conflict and lower levels of family cohesion associated with more recurrent DKA. Again, this relationship is limited to girls and is independent of variations in HbA<sub>1c</sub> values. Boys showed relatively low rates of recurrent DKA (6% vs 20%) but very high rates of recurrent hypoglycemia (22.6% vs 3%); the latter were unrelated to psychosocial variables shortly after diagnosis. Even after several years of diabetes, family functioning processes can have a major impact on risk for DKA. Adolescents who reported their parents expressed more negativity to their diabetes regimen had a greater risk of experiencing DKA [81]. It is likely that the link between early behavior problems and DKA in girls is mediated by psychosocial factors, such as poor adherence [82], although definitive evidence for that possibility is currently lacking.

### Diabetes treatment-induced fears and phobias

Phobic disorders are twice as common in adults with diabetes than the general population [46]. Earlier work failed to explore the possible reasons for that difference, but an increasing body of research has identified injection or blood and injury phobia, and fear of hypoglycemia, as two sequelae of insulin treatment for diabetes [83]. For example, Berlin *et al.* [84] studied more than 100 adults with T1DM and not only found that 94% of their sample reported at least one phobic symptom, but that patients with poorer glycemic control had more symptoms of fear of blood or injury than did those with better control. Those individuals also measured their blood glucose less frequently and endorsed more symptoms of anxiety and depression. Statistical modeling techniques support the possibility that the association between poorer metabolic control and lower rates of daily blood glucose monitoring is mediated by patients' fear of blood and injury. The prevalence of this phobia remains controversial, with estimates ranging from approximately 1.3% [85] to approximately 25% [86], depending on the questionnaire used to ascertain injection phobia and the criterion used operationally to define the severity of the disorder.

Fear of hypoglycemia is also common in children [87] and adults [88,89] with diabetes, as well as in spouses [90] and parents

[91]. The development of hypoglycemic fear, and the corresponding effort to avoid any situation that may lead to a recurrence of a hypoglycemic event, is not at all surprising. Acute hypoglycemic episodes are uncomfortable and unpredictable. They are accompanied by autonomic arousal characterized by aversive symptoms such as trembling, sweating, light-headedness, pounding heart, nervousness [92], feelings of anger and “tense-tiredness” [93,94] and worries that this episode could lead to a seizure, coma or death if not treated promptly.

Individuals who experienced recurrent hypoglycemia [88], or even a single episode of severe hypoglycemia when accompanied by seizure or coma [95], have higher hypoglycemic fear scores, although this is likely to be a consequence of several factors, including pre-existing personality traits, particularly neuroticism [89] or trait anxiety [96], and current level of psychologic distress [88]. In addition to being associated with higher levels of generalized psychologic distress, fear of hypoglycemia may lead patients with diabetes, and the parents of pediatric patients, to avoid hypoglycemia by treating falling blood glucose levels prematurely and hence maintain ambient blood glucose at higher values than desirable [97]. Programs that teach insulin-treated patients to recognize and anticipate blood glucose fluctuations have also been successful in reducing fear of hypoglycemia [98]. One might expect that fear of microvascular and macrovascular complications would also influence the self-management of the diabetes by the patient, but there has been little formal research on this topic. The recent development of a psychometrically sound “fear of complications” scale is an important first step [99].

### Quality of life

Psychologic distress has so far been the primary focus of this discussion, but the extent to which diabetes affects the individual’s perceived quality of life is also crucially important. Defining and measuring quality of life remains controversial, although it is generally agreed that this concept should include an understanding of how health-related variables affect physical, social and mental functioning as well as the individual’s overall feelings of well-being and satisfaction with life [100].

### General health-related quality of life

Large-scale studies of groups of individuals with various chronic illnesses have typically found little evidence that quality of life is differentially disrupted in adults with diabetes. Patients with diabetes do not differ from those with arthritis, renal disease, dermatologic disorders or from the general population on measures of anxiety, depression, positive affect, emotional ties, loss of control or overall mental health [101]. When health-related quality of life was assessed in a large cohort of adults with diabetes with the Medical Outcome Study (MOS-36) questionnaire, patients with diabetes reported more problems in physical and social functioning than patients without chronic conditions, but tended to function better than patients with cardiovascular, pulmonary or gastrointestinal disorders [102].

For individuals with T1DM, poorer health-related quality of life is associated with being older, having biomedical complications, being female, being less physically active and having a lower income [103]. Even the presence of a single biomedical complication can have a measurable impact on quality of life, and as the number of complications increase, there is a corresponding decline in quality of life as assessed by virtually all MOS-36 scales [103,104]. Chronic hyperglycemia, as indexed by higher HbA<sub>1c</sub> levels, is also associated with poorer general health, even after the presence of complications is taken into account statistically [105]. Recurrent hypoglycemia, defined as one or more episodes a month, also predicts poorer health-related quality of life, particularly on measures of mental health and social function [103] and physical health [105,106]. Many of these same variables are associated with poorer health-related quality of life in older adults with T2DM. Among the best predictors are the presence of diabetes-related complications [107], certain demographic characteristics (female, poorly educated, lower income) and lower levels of physical activity [105,108]. The relationship between metabolic control and health-related quality of life remains controversial, with some [105], but not all [109] studies finding statistically reliable correlations.

### Diabetes-specific quality of life

The use of diabetes-specific quality of life measures leads to similar conclusions [104]. The Diabetes Quality of Life (DQOL) measure, first developed to assess changes in quality of life during the course of the DCCT, explicitly examines factors such as satisfaction, impact of diabetes, social/vocational worry and diabetes-related worry [110]. When evaluated with either a generic pediatric quality of life measure [111] or with disease-specific questions, adolescents reported a relatively good quality of life which was only moderately affected by their diabetes, yet there was a great deal of inter-individual variation in response [112]. Differences in metabolic control or other biomedical or psychosocial factors may be responsible for this variability, although there is little consistency across studies. For example, improved metabolic control has sometimes [113], but not invariably [112], been found to be associated with better diabetes quality of life in adolescents.

Healthy adults with T1DM also report being satisfied overall with life, and indicate that diabetes has had little impact on their lives [114]. These relationships occur regardless of type of treatment (conventional or intensive insulin therapy) [31], or type of diabetes-associated quality of life measures employed [115]. Despite the demands made on individuals treated with intensive therapy, there is no evidence that treatment over a long period of time (6–9 years) adversely affects quality of life [31]; in fact, over a short-term (4 month) period, it is associated with improvements in diabetes quality of life [116]. The relatively benign experience of intensively treated patients participating in the DCCT may be a consequence of the greater level of psychologic and medical support that is provided to the participants in such clinical trials [41] or, alternately, may reflect the relative insensitivity

of a measure like the DQOL to small changes in quality of life over time [100]. More recent studies evaluating changes in quality of life associated with the use of continuous subcutaneous insulin infusion have been mixed, with some indicating no benefit, while others suggesting modest benefit [117], particularly amongst children and their parents [118].

Age at onset of diabetes may also affect certain aspects of life quality. One survey of marital satisfaction found that adults diagnosed with T1DM before 9 years of age were more satisfied with their marriage, and were more likely to have children than those diagnosed later [119]. Those authors suggest that individuals diagnosed earlier in development may be more adept at integrating the disease as part of their lifestyle and thus find less disruption from diabetes later in life. More recent work also suggests that the linkages between marital satisfaction, higher levels of diabetes-related satisfaction and better metabolic control may reflect better psychosocial adaptation to a variety of illness-related and marital role stresses and strains [120].

Diabetes-specific quality of life measures have been used less frequently with older adults with T2DM, but those studies have typically obtained results that do not vary appreciably from those noted in patients with T1DM [104]. When quality of life is operationally defined by measures of mood, cognitive mistakes or work symptoms, most adults with T2DM report little disruption in most areas of life, although an appreciable minority (27%) report loss of enjoyment from previously valued activities, particularly social eating and drinking [121]. Worse quality of life seems to be especially evident in patients with T2DM treated with insulin [122], although several studies, including the UK Prospective Diabetes Study, have found no effect of intensive therapy regimens on quality of life [123].

## Interventions to reduce psychologic distress

### Traditional psychotherapy

Individual or group psychotherapy or supportive counseling should be as effective in children or adults with diabetes as in individuals without diabetes but with similarly high levels of psychologic distress [124]. Many recommendations have been made for such interventions [16,125], and while there are now a large number of studies that have made use of these, data from several recent meta-analyses have generally found them to have, at best, modest effects in reducing psychologic distress and in improving metabolic control [126–128].

Traditional individualized and group therapy has been used to provide emotional support for both children and adults with diabetes, and may be particularly beneficial for patients who are confronting the development of complications such as blindness [129,130]. Studies of individual psychotherapeutic interventions are rare, but data from a single, very small randomized trial are quite promising. When a time-limited problem-oriented individualized treatment was compared with standard insulin treatment counseling in adults with T1DM, patients receiving the psychotherapeutic treatment showed greater reductions in both

problem severity and in HbA<sub>1c</sub> values than those receiving conventional diabetes care [131].

Group therapy programs, which are far more common, have similarly shown either very small positive effects or no reduction in distress. Such groups are typically led by mental health professionals, have 4–12 participants, meet weekly or fortnightly for 90 minutes; they may run for as long as a year [132], although interventions as brief as 7 weeks have been conducted [129]. A major focus for such groups, at least early on, is to provide participants with more medical information about diabetes [130,132]. Over time, participants become more comfortable in discussing personal concerns, diabetes-related and otherwise. The broad range of topics discussed may include coming to terms with unfinished grieving over diabetes-associated problems, dealing with guilt that they may have caused their own complications and coping with fears about loss of independence [133]. As with individual psychotherapy, the efficacy of formal group therapy, in terms of improved mood or metabolic control, has not been studied extensively in large, carefully designed studies [134] and the quality of the current research is considered “weak” from a methodologic perspective [128]. Anecdotal reports suggest that many participants leave the group happier, or better adjusted, and various “curative factors” have been identified by patients as being a major benefit of group therapy, including interpersonal learning, the experience of catharsis, development of insight into problems and an understanding that the individual is not alone in experiencing disease-related psychologic distress [135,136], but analyses of outcomes from formal clinical trials with children and adults with diabetes have been less sanguine [126,128,137].

### Cognitive-behavioral therapy

Of the different psychotherapeutic modalities available, cognitive-behavioral therapy (CBT) appears to be particularly promising in reducing the severity of depressive symptomatology. CBT teaches patients to use problem-solving strategies to reduce stressful situations and trains them to use cognitive techniques to “think away” their distorted beliefs, and replace them with more accurate and adaptive thoughts. Comparing 10 weeks of individualized CBT with non-therapeutic diabetes education (control condition), Lustman *et al.* [138] found that 85% of patients with T2DM receiving CBT achieved remission of depressive symptoms, in contrast to 27% in the control condition; at 6-month follow-up, similar rates of remission were seen (70% vs 33%). Individuals who are most likely to benefit from CBT are those with fewer complications and/or better compliance with blood glucose monitoring [139]. Variations of this approach have been used in studies of adults with T1DM, and while there were marked reductions in diabetes-related distress and in symptoms of depression, they were no differences between those subjects treated with group CBT and those in an active comparator condition who were treated with blood glucose awareness training. In neither group were there meaningful changes in glycemic control at 6 or 12 months after therapy initiation, but both were equally effective in lowering depressive symptoms to a modest degree

[140]. The fact that blood glucose awareness training, which has a minimal psychologic component, is effective in reducing psychologic distress is quite surprising, and emphasizes the potential effects that simple training in diabetes management may have on an individual's level of psychologic distress.

### Pharmacotherapy

Diabetes-related depression and anxiety disorders have also been treated successfully with pharmacotherapy [141,142]. Placebo-controlled studies have demonstrated that SSRIs such as fluoxetine [143] and sertraline [77], and tricyclic antidepressants such as nortriptyline [144] effectively reduce severity of depression and its subsequent recurrence in patients with diabetes, whereas the benzodiazepine alprazolam [145] effectively reduces anxiety. These different psychoactive drug classes differentially affect metabolic control. Nortriptyline produces a sustained increase in HbA<sub>1c</sub> values; in contrast, both fluoxetine and alprazolam reduce HbA<sub>1c</sub> values significantly. The physiologic basis for these differential effects remains unknown, but most experts believe that pharmacotherapy-induced hyperglycemia can be handled readily with appropriate adjustments to the diabetes management regimen [146].

Pharmacotherapy alone, or paired with a form of psychotherapy such as CBT, may not only improve mental health, but it may also reduce the risk of death, as recently demonstrated in the PROSPECT trial [147]. In that medical practice-based study, older depressed adults with and without diabetes were randomized to usual care or to an intervention in which trained depression-care managers monitored psychopathology, adherence to treatment regimens, patients' responses and side effects, and provided subjects either with a first-line antidepressant medication (an SSRI) or interpersonal psychotherapy. All subjects were followed for a median of 52 months, and only mortality outcomes were reported. There was a significant reduction in all cause mortality, but only for those depressed patients with diabetes who received this simple depression management strategy, demonstrating that even minimal management of depression can have salutary effects in the health of older adults with diabetes. Given the nature of that study's design, however, it is impossible to identify the processes underlying these effects.

---

## Neuropsychologic impact of diabetes

Diabetes has long been thought to affect cognition, as well as emotion, but it was not until the development of clinical neuropsychology (the study of brain-behavior relationships) that researchers were able to demonstrate unequivocally that mental efficiency can be disrupted by diabetes, its complications and its management, and that this neuropsychologic dysfunction reflects changes occurring in the CNS. The magnitude of these effects is relatively modest in most individuals, and few patients with diabetes manifest cognitive changes that would be characterized as being "clinically significant" – unless they developed diabetes

early in life. Until very recently, when cognitive dysfunction was found in patients with diabetes it was invariably attributed to the adverse effects of severe and/or recurrent hypoglycemia on the CNS. New research suggests that chronic hyperglycemia, and the metabolic and vascular complications that are associated with it, underlie the development of most structural and functional changes to the CNS, particularly in adults. Although hypoglycemia can never be considered to be entirely benign, it may have a relatively small role in the etiology of neurocognitive changes in patients with diabetes [148,149].

## CNS sequelae of diabetes in children and adolescents

### Cognitive manifestations

The nature and extent of cognitive dysfunction in children and adolescents differs depending on age of diagnosis. Those diagnosed in the first 5–7 years of life appear to have an elevated risk of manifesting a moderately severe cognitive impairment which is evident across a broad range of cognitive domains, including measures of attention, mental flexibility, psychomotor efficiency, learning, memory, problem-solving and overall intelligence [150–156]. In contrast, those diagnosed after that early "critical period" show very mild cognitive dysfunction which is limited primarily to measures of overall intelligence and to performance on speeded tasks, particularly those having a visuo-perceptual component [156]. Learning, memory and problem-solving skills are largely intact in this "later onset" patient population, or are only very minimally [157] and inconsistently affected [158,159]. Regardless of age at diagnosis, children with diabetes also tend to achieve lower scores than their peers without diabetes on measures of academic achievement [157,160], and have somewhat poorer grades in school [161], with these latter effects especially pronounced in children with a very early onset of diabetes [162].

The magnitude of the cognitive dysfunction seen in children with diabetes tends to be quite modest, as demonstrated by a formal meta-analysis of 19 pediatric studies encompassing 1393 children with diabetes and 731 healthy comparison subjects. When effect sizes were calculated (between-group difference divided by pooled standard deviation: "Cohen's *d*" [163]) for studies comparing later-onset children with control subjects, *d* values were approximately 0.20 or less – indicative of "small" to negligible effects. In contrast, effect sizes were more than twice as large when comparing early-onset subjects with diabetes with their peers without diabetes [156]. Using clinical rather than statistical criteria, one similarly finds marked differences between children with an early, as compared with a later, onset of diabetes. One large study found that 24% of children with an early onset of diabetes meet criteria for clinically significant impairment, as compared with only 6% of children with a later onset of diabetes, and 6% of a comparison group without diabetes [153].

This age at onset phenomenon has also been reported in adults diagnosed with diabetes early in life. Young adults who developed diabetes before 7 years of age performed more poorly on measures of information processing speed, and earned lower performance IQ scores than their peers with diabetes diagnosed at or after

age 7 [164]. Abnormalities in brain structure are also evident. Magnetic resonance imaging (MRI) scans showed higher rates of mild to moderate ventricular atrophy (61% vs 20%), as well as somewhat higher rates of small punctate white matter lesions within the hippocampus (14% vs 2%). Smaller brain volumes were also correlated with poorer cognitive test performance, supporting the view that cognition dysfunction is necessarily linked to changes in CNS morphology.

Neurocognitive abnormalities appear relatively early in the course of diabetes, having been reported within 2–3 years of diagnosis. In the largest longest prospective pediatric study to date, a representative sample of 90 newly diagnosed youngsters with diabetes and 84 healthy children drawn from the community have been followed over a 12-year period. No between-group differences were evident at study entry [165] but, 2 years later, those children diagnosed before age 4 manifested developmental delays in so far as their scores on both the Wechsler Vocabulary and Block Design subtests improved less over time, relative to either children with a later diabetes onset or to community control subjects [166]. After 6 years of follow-up, children with diabetes – regardless of age at diagnosis – performed worse than their peers without diabetes on measures of intelligence, attention, processing speed, long-term memory and executive skills. Children with an early age at onset were particularly affected, and performed significantly worse on measures of attention and executive function than those with a somewhat later onset of diabetes [151]. After 12 years of follow-up, these children with diabetes – now young adults – continued to earn lower verbal and full-scale IQ scores, demonstrating that these effects are not a “developmental delay,” but reflect a true, albeit modest, loss in cognitive efficiency, relative to those without diabetes [167]. Several other reports have also noted gradual decline in IQ scores as diabetes duration increases [161,167,168].

### Effects of hypoglycemic episodes on brain function

Hypoglycemia has long been considered to be the cause of these neuropsychologic deficits, particularly in children with an early onset of diabetes [153,155]. Not only are rates of severe hypoglycemia significantly higher in children younger than 5 years of age, compared with children older than 5 (48% vs 13%), but hypoglycemia is also more likely to recur in this younger group [169]. Behavioral factors could also contribute to the high rates of hypoglycemia early in life. Falling blood glucose levels may go unrecognized and untreated because very young children cannot adequately communicate that they are developing hypoglycemic symptoms. Although that view seems quite plausible, recent large well-designed cross-sectional [164,170] and longitudinal [171,172] studies completely failed to find any relationship between recurrent episodes of hypoglycemia and cognitive impairment, whereas others have reported only very weak and inconsistent findings [159] or have data sets in which severe hypoglycemia and age at onset tend to be confounded [173]. Similarly, both animal neuropathology [174] and human neuroimaging studies [167,175,176] are consistent with that view.

For example, no changes in neuronal morphology were found in very young (1 month old) rats despite recurrent bouts of experimentally induced severe hypoglycemia, whereas 2 months of insulin-controlled diabetes caused a reduction in dendritic branching and fewer dendritic spines on neurons, and this was associated with poorer performance on measures of spatial memory [174]. These findings suggest that hypoglycemia is unlikely to be sufficient to induce significant brain dysfunction in most children, at least in those diagnosed with diabetes after the age of 7 years; however, for children with an early onset of diabetes, hypoglycemia may have a contributory role in the development of brain dysfunction [154,159].

### Other CNS changes associated with diabetes in childhood

In addition to cognitive dysfunction, children with diabetes manifest multiple other changes in the CNS. Slowed neural activity is a very robust phenomenon. Compared with their peers without diabetes, adolescents with diabetes in good metabolic control showed significant increases in delta and theta (slow wave) activity, significant declines in alpha peak frequency in frontal brain regions, and declines in alpha, beta and gamma fast wave activity in posterior temporal regions [177]. When electroencephalogram (EEG) recordings were evaluated clinically, one large study noted that 26% of their subjects with diabetes had abnormal EEG records, compared to only 7% of healthy controls [178]. Both earlier age of diabetes onset and episodes of severe hypoglycemia were strong predictors of abnormality in that study, as well as in several earlier studies [179]. When auditory or visual evoked potentials were recorded, children and adolescents with a 2 years or more history of diabetes showed significant neural slowing, as evidenced by increased latencies, whereas those with less than 2 years of diabetes had normal latencies [180].

Cerebral blood flow has been measured only infrequently in children with diabetes, but the one study that used single photon emission computed tomography (SPECT) found lower levels of cerebral blood flow in children with diabetes than in healthy comparison subjects [181]. The greatest reductions in brain perfusion were found in the basal ganglia and frontal regions, followed by parietal and temporal areas. This pattern is similar to that reported in adults with T1DM [182], and provides limited support for the view that changes in brain perfusion may occur relatively early in the course of diabetes. The extent to which these cerebrovascular changes contribute to cognitive dysfunction remains to be determined.

Brain structure anomalies, documented with MRI, have only recently been reported in children with diabetes. The one study that focused exclusively on children with an early onset of diabetes noted greatly elevated rates of a very unusual brain anomaly – mesial temporal sclerosis. Within this cohort, 16% manifested this anomaly compared to less than 1% of the general pediatric population [175]. These anomalies apparently developed within a relatively brief period of time (mean duration of diabetes in this sample was approximately 7 years), and were unrelated to a past history of hypoglycemia. By contrast, children who experienced

one or more episodes of severe hypoglycemia (seizure or coma) had smaller gray matter volumes than those with no such history (724 vs 764 cm<sup>3</sup>), regardless of whether the hypoglycemic event occurred early in life or at a somewhat later age.

A second neuroimaging study used a semi-quantitative voxel-based morphometry technique to ascertain gray and white matter volumes in 108 children with diabetes and 51 age-matched children without diabetes who were 7–17 years of age [176]. Total brain volume was comparable in the two groups, but those children with diabetes who experienced one or more episodes of severe hypoglycemia had a slight reduction in gray matter in the left (but not right) temporal occipital region. This pattern of highly circumscribed effects, localized primarily to the left hemisphere, is consistent with what has been reported in adults with a long history of childhood-onset diabetes [183], as well as in several case reports [184]. Lifetime HbA<sub>1c</sub> values, used to estimate of chronic hyperglycemia, were associated with less cortical volume in the right posterior brain regions (particularly the right cuneus and precuneus), also replicating findings in adults with diabetes [183]. Chronic hyperglycemia was also associated with less white matter, and these effects were most pronounced in parietal brain regions.

At this point, the underlying pathophysiologic basis for the development of CNS dysfunction in children remains unresolved, because at least some studies have found relationships between neurocognitive outcomes and both hypoglycemia and chronic hyperglycemia; however, there is increasing interest in studying the many metabolic – and potentially neurotoxic – events that occur around the time of diabetes diagnosis such as changes in brain glucose during the peri-onset period, dramatic metabolic perturbations, including the occurrence of DKA, that now seem to have the potential to alter the structure of the developing brain in the child with diabetes [154,185].

### Brain structure and function in adults with type 1 diabetes

#### Neurocognitive manifestations

A highly circumscribed pattern of mild cognitive dysfunction characteristic of adults with T1DM has been identified from a systematic meta-analysis of data from 31 studies published in English between 1980 and 2004 that compared the performance of subjects with and without diabetes on multiple cognitive domains [186]. As illustrated in Table 49.1, subjects with diabetes, who were 18–50 years of age and in relatively good health, performed significantly more poorly on measures of intelligence, attention, psychomotor speed, cognitive flexibility and visual perception, whereas no between-group differences were found on measures of language, learning and memory. Even when differences were detected, they were modest at best, with effect sizes (**d**) ranging from 0.3 to 0.8 standard deviation units. It is important to note that not all cognitive domains were affected. Learning and memory skills, which are generally considered to be sensitive to early brain damage [187], were well preserved in this diverse patient population, despite an average of 20 or more years of

**Table 49.1** Cognitive characteristics of adults with T1DM, based on a meta-analysis of published papers. Standardized effect sizes (Cohen's **d**) for each cognitive domain reflect differences between subjects with and without diabetes. Adapted from Brands *et al.* [186].

Domain	Effect size	Significance	Total number	Studies
<b>Overall cognition</b>	0.40	<i>P</i> < 0.001	660	16

NS, non-significant.

T1DM. Moreover, with only one exception (“crystallized intelligence”), virtually all of the cognitive tasks on which patients with diabetes perform more poorly were those that also required rapid responding. That is, mental slowing appears to be the fundamental deficit associated with T1DM in adulthood [188]. A similar pattern of results has been found in adults with T1DM who are over the age of 60 [189]. Remarkably, the magnitude of the cognitive differences found in these older adults was similar (**d** = 0.3–0.5) to that reported in their younger counterparts, despite their longer duration of diabetes.

As noted in studies of children with diabetes, adults with diabetes also manifest slowed neural processing on measures of brainstem auditory evoked potentials [190,191], visual evoked potentials [192] and EEG recordings [193]. The magnitude of these effects is greatest in those individuals who have clinically significant microvascular complications [194–196]. Multiple studies have also demonstrated that cerebral blood flow patterns are abnormal in adults with diabetes, with these effects greatest in frontal and frontotemporal brain regions [197]. Changes in cerebral perfusion, measured by SPECT, are common. In one large study, 85% of middle-aged adults with diabetes showed hypoperfusion in one or more region of interest compared to 10% of controls; similarly, 58% of subjects with diabetes showed hyperperfusion, compared to 20% of controls [182]. Again, these effects were greatest in subjects with microvascular complications.

### Changes in gray and white matter

Marked reductions in brain matter density, as demonstrated by voxel-based morphometry, are also associated with T1DM. Compared with a group of healthy individuals without diabetes, young adults with a childhood onset of diabetes manifested significantly less gray matter (approximately 5%) in the right superior temporal gyrus, and in several left hemisphere regions, including the temporal gyrus, angular gyrus, medial frontal gyrus, inferior parietal lobule and thalamus [183]. These structures are especially important for attention, memory and language processing. The strongest predictor of gray matter density reduction was degree of chronic hyperglycemia in so far as higher lifetime HbA<sub>1c</sub> values were consistently correlated with lower gray matter density.

Similar findings have been reported in a case-control study demonstrating that individuals with diabetic proliferative retinopathy manifest small but statistically reliable reductions in gray matter density in the left middle frontal gyrus, the right inferior frontal gyrus, the right occipital lobe and the left cerebellum, whereas the gray matter values of patients with diabetes without retinopathy were comparable to adults without diabetes [198]. Reductions in white matter volume have also been noted, with effects being greatest amongst adults with a longer history of chronic hyperglycemia and microvascular complications [199].

### Retinopathy as a risk factor for CNS abnormalities

In reviewing these structural and functional findings it appears that a long history of chronic hyperglycemia, as indexed by the occurrence of microvascular complications, is a robust risk factor for neurocognitive abnormalities. The most direct support for this possibility comes from a longitudinal study that followed a group of young and middle-aged adults with a childhood onset of T1DM over a 7-year period [200]. Subjects who had clinically significant proliferative diabetic retinopathy at study entry, or who developed retinopathy during the course of the follow-up period, showed a significant decline in psychomotor efficiency, compared to demographically similar subjects without diabetes. In contrast, those without retinopathy at either time showed no evidence of psychomotor slowing. The risk of cognitive change was predicted by four variables: the presence or development of proliferative retinopathy, the presence of autonomic neuropathy, elevated systolic blood pressure and longer duration of diabetes. The resulting statistical model identified, with 83% accuracy, subjects who showed significant cognitive decline and explained 53% of the variance.

Cross-sectional studies of young adults have similarly demonstrated that background retinopathy is associated with white matter abnormalities on MRI and poorer performance on measures of attention, fluid intelligence and information processing speed [201]. Abnormal brain activation patterns during the performance of a working memory task have also been identified in patients with clinically significant retinopathy who were evaluated with functional MRI [202]. Other microvascular complications, particularly peripheral neuropathy, are

also associated with changes in brain function and structure [177,193,196,203,204].

Because middle-aged adults without diabetes who have retinal microaneurysms also show a pattern of cognitive decline that is characterized by psychomotor slowing [205], it has been suggested that retinopathy may serve as a general marker of cerebral microangiopathy [148,206]. This is quite plausible, given the well-known homology between the retinal and cerebral microvascular systems [207]. In patients with clinically significant diabetic retinopathy, the resulting microangiopathy could lead to cerebral hypoperfusion and thereby contribute to the development of abnormalities in brain structure and function by interfering with the efficient delivery of glucose and other key substances to neural tissue [148,198]. The relationship often reported between peripheral neuropathy and brain dysfunction in patients with diabetes may simply reflect the fact that microvascular complications tend to appear contemporaneously and have a common origin [208,209]. That is, microvascular disease may be the primary mechanism underlying the development of neurocognitive dysfunction in young and middle-aged adults [150].

### Repeated episodes of severe hypoglycemia and cognitive dysfunction

The widespread belief that moderately severe hypoglycemia will induce cognitive impairment in adults with diabetes appears to have little support from a growing body of research on this topic. The most compelling negative data come from the DCCT and its follow-up natural history study, the Epidemiology of Diabetes Interventions and Complications (EDIC). Cognitive functioning was assessed over an 18-year period in 1144 patients with T1DM who were between 29 and 62 years of age (mean 46 years) at the time of their final cognitive evaluation. Lifetime rates of severe hypoglycemia, defined as including a seizure or coma, were high, with a total of 1355 episodes reported in 453 subjects over the course of the study. Despite that, no relationship whatsoever was found between the cumulative number of severe hypoglycemic episodes and performance on a comprehensive battery of cognitive tests [210].

Cross-sectional studies have also failed to find robust relationships between cognition and episodes of severe hypoglycemia [186,201]. Several earlier studies did note a link between hypoglycemia and brain damage [211], but all relied on small samples of highly selected subjects who were assessed with a limited number of cognitive tests which yielded a pattern of results that was not entirely consistent with brain damage. For example, subjects with repeated hypoglycemia performed slower, but no less accurately, on a number of tests, and earned somewhat lower scores on the Performance subtests of the Wechsler Adult Intelligence Scale, yet learning and memory skills were intact. This latter finding is unexpected because of the well-known associations between memory and the hippocampus, a major focus of structural damage following profound hypoglycemia in rodents [212], non-human primates [213] and humans [184,214]. Whether moderately severe bouts of hypoglycemia adversely affect brain structure

remains controversial, with some [215] but not all [174] studies finding evidence of neuronal necrosis in rodent models. In human studies it can be quite difficult to make attributions specifically to hypoglycemia, rather than to chronic hyperglycemia, because patients who experience hypoglycemia also have a history of poor metabolic control [177].

As described in Chapter 33, severe and profound hypoglycemia can induce significant structural and function brain damage, but the prevalence of this phenomenon in adults with diabetes seems extremely low.

### Hyperglycemia and neurocognitive dysfunction associated with T2DM

Older adults with T2DM also show evidence of psychomotor slowing [216–218] and, in that way, are somewhat similar to young and middle-aged adults with poorly controlled T1DM. In addition, elderly adults with T2DM consistently learn new verbal and non-verbal information more slowly, and remember less of it over a brief delay, compared with subjects without diabetes [219–221]. Interestingly, this phenomenon appears to be limited to individuals over 60 years of age; younger adults with T2DM rarely show memory impairments [222]. Other cognitive skills, particularly problem-solving ability, may also be affected in older adults with T2DM [221], but those skills have been assessed less frequently (for reviews, see [219,223,224]).

The cognitive effects associated with T2DM are similar in magnitude to those reported in younger adults with T1DM. One recent study comparing 119 patients with T2DM (mean age 66 years; mean HbA<sub>1c</sub> 6.9% [52 mmol/mol]) with 55 age-matched healthy subjects without diabetes found the subjects with diabetes to perform worse only on measures of information processing speed ( $d = 0.50$ ), memory ( $d = 0.43$ ) and attention and executive function ( $d = 0.43$ ) [225]. The strongest predictor of poorer cognitive function was poorer metabolic control; neither duration of diabetes nor severity of peripheral neuropathy were related to any cognitive outcome variable [226]. Other studies have also noted strong negative relationships between HbA<sub>1c</sub> values and cognition. For example, one very large epidemiologic study has demonstrated that each 1.0% (11 mmol/mol) increase in HbA<sub>1c</sub> was associated with significantly poorer performance on tests of psychomotor speed, memory and executive function [227].

Despite their often brief duration of diabetes, patients with T2DM also manifest evidence of neural slowing [190,196], overall reductions in cerebral blood flow [228,229] and significant changes in brain structure, including smaller gray matter volumes (approximately 22 mL reduction), greater subcortical atrophy (approximately 7 mL increase in lateral ventricle volume) and larger white matter lesion volume (approximately 57% increase) [230]. Structural changes appeared to be more prominent in women and were associated with higher HbA<sub>1c</sub> values and older age, but were unrelated to diabetes duration, hypertension or hyperlipidemia. Compared with patients with T1DM, those with T2DM showed significantly greater cortical atrophy and deep

white matter lesions, with effect sizes ranging between 0.50 and 0.66 [231], even though the patients with T2DM had diabetes for a shorter period of time (7 vs 34 years) and had lower rates of clinically significant microvascular complications (laser-treated retinopathy: 8% vs 38%). The higher rates of macrovascular disease and atherosclerotic risk factors may underlie the development of the CNS changes seen in the T2DM cohort, although there is evidence to suggest that impairments in glucose and/or insulin regulation may be contributory [232,233]. The hippocampus, which has only infrequently been evaluated in most modern neuroimaging studies, was also found to be reduced in a group of relatively healthy adults with T2DM compared to healthy controls (5.4 vs 6.2 cm<sup>3</sup>;  $d = 1.4$ ) [234]. This could explain, at least in part, the poor memory function seen in many older adults with T2DM. The best predictor of hippocampal atrophy was HbA<sub>1c</sub> values.

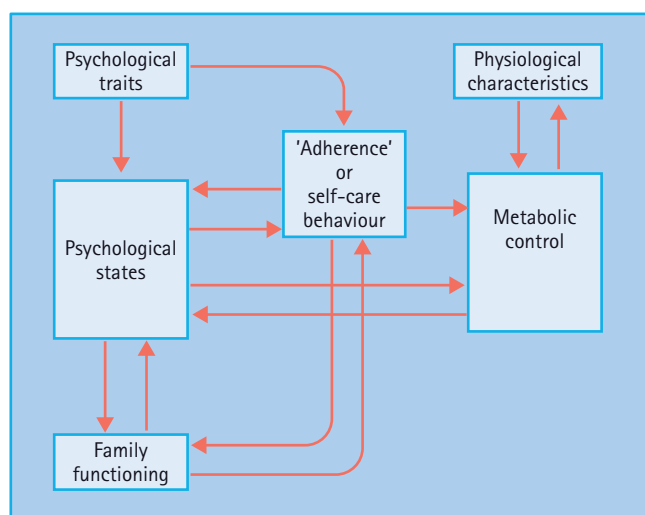

Much attention has recently been focused on rates of dementia in older patients with T2DM and it has been argued that diabetes is a significant risk factor for the subsequent development of Alzheimer disease or vascular dementia. Several recent studies and review articles have noted an increased risk of dementia that ranges 1.2–2.3 for Alzheimer disease and 2.2–3.4 for vascular dementia [235–237]. T2DM also has a significant negative impact on activities of daily living, with rates of functional disability doubled (e.g. ability to do housework efficiently and without assistance; walk 2–3 blocks) [238].

The degree of chronic hyperglycemia, as indexed by HbA<sub>1c</sub> levels, is the best (albeit imperfect) predictor of impairment in the older patient with diabetes, although a growing body of research has identified other diabetes-related conditions, including hyperinsulinemia [239,240], hypertension [220] and hypercholesterolemia [241]. Many patients with T2DM are beset with multiple medical problems or diabetic complications, some of which, such as cerebral atherosclerosis, could contribute to cognitive decline [219,224]. Nevertheless, it is clear that factors other than vascular disease must play a part in the etiology of these cognitive impairments because they can be identified in otherwise healthy adults with T2DM who have no clinically apparent vascular complications [217].

---

## Diabetes management and psychologic processes

The management of diabetes is an extraordinarily complex endeavor. The person with T1DM must take responsibility for injecting insulin two or more times each day, carefully monitor food intake at each meal, periodically measure glucose in blood, and readjust insulin, food and/or exercise during acute illnesses or in response to excessively high or low blood glucose values. Similar demands are placed on those with T2DM. The medication regimen may be less onerous, but dietary and lifestyle changes are often harder to tolerate. In either instance, patients and their families assume primary responsibility for these self-

**Figure 49.2** A systems model of the relationships between psychological and metabolic variables.

care behaviors, all of which are directed at maintaining optimal metabolic control. Good control signals that the patient's management efforts have been successful, while poor control may be interpreted as evidence that the patient has failed. This latter outcome may adversely affect mood and general psychologic well-being. Conversely, certain personality traits or coping styles that are intrinsic to an individual's psychologic make-up may modulate the patient's ability to manage diabetes self-care activities, as may environmental and psychosocial factors such as peer pressure to engage in certain "forbidden" activities, disruptive interpersonal conflicts and the normal stresses and strains of everyday life. Overall, an individual's "psychology" may influence, and be influenced by, the process of diabetes management.

According to a systems model of health, there is no simple direct relationship between any single psychologic variable and metabolic control [242]. Rather, health outcomes are determined by a system of reciprocal relationships amongst multiple psychologic, behavioral and physiologic variables. Figure 49.2 shows one such model of this process. Psychologic traits are relatively enduring characteristics that include personality, temperament and coping style. These may have a direct impact on self-care behaviors (adherence), and may also have a direct impact on emotional state. Psychologic states are more transitory and reflect emotions or feelings at a given point in time. Both family interactions and self-care behaviors may affect, and be affected by, the individual's mood or level of stress. Theoretically, at least, certain emotional states, especially stress, may also influence metabolic control directly via the autonomic nervous system or, indirectly, by interfering with the patient's ability to manage his/her diabetes. Family functioning, including conflicts and degree of family cohesiveness, can affect psychologic state (and vice versa), but can also influence self-care behaviors. Self-care or adherence behaviors include medication use, diet, exercise and monitoring, and these

behaviors serve as the primary final common pathway to metabolic control. The frequently reported absence of a strong relationship between adherence and glycemic levels may reflect the effects of physiologic characteristics, such as intercurrent illness or hormonal fluctuations secondary to puberty.

### Psychologic traits and their impact on metabolic control

These encompass a series of overlapping psychologic concepts that include "personality," "temperament" and "coping style." Individuals with personality characteristics indicative of a strong need for achievement and a high level of responsivity to social demands enjoy better metabolic control [243]. By contrast, HbA<sub>1c</sub> values tend to be higher in adults who are opportunistic and alienated [244] or who have poor impulse control, a propensity for self-destructive behaviors and difficulty maintaining interpersonal relationships [245]. Being a worrier or highly emotional, as reflected by elevated neuroticism scores or higher levels of trait negative affect, may also be associated with poorer metabolic control [246,247], although there is not complete agreement [248,249]. Indeed, in adults with T2DM, higher neuroticism levels were associated with better metabolic control, and it has been suggested that moderate levels of worry may be needed to motivate these older adults to manage their diabetes [250].

Locus of control is another psychologic trait that may affect glycemic state. Individuals who have an "internal" locus of control believe that they are responsible for their health, whereas those who have an "external" locus believe that they are at the mercy of chance, or some other outside force. In general, individuals with an internal locus seem more likely to have better metabolic control [251–253], although that is not invariably the case [33,254,255]. One would expect that individuals with an internal locus of control would do a better job of managing their diabetes, and that this would lead to better metabolic control, yet most studies have failed to demonstrate a strong link between locus of control and adherence [252,256]. Reconciliation of these discrepancies may require a reconceptualization of the locus of control construct. For example, internal locus of control may have multiple dimensions such as autonomy and self-blame that are not typically measured in a systematic fashion yet may lead to somewhat different health outcomes [257]. Multidimensional measures that examine different aspects of sense of control as well as different modes of control and motivation for control may ultimately provide investigators with more accurate insights into the complex inter-relationships between perception of control and optimal diabetes management but, to date, they have been used only infrequently [258].

The complexity of these interactions has recently been underscored in a study that measured locus of control, self-efficacy and outcome expectancy, and used this information to predict patients' HbA<sub>1c</sub> values. Within a sample of patients with T2DM from a predominantly disadvantaged background, those with an internal locus of control who reported low self-efficacy and low outcome expectancy tended to be in better metabolic control, whereas those with an internal locus of control but also expressed

low self-efficacy and high outcome expectancy tended to be in poorer metabolic control [259]. Having an internal locus of control may be particularly beneficial to those patients with little confidence in their ability to follow their physicians' recommendations (i.e. low self-efficacy), as well as little confidence that following those recommendations will actually improve their health (low outcome expectancies).

Coping styles, broadly categorized as emotion-focused and problem-focused [260], serve to modulate the individual's response to stressful situations. Emotion-focused or cognitive coping attempts to reduce threats from the environment by reinterpreting or reappraising the situation ("Stay calm, it really can't hurt you"). Problem-focused coping, in contrast, seeks to change the environment and thereby eliminate the threat (e.g. reduce excessive carbohydrate consumption by removing all high fat snacks). Within each of these categories, specific behavioral strategies may be differentially effective. Some may actually exacerbate stress (e.g. emotion-arousing strategies that include anger, impatience or anxiety), while others (e.g. stoicism) may reduce or "buffer" the effects of stress [261]. In adults with T1DM, higher levels of stress were associated with poorer metabolic control, but only in people who use ineffective coping styles that tend to increase emotional arousal [262]. In adolescents, emotion-focused coping styles (e.g. behavioral and mental disengagement; aggressive coping) was also associated with poorer metabolic control and reduced diabetes-related quality of life, whereas the use of active coping strategies directed at approaching and making a direct effort to change the situation causing psychologic distress was linked to better metabolic control [263]. Data from a meta-analysis of 21 studies have shown that the use of approach coping was associated with both better overall psychologic adjustment and with somewhat better metabolic control [264].

If traits truly reflect enduring behavioral characteristics, they ought to predict long-term adherence. Support for that possibility has been provided by Jacobson *et al.* [256] in their longitudinal study of children and adolescents with diabetes. Coping style assessed soon after diabetes onset predicted adherence behaviors 4 years later. Those children who used more mature defense mechanisms and showed greater adaptive capacity such as higher stress tolerance or greater persistence shortly after diagnosis were most likely to manage their diabetes satisfactorily in the long term.

### **Psychologic states: stress, depression and anxiety**

Many adults with diabetes consider stress to be a powerful determinant of their ability to maintain good metabolic control [265]. Higher levels of stress are associated with poorer glycemic control in adolescents [266,267] and adults [262,268], although there are very high levels of inter-individual variability. Like depression and other negative mood states [269], stress may affect metabolic control indirectly by disrupting the individual's ability to manage diabetes effectively [242,267]. Furthermore, elevated stress levels may affect metabolic control more directly by stimulating the

autonomic nervous system to initiate a series of neuroendocrine responses that raise circulating blood glucose and catecholamine levels [270] and alter the activity of the hypothalamic-pituitary-axis, which may, in turn, further disrupt metabolic regulation and brain function [271]. Although this mechanism is theoretically attractive, several physiologic studies using carefully controlled acute stressors failed to find evidence of acute metabolic derangements in children and adults with T1DM [272–274]. No experimental studies have systematically examined the relationship between chronic stress and long-term metabolic changes, and it remains possible that both indirect (behavioral) and direct (neuroendocrine) pathways are involved in mediating the relationship between heightened stress and poor metabolic control [242].

Investigators have also considered the possibility that high levels of stress may trigger the appearance of diabetes in genetically susceptible individuals [275]. Although there is evidence that children with diabetes experienced greater stress (particularly actual or threatened losses within the family) prior to diagnosis than healthy control subjects assessed in the same fashion [276–278], no evidence of a similar relationship has been found in young adults newly diagnosed with T1DM [279]. Nevertheless, the occurrence of major stressful life events [280], or pre-existing depression [281], increases the risk of T2DM by as much as 37% [282]. Although the physiologic basis for this effect remains incompletely understood, it is generally assumed that stress induces a dysregulation of glucose metabolism [283] and/or disrupts insulin signaling processes within the CNS [271] in individuals genetically and constitutionally predisposed to develop diabetes.

Depression and anxiety has been found by some [284–286] but not all studies [45,73,256] to be associated with poorer metabolic control. Some of the strongest evidence for a link between affect and glycemic state comes from an early study in which adults with diabetes were followed during 36 weeks of treatment [287]. As glycemic control improved, symptoms of depression and anxiety declined; as control worsened, depression and anxiety increased, giving the appearance that success (or lack thereof) in managing diabetes led to corresponding changes in mood state. Taking a different approach, more recently researchers focused their attention on the extent to which changes in depressive symptomatology over a 12-month follow-up period influenced HbA<sub>1c</sub> values [288]. Although there was a marked reduction in depressive symptoms regardless of type of diabetes, there was no corresponding improvement in metabolic control over time, leading to the conclusion that mood state has no meaningful impact on metabolic control.

The absence of an obvious relationship between depression and metabolic control [288] is not only counterintuitive, but it is inconsistent with the growing body of literature that suggests that the presence of depression adversely affects the medication adherence and self-care behaviors of people with diabetes. Particularly in older adults with T2DM, major depression is associated with less physical activity, a more unhealthy diet and poorer adherence to complicated medication regimens that

includes taking multiple oral hypoglycemic, antihypertensive and lipid-lowering drugs at various times during the day [75,289–291]. Given those relationships, one would expect that reducing the level of depression would lead to corresponding improvements in their metabolic control as the person with diabetes begins to take better care of themselves but, to the best of our knowledge, no data support that possibility. The only prospective data available demonstrate that the presence of depressive symptoms at baseline predicts poorer adherence 9 months later [292]. Whether adherence would improve as depressive symptoms reduce in severity remains unexamined.

### Family characteristics

Diabetes can dramatically disrupt the entire family, particularly when the patient is a child or adolescent [293]. Children, especially younger ones, enjoy better metabolic control when their parents take an active role in managing their diabetes, whereas adolescents are in better control when parents share management responsibilities with them [294–297]. Within the family, low levels of conflict [298], including sibling conflict [299], high levels of cohesion [8,300] and better communication skills [301] are associated with better control, as is a higher level of social support from family and friends [302]. Parental marital satisfaction also predicts control [300], perhaps because it serves as a surrogate for family cohesion and lack of conflict. Maternal trait anxiety [303] and parental intelligence also predict the child's metabolic control [304]; whether this association is mediated by better diabetes management or by less family conflict remains to be determined. Family factors such as lower adherence levels associated and greater levels of family stress, more family conflict and less family cohesion and sociodemographic variables (e.g. single-parent households) are also thought to explain the clinically significant disparity in metabolic control between African-American and Caucasian adolescents in the USA (mean HbA<sub>1c</sub> 10.1 ± 2.1% [87 ± 2.3 mmol/mol] vs 8.6 ± 1.3% [70 ± 14 mmol/mol], respectively) [305,306]. Consistent with those data is the observation that children raised by single mothers have poorer metabolic control than those from two-parent families [307]. In adults with diabetes, better marital satisfaction is associated with better diabetes-related quality of life and marginally better glycemic control [308] but, not surprisingly, more global variables such as family [309] and work environment [310] do not predict glycemic control, although they do predict degree of psychologic adjustment.

The relationship between family characteristics and glycemic control in children is most likely mediated via a purely behavioral pathway whereby family conflicts disrupt performance of self-care behaviors. Support for this interpretation comes from Jacobson *et al.*'s [311] and Hauser *et al.*'s [312] seminal 4-year follow-up study of recently diagnosed youngsters with diabetes. Degree of family conflict and extent of family organization at diagnosis were the best predictors of both short and long-term adherence to diet, exercise, insulin administration and self-monitoring. Children whose families had less conflict as well as a

family structure for planning activities and responses to problems were more likely to manage their diabetes satisfactorily [312] and to have better metabolic control [311]. This pattern of results has subsequently been supported by other large prospective [305] and cross-sectional analyses [313].

### Self-care or “adherence” behaviors

The terms “adherence” and “compliance” have been used interchangeably, and refer to the extent to which an individual follows a medical management regimen. Adherence to a diabetes regimen cannot easily be determined, however, because there is no standard against which the person's actual behavior can be compared [314]; for example, few physicians provide a written management plan that specifies all aspects of diabetes care. Because it is the patient, and not the health care professional, who is responsible for nearly all diabetes care [315], an increasing number of writers have suggested that diabetes management efficacy be assessed by determining the extent to which a patient engages in “self-care” behaviors [316,317]. The shift in terminology from “adherence” to “self-care behaviors” acknowledges the behavioral complexity of diabetes management, and takes into account recent data demonstrating that specific self-care behaviors (e.g. taking medication, diet, monitoring and exercise) are not strongly related to one another in either adults [318] or children [319].

Certain self-care behaviors are far more likely to be followed than others. For example, data from a large survey of more than 2000 adults with diabetes indicated that 97% of insulin requiring patients and 93% of oral medication requiring patients always or usually took their medications as recommended, but only 77% reported that they always or usually followed blood glucose self-monitoring recommendations, and even fewer followed diet (63%) and exercise (40%) recommendations [320]. These findings are consistent with earlier studies demonstrating that more behaviorally complex activities such as diet and exercise are performed less consistently than medication-taking and blood glucose monitoring [321]. Not all self-care activities are equally predictive of glycemic control for children or adults [314,322] but, overall, the more self-care behaviors that are performed well, the greater should be the improvement in blood glucose control [257].

Blood glucose self-monitoring frequency ought to be a particularly salient self-care activity. A large medical registry study found that adults with T1DM who self-monitored blood glucose three or more times daily subsequently had HbA<sub>1c</sub> values that were 1% (11 mmol/mol) lower than those who monitored less frequently; for T2DM adults, the difference was somewhat smaller (0.6%, 7 mmol/mol), albeit statistically significant [323]. Other studies have provided less positive results. For example, studies of patients with T2DM have either failed to find any evidence whatsoever that traditional fingerstick self-monitoring of blood glucose (SMBG) had any impact in reducing HbA<sub>1c</sub> values over a 1-year period [324] or have noted only weak and inconsistent effects [325]. Similarly pessimistic conclusions have been drawn from several studies of children and adults with T1DM. Data

from a recent clinical trial comparing continuous subcutaneous glucose monitoring HbA<sub>1c</sub> with SMBG technique found the degree of change in HbA<sub>1c</sub> values to be quite small, ranging from a 0.5% (6 mmol/mol) improvement to essentially no change over a 26-week time period. Moreover, somewhat surprising, the superiority of the CGM technique was limited to those subjects who were 25 years of age or older [326]. These data suggest that simply monitoring blood glucose values, and not using that information to adjust insulin or oral medications frequently and systematically, may have little meaningful impact on patients' long-term metabolic control.

Treatment adherence varies at different ages and changes with time. Younger children with diabetes tend to show better adherence (perhaps because of greater parental involvement) than adolescents [256,322]. Even after controlling for age, however, a longer duration of diabetes tends to be associated with declines in adherence [16,256], at least during adolescence. Other factors associated with better adherence are good family support [296], more shared responsibility between the child with diabetes and parent for self-care behaviors [327], greater cognitive maturity [328], more knowledge of diabetes and its management and better memory skills [319]. The nature of the physician–patient relationship can also influence adherence behaviors [329]. Doctor-centered discussions discourage patients from asking questions and increase their level of uncertainty and discomfort [330], whereas patient-centered communications are predictive of better self-reported adherence [331].

The generally weak relationship between self-care behaviors and metabolic control remains problematic for any model purporting to predict successful diabetes management. To some extent, this could reflect the possibility that the HbA<sub>1c</sub> concentration is not the most appropriate measure of metabolic control [314], but it is more likely that the unexplained variance in glycemic control reflects unspecified physiologic or situational characteristics, as well as difficulties inherent in measuring self-care behaviors [317]. Because adherence is typically assessed by asking subjects to describe their behavior, rather than by direct observation, it is possible that self-reports may exaggerate or otherwise misrepresent the extent to which patients performed a particular self-care behavior [317].

## Psychologic interventions to improve adherence

### More traditional psychotherapeutic approaches

Several psychologic interventions have been developed to improve adherence in patients with diabetes. For adults who are most seriously non-compliant and whose consistent refusal to follow medical advice has led to “brittle diabetes,” Boehnert & Popkin [332] have recommended a therapeutic approach that begins with crisis management, followed by psychotherapy of the sort typically used with patients diagnosed with “borderline personality.” Intensive inpatient psychoanalytic psychotherapy, with 3–5 weekly sessions over a 5–28 week period, has also been found to improve metabolic control over a 1-year period [333], but this may be the least practicable way of treating brittle diabetes,

because relatively few hospital settings offer this type of psychotherapy to children.

For less severe adherence problems, a variety of behavioral and psychosocial interventions have been used to improve diabetes management [334,335]. These differ from more traditional group therapy programs in so far as they use several sessions to target one or more self-care behaviors and/or the psychologic factors that may interfere with good adherence. A typical self-management program may meet once or twice monthly for seven or more sessions, discuss specific self-care strategies (e.g. blood glucose monitoring; exercise), role play appropriate behaviors, use homework assignments to practice what has been learned and resolve problems or barriers encountered during diabetes management [336].

Variations on this basic theme include the use of “booster” sessions, scheduled 6 or 12 months following the end of the program and designed to review and reinforce previously learned material. Interventions may include spouses or family members at some or all of the sessions, or incorporate separate but concurrent sessions for parents and adolescents with diabetes [337,338]. The program content also varies. Some focus on basic diabetes management and the acquisition of effective problem-solving skills [336,338] while others emphasize handling stress [339,340] or other psychologic issues that are especially problematic for participants, including fears about hypoglycemia or the development of hyperglycemic complications [130]. Most include homework assignments and extensive self-monitoring [336,340]. Interventions developed initially for patients without diabetes with high levels of psychologic distress are increasingly being applied to patients with diabetes, and both CBT [140] and “motivational interviewing” [341,342] or “motivational enhancement therapy” [127] programs have led to modest improvements in HbA<sub>1c</sub> levels and in self-reported quality of life.

Family-focused behavioral interventions have been found to be particularly successful in improving diabetes management in children. In one of the largest studies of its kind, Wysocki *et al.* [343] randomized 119 families of adolescents to either 10 sessions of behavioral family systems group therapy, 10 sessions of an education and support group or standard diabetes therapy (with minimal psychologic support). Behavioral family systems therapy included four modules: problem-solving training which focused on conflict resolution; communication skills training; cognitive restructuring to identify and change those attitudes and beliefs that impede effective communication; and specialized family therapy interventions. In the 12 months following treatment, adolescents who participated in behavioral family systems therapy showed long-term improvement in relationships with their parents compared with adolescents in the other two treatment groups, and also manifested improved adherence to their diabetes management regimen, although these behavioral and psychologic changes were not associated with improvements in metabolic control [344]. Similar interventional approaches have also been applied to older adults with T2DM and, as is the case with children and adults with T1DM, there are reductions in psychologic

distress and occasionally, but not invariably, small improvements in long-term glycemic control [345].

**Cognitive-behavioral approaches**

Coping skills training programs have also been found to be effective in improving the diabetes management skills of adolescents treated with intensive insulin therapy [346]. Based on a cognitive-behavioral skills-building model, coping skills training presents participants with a series of social situations that are particularly problematic for adolescents, and asks them to demonstrate how they would resolve that situation (e.g. manage food choices with friends). As implemented by Grey *et al.* [346], groups of 2–3 adolescents role play each scenario with a highly trained group leader who provides correction and models appropriate coping behavior. Sessions last 60–90 minutes and, in the typical training program, subjects participate in six weekly sessions followed by monthly visits. Over a 12-month follow-up period, adolescents randomized to coping skills training plus intensive diabetes management had significantly lower HbA<sub>1c</sub> values (7.5% vs 8.5%; 58 vs 69 mmol/mol) and reported higher levels of self-efficacy as well as less difficulty in coping with diabetes and less depression when compared with adolescents who received intensive diabetes management alone [297].

Another successful approach is to “empower” patients, and encourage them to take personal responsibility in managing their diabetes [347]. Empowerment programs aim to improve patients’ ability to identify and set realistic goals, apply problem-solving strategies to overcome barriers to those goals, develop more effective coping strategies in general, manage stress more effectively, increase levels of social support and improve self-motivation [348,349]. Results from a randomized controlled trial demonstrated that following a 6-week patient empowerment program, adults with diabetes showed a significant decline in HbA<sub>1c</sub> level as well as increases in ability to set goals, manage stress, obtain external support and make decisions about diabetes management [348].

Individually tailored programs have also been used to help patients manage stress. If elevated levels of stress are a barrier to optimal metabolic control, then the stress-reduction effects of biofeedback-assisted relaxation training ought to reduce blood glucose levels appreciably. Results from various studies are mixed, with some [350], but not all [351,352] reporting significant improvements in glucose control following relaxation training. Results from a recent study suggest that the effectiveness of stress management programs may be determined, at least in part, by the patient’s underlying personality. Patients with T2DM who were anxious, angry or hostile showed improved metabolic control following a stress management program that included progressive muscle relaxation training [352].

In their very thoughtful and thorough review of behavioral and psychosocial interventions in diabetes, Peyrot & Rubin [334] discuss the utility of including both problem-focused and emotion-focused interventions as part of an integrated behavior change support program. According to their model, interventions must occur in a particular sequence of five steps:

**Table 49.2** Behavioral and/or psychosocial interventions: a step-by-step approach. From Peyrot & Rubin [334].

Intervention	Sample question
<b>Problem-focused interventions</b>	
1 Start with the patient’s problem	“What’s the hardest thing about managing your diabetes?”
2 Specify the problem	“Can you give me an example?”
3 Negotiate an appropriate goal	“What is your goal for changing your self-care behavior?” “Is that realistic?”
4 Identify barriers to goal attainment	“What could keep you from reaching your goal?” “Why would that keep you from reaching your goal?”
5 Formulate strategies to achieve the goal	“How can you overcome that barrier to reaching your goal?” “How have you successfully dealt with that before; would that work now?”
6 Contract for change	“What are your criteria for defining success?” “How will you reward yourself for success?”
7 Track outcomes	“How will you keep track of your efforts?”
8 Provide on-going support	“What will you do if you slip in your efforts to reach your goal; what can I do to help?”
<b>Emotion-focused interventions</b>	
9 Identify diabetes distress	“Do you feel overwhelmed by diabetes?”
10 Alleviate diabetes distress	“What are you saying to yourself when you deal successfully/unsuccessfully with a diabetes-related challenge?”
11 Identify depression	“In the past 2 weeks have you felt depressed or lost interest or pleasure in things?”
12 Treat disorder or refer for treatment	“Would you like to talk to someone who can help you resolve these problems?”

- 1 Specify the patient’s problem;
- 2 Translate the patient’s intentions to change into concrete, attainable goals;
- 3 Collaborate with the patient to identify barriers to reach those goals and formulate effective strategies;
- 4 Establish a “contract” with the patient to meet, or approach, those goals; and
- 5 Provide continuing support.

The framework provided by these commentators makes much sense from a clinical perspective, and their step-by-step approach is summarized in Table 49.2. The extent to which such an approach will be successful in initiating lasting clinically significant changes in mood, behavior and metabolic control remains unknown at the present time, but it is certainly an approach worth evaluating in formal clinical trials.

**Conclusions**

This chapter closes with a discussion of psychological intervention programs because it is here where psychologists and diabetolo-

gists can work together effectively to improve their patients' mental as well as their physical health. One of the greatest problems facing mental health professionals is the failure, or inability, of many physicians to identify patients with psychologic distress quickly and provide appropriate treatment. A plethora of complex psychologic tests and questionnaires have been developed for research studies with patients with diabetes [353], yet the easiest way to determine whether a patient is having psychologic problems is to ask them explicitly. When psychologic problems are uncovered, immediate referral should be made to a mental health professional who is familiar with diabetes-related psychologic issues. It has been argued that it is the physicians who should diagnose and treat emotional disorders in their patients with diabetes, but that view is unrealistic. Few physicians have the expertise or the time to provide appropriate psychotherapeutic interventions. A far better solution is to add a psychologist, psychiatrist or social worker to the diabetes treatment team [41]. This approach was taken in the DCCT, and it may be one of the reasons why overall levels of psychopathology were so low, and perceived quality of life was so high, despite the arduous demands made on patients.

From this chapter it is clear that patients with diabetes have a remarkable level of psychologic resilience but, like anyone else, they are likely to experience psychologic distress at some time. Psychologists and diabetologists must continue to develop better ways of delivering psychologic support in order to alleviate their distress.

## Diabetes and Infections

Clive S. Cockram<sup>1</sup> & Nelson Lee<sup>2</sup>

<sup>1</sup>Chinese University of Hong Kong, Hong Kong

<sup>2</sup>Department of Medicine and Therapeutics, Prince of Wales Hospital, Chinese University of Hong Kong, Hong Kong

### Keypoints

- Diabetes is associated with an increased overall risk of infections.
- The presence of diabetes also modifies the course of many infections and increases morbidity and mortality.
- Multiple disturbances in innate immunity have a role in the pathogenesis of the increased prevalence of infections in people with diabetes.
- Impaired phagocytosis by neutrophils, macrophages and monocytes, impaired neutrophil chemotaxis and bactericidal activity, and impaired innate cell-mediated immunity appear to be the most important disturbances of the immune system.
- Humoral immunity appears relatively unaffected, hence plasma levels of antibodies and responsiveness to vaccination are relatively unaffected.
- In general, better regulation of the diabetes leads to an improvement in cellular immunity and function.
- Increased skin and mucosal carriage of *Staphylococcus aureus* and *Candida* species may increase risk of infection with these organisms.
- Some microorganisms become more virulent in a high glucose environment; examples include certain *Klebsiella* serotypes and *Burkholderia pseudomallei*.
- Viral infections such as hepatitis C are associated with a higher prevalence of diabetes.
- Highly active antiretroviral therapy for HIV/AIDS may also precipitate diabetes.
- Vascular disease such as microangiopathy can further impair the expression of the immune response as well as affecting the overall function of the microcirculation. It is commonly a factor in severe infections such as malignant otitis externa, emphysematous pyelonephritis and necrotizing fasciitis.
- Urinary tract infections and asymptomatic bacteriuria are more common in people with diabetes. Autonomic neuropathy is a common and important underlying factor.
- Skin and soft tissue infections are more common, with the infected diabetic foot as a prime example. Vascular disease and diabetic neuropathy are important underlying factors in the vulnerability of the foot to infection. Skin infection or infections of the external genitalia are common presenting features of diabetes. Necrotizing fasciitis is also associated with diabetes.
- Some uncommon but life-threatening infections occur almost exclusively in people with diabetes. Examples include the rhinocerebral form of mucormycosis, malignant otitis externa, Fournier gangrene and emphysematous forms of cystitis, pyelonephritis and cholecystitis.
- Diabetes increases the risk of tuberculosis and also increases the risk of treatment failure. Unusual or extrapulmonary sites of infection may be important and cavitary disease more common.
- Other underlying factors that can predispose to infection include renal failure, obesity, need for hospitalization, indwelling catheters and delayed wound healing.

### Introduction

People with diabetes develop infections more often than those without diabetes and the course of the infections is also more complicated. Historically, infections have been well recognized as an important cause of death in diabetes and remain a very important cause of morbidity and mortality in people with diabetes. This is particularly true in less well-developed countries and areas, where infections are commonly the first presenting feature

of previously unknown diabetes. The infected diabetic foot remains a prime example of this phenomenon despite its potential preventability.

While the association between diabetes and infections is well recognized, the relationships are complex, not always clear-cut and often controversial. Data on the true incidence of certain infections are lacking and a number of factors complicate efforts to assess risk of infections and outcomes. Studies are often retrospective and uncontrolled in nature.

Some infections, which occur predominantly in people with diabetes, are uncommon and inevitably have limited data. Examples include malignant otitis externa, mucormycosis, emphysematous forms of cholecystitis, cystitis and pyelonephritis, and Fournier gangrene.

In the case of more common infections that, while not limited to people with diabetes, have diabetes as a complicating factor, many potential variables make for considerable heterogeneity in the clinical course. Examples of such factors include duration of disease, presence of diabetic complications, glycemic control (both recent and longer term), access to and provision of medical services, and presence or absence of other concurrent illnesses.

A recent carefully controlled study from Utrecht, the Netherlands, has confirmed that, in general terms, patients with type 1 (T1DM) and type 2 diabetes mellitus (T2DM) are at increased risk of lower (but not upper) respiratory tract infection, urinary tract infection and skin and mucous membrane infections [1]. In this study, the well-documented increased risk of urinary infection was extended to include both risk of recurrence in both sexes and risks in males (perhaps explained by prostatitis).

Another recent study, conducted in Ontario, Canada, compared people with diabetes with matched control subjects without diabetes [2]. The investigators calculated the risk ratios, both for contracting an infection and for death from infection. Forty-six percent of all people with diabetes had at least one hospitalization or outpatient visit for infections compared with 38% of those without diabetes, the relative risk ratio being 1.21. The risk ratios for infectious disease-related hospitalization or death were noticeably higher at 2.17 and 1.92, respectively. This may be attributable to increased severity and presence of complications. In the case of hospitalization, it could also reflect a lower threshold on the part of physicians to admit people with diabetes to hospital when they have intercurrent illnesses. A separate study also from Canada, in this case from the Calgary Health Region, has conducted a population-based assessment of severe bloodstream infections requiring intensive care admission. Demographic and chronic conditions that were significant risk factors for acquiring severe bloodstream infection included diabetes, with a relative risk ratio of 5.9. The most common organisms were *Staphylococcus aureus*, *Escherichia coli* and *Streptococcus pneumoniae* [3].

Data from a study by Bertoni *et al.* [4] suggest that adults with diabetes are at greater risk for infection-related mortality, and that the excess mortality risk may be mediated by cardiovascular disease (CVD). When diabetes was combined with CVD, the relative mortality risk was 3.0 (1.8–5.0), whereas individuals with diabetes without CVD had a risk of 1.0 (0.5–2.2).

Evidence that the presence of diabetes can worsen the outcome or prognosis of infections comes from a number of sources. There is evidence that the presence of T2DM is associated with an increased mortality from community-acquired pneumonia. While much of this may be explained by factors such as age and coexisting comorbid illnesses, admission hyperglycemia has been shown to be a particularly important predictor of death. Also, even in patients without previously diagnosed diabetes, glucose levels in general assume importance [5]. During the outbreaks of severe acute respiratory syndrome (SARS) in 2003 in Toronto, the presence of diabetes was an independent risk factor for poor

outcomes (intensive care unit admission, mechanical ventilation and death) with a threefold increase in relative risk [6].

Both host- and organism-specific factors appear to be implicated in the increased susceptibility to particular infections. From the host perspective, defects in innate immunity are important, notably decreased functions (chemotaxis, phagocytosis and killing) of neutrophils, monocytes and macrophages. Other factors include effects of diabetic complications, poor wound healing and the presence of chronic renal failure. Frequent hospitalizations, with the attendant risk of nosocomial infection, can also be contributory.

Infections, as well as leading to considerable morbidity and mortality in people with diabetes, may also precipitate metabolic derangements, producing a bidirectional relationship between hyperglycemic states and infection. Some infections may also be implicated more directly in the etiology of diabetes.

Physicians working in primary care need to have high levels of awareness of the relationships between diabetes and infection, and of the important infections that may be involved. Infections involving the foot, soft tissues, skin and nails, as well as the urinary tract, are of particular importance in the setting of primary care. These infections are commonly encountered in people with diabetes, may be present at diagnosis and may be the presenting feature that leads to the diagnosis of diabetes being suspected. Infections of the foot and skin will receive additional attention elsewhere in this textbook so, in order to avoid duplication, coverage in this chapter is curtailed. This should not be taken as an indication of lack of relative importance, the opposite is the case. The other chapters concerned should be taken as forming part of the overall coverage of the topic of diabetes and infections (see Chapters 44 and 47).

---

## Diabetes, the immune system and host factors

### Host immune response

Although the increased susceptibility of people with diabetes to bacterial (and other) infections is well established, the mechanisms remain incompletely understood. Deficiencies in the host innate immune response are apparent and appear more important than changes in adaptive immunity.

The presence of diabetes has multiple effects upon innate immune responses, including effects upon neutrophils, monocytes and other components of innate immunity. These disturbances have important roles in the increased prevalence and enhanced severity of infections in people with diabetes. The effects include reduced chemotaxis, phagocytosis and impaired bactericidal activity.

Some disturbances in the complement system and in cytokine responses have been described in people with diabetes (e.g. low complement factor 4 and decreased cytokine responses after stimulation), but their role in the increased susceptibility to infection is less clear [7]. Consistent defects have not been demonstrated. No clear disturbances in adaptive immunity have been

described. Humeral adaptive immunity, in particular, appears relatively unaffected as exemplified by the relatively normal antibody responses to most vaccinations and the fact that serum antibody concentrations and responses in patients with diabetes are generally normal. For example, people with diabetes respond to pneumococcal vaccine equally as well as controls without diabetes [8,9].

The complexity of the component systems involved in the immune system makes comparison between studies difficult and it is obviously simplistic to study individual components of the immune system in isolation given the interdependency of these components. Many studies have relied upon *in vitro* or animal model methodology.

Investigations to identify the mechanisms of immune impairment in animal models of diabetes and *in vitro* experiments have been numerous. A full review of these animal and *in vitro* studies is beyond the scope of this chapter; however, the observations that follow may serve as examples from within the range of abnormalities that have been found, although many questions remain as to the nature of the defects produced by diabetes and their effects upon infection risk.

Neutrophil chemotaxis, neutrophil adherence to vascular endothelium, phagocytosis, intracellular bactericidal activity, opsonization and other aspects of innate immunity are all depressed in hyperglycemic patients with diabetes, although adaptive immunity appears relatively unaffected [10–12]. These changes lead to reduced host defense in response to infection with extracellular bacteria. Both impaired chemotaxis and phagocytosis have been described in monocytes of people with diabetes [13]. Defects in innate immunity have also been shown to predispose *db/db* mice to *S. aureus* infections. Interestingly, these mice show a heightened inflammatory response which occurs in association with an impaired neutrophil respiratory burst, and the recruited neutrophils fail to resolve the infection [14]. A possible role for advanced glycosylation end-products (AGEs) is postulated as a component in the pathogenesis of the impaired neutrophil function.

While release of tumor necrosis factor  $\alpha$  and interleukin  $1\beta$  (IL- $1\beta$ ) from lipopolysaccharide-stimulated macrophages has been shown to be reduced in diabetic mice compared with control mice [15], study of monocytes from patients with diabetes indicates upregulation of the secretion of the same inflammatory mediators [16]. This further illustrates the difficulty in comparing studies conducted in different settings and species. Some innate (e.g. cytokines, complement) immune functions are decreased while others remain the same in patients with diabetes as those without diabetes. For example, while unstimulated cytokine concentrations may be higher, cytokine responses to stimuli are often reduced [17]. Interpretation of the complexity of the underlying mechanisms may also need to take into account potential underlying proinflammatory effects associated with diabetes itself.

The level of macrophage inflammatory protein 2, a mediator of lung neutrophil recruitment, is significantly decreased in diabetic mice compared to control mice [18]. The deficiency causes

a delay in neutrophil recruitment in the lungs. This may be an important factor influencing the susceptibility of people with diabetes to infections of the lower respiratory tract.

Hyperglycemia impairs opsonophagocytosis by diverting nicotinic acid adenine dinucleotide phosphate (NADPH) from superoxide production into the aldose reductase-dependent polyol pathway [19], providing one further example of a mechanism by which hyperglycemia directly impairs phagocytosis.

Diabetic mice show greater than twofold induction of genes that directly or indirectly induce apoptosis [20]. By contrast, it is known that blocking of apoptosis allows for a significant improvement in wound healing and bone growth. This may influence many aspects of responses to infection, including impaired wound healing, which are important in the setting of diabetes.

These examples, while somewhat piecemeal, serve to demonstrate the range of abnormalities in the innate immune system that result from hyperglycemia. Of particular importance are those spanning macrophage, monocyte and neutrophil function, and which impair adherence to endothelium, chemotaxis, phagocytosis and bacteriocidal activity. They also point to other abnormalities (e.g. involving apoptosis), wound healing and cytokine responses to infection. The antioxidant systems involved in bacteriocidal activity may be compromised. These impairments, which are exacerbated by hyperglycemia and acidemia, may be reversed substantially, if not entirely, by normalization of pH and blood glucose levels. It needs to be emphasized, however, that the severity of effects correlates somewhat unpredictably with direct contemporaneous measures of glycemic control such as HbA<sub>1c</sub>, perhaps reflecting longer term or persistent changes such as accumulation of AGEs [21]. In general, a better regulation of the diabetes leads to an improvement of the cellular aspects of immune function.

### Other host-related factors

Other host-specific factors, over and above direct diabetes-related impairment of immune defenses, can further the predisposition to infection. These include vascular insufficiency (microangiopathies and macroangiopathies), sensory peripheral neuropathy, autonomic neuropathy, and skin and mucosal colonization with pathogens such as *S. aureus* and *Candida* species. Abnormalities of the structure and function of the microcirculation can also have additional indirect adverse effects on the immune responses themselves. Thus, immunologic responses may be further compromised by microangiopathy, and additional factors related to diabetes complications specifically increase the risks of certain infections, especially those involving the foot and the urinary tract.

While beyond the direct scope of this chapter, obesity, which is commonly associated with diabetes, also increases the risk of certain infections. These include nosocomial infections, wound and surgical site infections, respiratory infections and infections involving the gastrointestinal tract. The presence of obesity also correlates with infected diabetic foot ulcers in people with diabetes [22].

### Diabetic complications

Vascular disease is an important component in the etiology of the diabetic foot and the attendant complications of infection, ulceration and gangrene. Vascular disease is very common in diabetes and macrovascular disease may be premature, extensive, severe and present in unusual sites. Vascular insufficiency results in local tissue ischemia that can, in turn, enhance the growth of micro-aerophilic and anaerobic organisms, while simultaneously depressing the oxygen-dependent bactericidal functions of leukocytes. The antioxidant systems involved in bacteriocidal activity may be compromised by the combination of microvascular disease and the diabetic metabolic derangement itself. Hyperglycemia and acidemia are important predisposing factors to this latter effect and are reversed substantially by normalization of pH and blood glucose levels. Vascular disease related to diabetes may also further impair the local inflammatory response and may also impair the tissue penetration of antibiotics.

Neuropathy, both peripheral and autonomic, also contributes to the risk of foot infections and ulceration, as well as to certain other infections. Sensory peripheral neuropathy masks the recognition of trauma. Minor local trauma in patients with diabetes-associated peripheral neuropathy may result in skin ulcers, which, in turn, lead to diabetic foot infections. Skin lesions are often either unnoticed or ignored until infection occurs. Autonomic neuropathy contributes to the etiology of diabetic foot infections by mechanisms such as decreased sweating, which predisposes to drying and fissuring of the skin, and by further exacerbating abnormalities in the control of the microcirculation. Both sensory and motor neuropathy can lead to deformity and alter the dynamics of the function of the foot. Fuller discussion of the etiologic factors related to sepsis and the diabetic foot is provided in Chapter 44.

Patients with diabetes-associated autonomic neuropathy may develop urinary retention and stasis in association with loss of innervation to the bladder. This predisposes them to urinary tract infections. This risk is particularly high in females. Autonomic neuropathy can also impair the function of the gastrointestinal tract, predispose to certain gastrointestinal tract infections and contribute to risk of aspiration pneumonia in the context of gastroparesis. Renal papillary necrosis can also contribute to the risk of renal failure as well as to infection within the urinary tract.

Thus, a number of factors contribute to the vulnerability of people with diabetes to infections. In addition to the abnormalities of the immune response, vascular disease and neuropathy can greatly enhance susceptibility (e.g. in the lower limb and urinary tract). Hyperglycemia per se may specifically heighten susceptibility to certain fungal and bacterial infections.

### Organism-specific factors

Certain organisms may show increased adherence to diabetic cells [12] and others may demonstrate increased virulence in hyper-

glycemic environments. Specific factors that predispose people with diabetes to infection with specific organisms include the following examples.

#### *Candida albicans* and fungi

Glucose-inducible proteins produced by *Candida albicans* are homologous to a complement receptor on phagocytes. These proteins may promote adhesion of *C. albicans* to buccal or vaginal epithelium. This adhesion, in turn, impairs phagocytosis, giving the organism an advantage over the host [12].

Ketone reductases produced by *Rhizopus* species allow these species to thrive in high glucose, acidic conditions typically present in patients with diabetic ketoacidosis [23].

#### *Klebsiella* spp.

A bacterial genus of note in the context of diabetes is *Klebsiella*. *Klebsiella* infections are the second most common causes of Gram-negative sepsis (after *E. coli*). In a report from Taiwan, diabetes was the most commonly associated underlying condition in patients presenting with community-acquired *K. pneumoniae* bacteremia (whereas neoplastic diseases were more commonly associated with nosocomial infections) [24]. The percentage of patients with underlying diabetes was 49%, which is even higher than in earlier reports [25,26]. Apart from the high proportion with diabetes, associations were also observed with serotype K1 (associated with impaired phagocytosis), liver abscess and other metastatic complications (endophthalmitis, meningitis, brain abscess) [24]. Primary liver abscess in other parts of Asia is also increasing in incidence, with 40% reportedly associated with diabetes [27]. Bacteremia is present in 50%, and 8–10% have metastatic complications (endophthalmitis, meningitis, brain abscess, pneumonia, skin and soft tissue infections, lung abscess, septic arthritis, renal abscess and prostatic abscess).

#### Melioidosis

A combination of organism-specific factors together with the changes in innate immunity may explain the increased susceptibility of people with diabetes to melioidosis. About 50% of cases of melioidosis occur in people with diabetes. The responsible organism, *Burkholderia pseudomallei*, has been shown to be selectively resistant to phagocytosis compared to *Salmonella typhimurium* and *E. coli* in subjects with diabetes.

In a study from Thailand, a country where melioidosis is relatively common, neutrophil responses to *B. pseudomallei*, in both healthy subjects and people with diabetes showed that *B. pseudomallei* displayed reduced phagocytosis by neutrophils compared to *S. enterica typhimurium* and *E. coli*. In addition, intracellular survival of *B. pseudomallei* was detected throughout a 24-hour period, indicating intrinsic resistance of *B. pseudomallei* to killing by neutrophils. Furthermore, neutrophils from subjects with diabetes displayed reduced migration in response to IL-8 and an inability to delay apoptosis. Thus, *B. pseudomallei* appears to be intrinsically resistant to phagocytosis and killing by neutrophils. When added to the impaired migration and

apoptosis seen in diabetes, the combination seems sufficient to explain the increased susceptibility to melioidosis in people with diabetes [28].

### **Bidirectionality: the effect of infections on diabetes**

Bidirectionality exists in the relationship between diabetes and infections. The effect of infections upon diabetes includes the effects of certain infections on the etiology and pathogenesis of diabetes itself, adverse effects upon hyperglycemia in established diabetes and exacerbation of diabetes complications. The importance of the potential adverse effects upon hyperglycemia in established diabetes needs to be stressed. Infections remain an important predisposing cause of both diabetic ketoacidosis and hyperosmolar hyperglycemia syndrome.

The importance of certain viral infections in the possible etiology of diabetes has received increasing attention in recent years with respect to both T1DM and T2DM.

Viral infections have been implicated in the etiology of T1DM for many years. Although this complicated topic is beyond the general scope of this chapter and is considered in detail in Chapters 3 and 9, it is noteworthy that type 1a (autoimmune) diabetes is increasing in prevalence globally, providing strong evidence that environmental factors are involved in the clinical expression of the disease. Viruses have long been included in the list of putative environmental triggers. Enteroviruses (especially coxsackie B viruses, B4 in particular), rubella, mumps, rotavirus, parvovirus and cytomegalovirus have all been implicated and continue to be reported [29,30]. Although correlations between the presentation of diabetes and the occurrence of a preceding viral infection have been recognized, a direct causal relationship, with fulfillment of Koch postulates, between viral infection and the diabetogenic process, remains difficult to prove, possibly because other inflammatory factors are also required. In this context, it is interesting to note that the process may be associated with a dominant CD4 T-helper type 1 immune response, whereas the dominance of a T-helper type 2 response, as seen in the face of certain infectious and parasitic agents, may protect against T1DM and other autoimmune diseases. Thus, the increasing freedom from such infections, especially in developed areas of the world, may allow the increased expression of an underlying genetic predisposition, and infection by certain viruses, such as the coxsackie B viruses, may then be associated with the appearance of (and persistence of)  $\beta$ -cell antigens, mediated by mechanisms such as molecular mimicry and activation of Toll-like receptors. Lack of exposure to infection and infestation in early childhood appears to dilute the ability of the innate immune system to withstand autoimmune responses and challenges. T1DM is not alone in this respect and the general concept has become known as the “hygiene hypothesis” [31].

The high prevalence of T2DM in association with hepatitis C infection and the progression of certain diabetes complications (e.g. diabetic nephropathy) in association with hepatitis B are other noteworthy examples. The treatment of HIV/AIDS with protease inhibitors predisposes to diabetes, metabolic syndrome

and increased cardiovascular risk. The public health implications of these issues are considerable given the concordance of the diabetes epidemic with these other highly prevalent diseases.

All infections, especially if severe, have the potential to exacerbate hyperglycemia by a number of mechanisms (e.g. worsening of insulin resistance by production of “stress” or counter-regulatory hormones and production of cytokines such as IL-1 and tumor necrosis factor) [32]. Infection remains a major factor in the pathogenesis of diabetic ketoacidosis or hyperosmolar hyperglycemia. Infections can also precipitate hypoglycemia if symptoms, such as anorexia, nausea and vomiting, lead to reduced food intake. Malaria and its treatment with quinine can also produce hypoglycemia.

### **Hepatitis C**

A number of reports from North America, Europe and the Middle East consistently demonstrate an increased prevalence of diabetes (ranging from 24% to 62%) among patients with chronic hepatitis C virus (HCV) infection compared both with persons with other forms of liver disease and with other control groups. Among HCV-infected individuals reported prevalence of diabetes (21–50%) is much higher when compared with other forms of chronic liver disease (2–12%) and with control subjects (2–6%) [33–38].

In the USA, T2DM occurs more often in persons with HCV infection who are older than 40 years of age, particularly in the range of 40–49 years where the relative risk ratio is 3.77. Apart from age, the prevalence of diabetes is greatest in subjects who are non-white, have a high body mass index, are below the poverty level and have a family history of diabetes. The prevalence of T1DM appears to be unaffected [39].

The suggestion that HCV infection predisposes to T2DM as a result of the progressive liver damage is supported by the observations that the association is most marked in the older age groups (>40 years), and that there is higher risk among patients with advanced HCV cirrhosis. The presence of diabetes is also associated with worse hepatic fibrosis; however, the higher prevalence of diabetes compared to other forms of liver disease suggests an additional mechanism specific to hepatitis C. Tumor necrosis factor  $\alpha$  has been suggested as one possible candidate for this role [40].

HCV infection is also strongly associated with diabetes among intravenous drug users and this is independent of HIV infection or use of highly active antiretroviral therapy (HAART) [41]. Thus, it is important to monitor patients with chronic HCV infection for development of diabetes. Bidirectionality again applies with weight loss and good glycemic control improving hepatitis outcomes.

### **HIV/AIDS**

Although HIV/AIDS has not in itself been reported to increase the risk of diabetes, the treatment of HIV/AIDS with HAART predisposes to T2DM, other metabolic risks and premature cardiovascular disease. This has become a major problem in the

management of this already very complicated disease. The effects occur via disturbances in lipid homeostasis and fat partitioning (lipodystrophy), insulin resistance, insulin secretion and mitochondrial function. The underlying cellular mechanisms are complex and incompletely understood. Combination HAART for HIV-1 infection is frequently complicated by lipodystrophy (peripheral fat loss and relative visceral obesity), dyslipidemia and insulin resistance. HIV-infected adults receiving HAART have an increased incidence of elevated blood pressure and cardiovascular morbidity.

Whether antiretroviral therapy-naïve patients have altered risk of subsequent CVD or T2DM is unclear, particularly in light of emerging data indicating that rates of CVD may also be higher in people with HIV who are not treated with antiretroviral therapy.

Exposure to antiretroviral therapy for more than 1 year is associated with increasing risk of diabetes. Although the risk is greatest among individuals treated with a protease inhibitors (PI) (attributed to a direct inhibitory effect on cellular glucose transport by PI medications) [41], an increased prevalence of diabetes among those receiving a PI-sparing regimen has also been found and insulin resistance has been reported among PI-naïve persons with HIV infection, in association with fat redistribution. Nucleoside analog-induced mitochondrial toxicity is probably of importance. Cessation of PI appears to have little beneficial effect in reversing lipodystrophy, although it may improve the metabolic control in diabetes. Alteration of thymidine analog nucleosidase reverse transcriptase inhibitors may, however, confer benefit on lipodystrophy [42,43].

In a study of almost 900 HIV-infected patients, initiation of antiretroviral therapy was evaluated for prevalence and incidence of metabolic syndrome (using the National Cholesterol Education Program, Adult Treatment Panel III [NCEP ATP-III] and the International Diabetes Federation [IDF] criteria) and subsequent diagnosis of CVD and T2DM over a 3-year period. The prevalence of baseline metabolic syndrome was 8.5% and 7.8% (ATP-III and IDF criteria, respectively). Substantial progression to metabolic syndrome occurred within 3 years following initiation of antiretroviral therapy. The presence of metabolic syndrome at baseline was significantly associated with an increased risk of T2DM while metabolic syndrome occurring during the 3-year period was associated with an increased risk of both CVD and diabetes [44,45].

In another study [46], 123 of 6513 HIV-infected persons developed diabetes during 27798 person-years of follow-up, resulting in an incidence of 4.4 cases per 1000 person-years of follow-up. An increased incidence rate ratio was found for male subjects, older age, obesity, Afro-American or Asian ethnicity. A weaker, although still significant, association of the incidence rate was also found with Centers for Disease Control and Prevention (CDC) disease stage C. Strong associations were observed with treatment using nucleoside reverse-transcriptase inhibitors (NRTI), NRTI plus PI and NRTI + PI + non-nucleoside reverse-transcriptase inhibitors (NNRTI), but not with an NRTI + NNRTI regimen.

Lipodystrophy is a crucial aspect of the association of HAART with insulin resistance, leading to relative preponderance of visceral fat, hepatic steatosis and fat deposition at other “ectopic” sites. HIV-infected persons with lipodystrophy, compared with those without lipodystrophy, have a reduction in plasma adiponectin and adipose tissue adiponectin mRNA levels of approximately 50%, correlating with insulin resistance and increased cytokine levels [45].

Because baseline and incident metabolic syndrome identifies individuals at risk for both CVD and T2DM, evaluation in all patients commencing HAART is warranted. A fasting plasma glucose concentration should be checked before initiation of therapy and monitored every 3–6 months, especially in patients receiving changes in treatment or who have significant risk factors for insulin resistance. An oral glucose tolerance test may be required, particularly in the presence of risk factors or equivocal glucose concentrations. Dietary guidelines established for the general population remain relevant for the management of glucose disorders in the context of HIV infection. Weight loss through increased activity and caloric restriction should be recommended for overweight HIV-infected patients.

Metformin improves insulin sensitivity in patients with HIV lipodystrophy and is an effective antidiabetic medication; however, it should be used with caution in patients receiving an NRTI, and in persons with impaired renal function because of the possibility of lactic acidosis. Thiazolidinediones also improve insulin sensitivity in patients with HIV lipodystrophy, although rosiglitazone treatment may worsen hyperlipidemia. Insulin therapy should be used according to standard recommendations. Substitution of an NNRTI for a PI has been observed to improve insulin resistance but this needs to be balanced against any risk to virus control. Careful discussion with the HIV physician is therefore essential and it may be deemed safer to increase the antihyperglycemic treatment rather than changing the components of the HAART regime [47–49].

### Hepatitis B

Although, in contrast to hepatitis C, hepatitis B virus (HBV) has been less consistently associated with an increased prevalence of diabetes, the presence of hepatitis B markers may nevertheless influence the natural history of diabetes and its complications and the relationship may be bidirectional as the presence of diabetes is associated with more severe fibrosis and cirrhosis. However, there is uncertainty as to cause and effect given the general association of diabetes with liver cirrhosis [50].

Chinese HBV-infected patients with T2DM have been shown to be more likely to develop end-stage renal disease than non-HBV infected patients with T2DM (8.7 vs 6.4%) with a hazard ratio of 4.5. The association of chronic HBV infection with increased risk of end-stage renal disease was independent of other potential confounding factors. HBV-infected patients also reported earlier onset of diabetes and had a higher frequency of diabetic retinopathy than non-HBV-infected patients (28%

compared to 22%). Cardiovascular complications appeared unaffected [51].

---

## Specific infections either strongly associated with diabetes or in which the presence of diabetes is important

### Infections involving the head and neck

Two head and neck infections that are associated with high rates of morbidity and mortality, malignant otitis externa and rhinocerebral mucormycosis, are particularly noteworthy in people with diabetes.

#### Malignant otitis externa

Malignant otitis externa is an invasive infection of the external auditory canal and skull base that typically arises in elderly people with diabetes. An early series of patients was described in 1968 [52]. Most cases (86–90%) have been reported in patients with diabetes. *Pseudomonas aeruginosa* is nearly always the causal organism (>98% of cases) although *Aspergillus* species are occasionally responsible. Microangiopathy in the ear canal has been suggested as a predisposing factor.

Presenting features include severe intractable headache and otalgia, otorrhea and deafness. Patients often report a duration of weeks to months of these symptoms. Intense cellulitis is combined with edema of the ear canal. Focal neurologic signs and cranial nerve palsies may occur. The pain may involve the temporomandibular joint and be aggravated by chewing. Osteomyelitis of the skull base and temporomandibular joint is a potentially life-threatening complication and the mortality in the pre-antibiotic era exceeded 50%. On otoscopy, granulation tissue may be seen in the floor of the ear canal, often in association with edema and intense cellulitis. The tympanic membrane is usually intact. Computed tomography (CT) and magnetic resonance imaging (MRI) studies are essential for defining the extent of bone and soft tissue involvement, together with the bony destruction of the skull base that may be seen in advanced cases.

Systemic antipseudomonal antibiotics are the primary therapy. Early referral to an otorhinolaryngologist is essential and allows diagnostic confirmation by surgical biopsy. Débridement of necrotic tissue can also be carried out if necessary, although the introduction of effective antibiotic therapy has reduced the requirement for surgery. With the introduction of quinolones, the cure rate has increased to 90%, with few adverse effects reported and oral therapy rendered possible. Prolonged treatment for 6–8 weeks is recommended, as for osteomyelitis [53]. Thus, treatment consists of prolonged administration (6–8 weeks) of an antipseudomonal agent (typically, an orally administered quinolone). The emergence of ciprofloxacin resistance is a potential problem. It is recommended that systemic quinolone use be reserved for treatment of invasive ear infections. An example of invasive aspergillosis involving the skull base is shown in Figure 50.1.

#### Mucormycosis (zygomycosis)

The term mucormycosis is used to describe a variety of infections caused by fungi of the *Rhizopus* and *Mucor* species which belong to the order Mucorales (class Zygomycetes). These fungi are ubiquitous saprophytes and infections produced by them are essentially confined to immunocompromised individuals. The fungi have a predilection to invade blood vessels. Ketone reductases produced by *Rhizopus* spp. allow them to thrive in high glucose, acidic conditions as are typically present in patients with diabetic ketoacidosis [23]. Rhinocerebral, pulmonary, gastrointestinal, cutaneous and disseminated forms of the infection are described. The rhinocerebral manifestation (and with sinus involvement) has the highest frequency and is potentially the most lethal in the context of people with diabetes (Figure 50.2).

The close connection with diabetes is becoming increasingly diluted as other causes of an immunocompromised state become increasingly common or survivable (notably hematologic cancer and bone marrow transplant recipients). Nevertheless, diabetes remains the most common underlying factor in most reports. In a review of 49 cases of pulmonary mucormycosis, diabetes was the underlying cause of the immunocompromised state in 9 (25%) [54]. In another study, the prevalence and mortality in people with diabetes were 36% and 44%, respectively [55]. It typically, although not exclusively, occurs in association with ketoacidosis, severe hyperglycemia and/or a debilitated state.

Rhinocerebral mucormycosis is a life-threatening fungal infection. Untreated it is universally fatal; if recognized early there is a 20% survival rate. Presenting features include facial or ocular pain and nasal stuffiness. Generalized malaise and fever may also be present. Intranasal black eschars or necrotic turbinates may be found and, if present, provide sites that can be biopsied. Treatment consists of surgical débridement of the involved sinuses and prolonged intravenous therapy with amphotericin B or alternative antifungal agents such as some newer azoles.

Acute invasive fungal sinusitis can also result from aspergillosis, as can malignant otitis externa. Biopsy confirmation of the microbiologic diagnosis is therefore useful [56].

#### Endophthalmitis

Secondary endophthalmitis may occur as a rare but devastating metastatic complication of septicemia and in this setting is almost entirely confined to people with diabetes. *E. coli* and *Klebsiella* are the more likely pathogens and urinary tract infection is reported as the most common underlying source of infection [57].

People with diabetes are also more prone to postoperative infections following eye surgery or infections secondary to eye trauma. Overall, the most common cause of endophthalmitis is as a postoperative complication of cataract surgery [58], a procedure commonly carried out in patients with diabetes.

#### Periodontal disease

People with diabetes are very prone to periodontal disease compared to the non-diabetic population, with a two- to fourfold

**Figure 50.1** Magnetic resonance imaging (MRI) scan of skull base in a 59-year-old male with a 20-year history of diabetes (with nephropathy), treated with insulin who developed severe extensive invasive aspergillosis. He presented with headache and vertigo followed by left sixth and seventh nerve palsies. He subsequently developed bilateral sensorineural hearing impairment and blindness secondary to extensive skull base infiltration by the invasive aspergillosis. MRI demonstrated enhancing soft tissue closely related to the left posterolateral wall of the nasopharynx with parapharyngeal, skull base, perineural and dural infiltration. Biopsy showed inflamed fibrous tissue with degenerated fungal filaments. Culture confirmed *Aspergillus flavus*. He is receiving lifelong therapy with voriconazole. He remains blind. MRI of skull base in the axial plane with:

(a) T1-weighted; (b) fat-saturated T2-weighted; and (c) post-gadolinium T1-weighted sequences. These show marked dural thickening (arrows) with enhancement in the left posterior cranial fossa. An abnormal signal with enhancement is also noted in the adjacent left petrous apex (open arrow). Note also the presence of inflammatory fluid within both mastoid air cells (arrowheads). Acknowledgements to Dr. K.T. Wong, Consultant Radiologist, for preparation and reporting of the figures, and to Professor A. Ahuja for permission to use the figures. Both are placed at the Department of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Chinese University of Hong Kong, Hong Kong.

relative increase in prevalence and a particular predilection for those whose diabetes is poorly controlled.

The associated periodontitis, if left untreated, can result in loss of attachment of ligament fibers and supporting alveolar bone, which in turn can increase the mobility of teeth and necessitate extraction. Tooth abscesses and episodes of bacteremia also become more likely. Diabetes may complicate the pathogenesis of periodontitis by causing abnormalities in the vasculature of the gingival tissues, in addition to the effects upon immune responses described earlier. Aggressive and difficult to treat forms of periodontitis are also more common in adults with diabetes. Periodontal health is influenced by glycemic control to the extent that the prevalence of periodontal diseases among people with well-controlled diabetes is not increased [59].

A bidirectional relationship has also been suggested whereby the presence of periodontal disease adds to the overall burden of chronic inflammation, thereby adversely affecting glycemic

control as well as overall risk of CVD and diabetic nephropathy.

### Respiratory tract infections and tuberculosis

The increased risk of mortality and morbidity from community-acquired pneumonia has been alluded to earlier and includes pneumonia either directly resulting from, or secondary to, common infections such as influenza and *S. pneumoniae* and also includes *Legionella* infections [60]. The risk of bacteremia following pneumococcal infection is increased [61]. Viral shedding may be more prolonged following influenza infections in subjects with co-morbidities including diabetes, which may influence decisions regarding initiation and duration of antiviral therapy [62].

Lower respiratory tract infections, resulting from *S. aureus* and Gram-negative organisms such as *K. pneumoniae*, are more

**Figure 50.2** Rhinocerebral mucormycosis. Typical appearance in a 45-year-old woman with poorly controlled type 1 diabetes. Periorbital and facial swelling had been present for 3–4 days before admission. Major reconstructive surgery was required. From Rupp ME. Rhinocerebral mucormycosis. *N Engl J Med* 1995; **333**:564.

common in people with diabetes. Melioidosis has also been discussed above as an example of organism-specific factors that interact with diabetes to increase risk of infection. People with diabetes are also thought to be at increased risk for *S. aureus* pneumonia and this may result from the well-documented higher rates of nasal carriage of *S. aureus* in people with diabetes (up to 30%) compared to 11% in healthy individuals [63].

Any respiratory infection in patients with diabetes is associated with increased mortality. In the USA, people with diabetes are reportedly 4 times more likely to die from pneumonia or influenza than are people without diabetes [64].

The importance of diabetes as the most common underlying predisposing factor for thoracic empyema has also long been recognized. A recent report indicates that *Klebsiella* are again notable as the most common pathogens, while other important pathogens include streptococci, *S. aureus* and anaerobes [65].

### Diabetes and tuberculosis

An association between diabetes and tuberculosis has been widely accepted in the past, albeit with varying estimates of overall risk

(encompassing two- to 11-fold) and variable levels of evidence. The importance of the association is often neglected in the larger arena of public health, for example when compared with the risk of tuberculosis associated with HIV/AIDS.

Diabetes has been confirmed in several recent studies to be associated with increased risk of active tuberculosis. The association of tuberculosis with diabetes presumably reflects impaired innate immunity as well as (in this case at least) a reduced adaptive T-helper type 1 response with reduced secretion of T-helper type 1-related cytokines. A recent review of 13 observational studies published between 1992 and 2007 [66] confirms an increased risk of tuberculosis regardless of study design, population, geographic region and background incidence of tuberculosis, the overall increase in risk being approximately threefold. The risk was greatest among younger people, in areas of high tuberculosis incidence and in non-North American populations. The public health impact may be particularly high in countries such as India and China, which are at the forefront of the diabetes epidemic. The impact of the diabetes epidemic on tuberculosis incidence in India has been modeled by Stevenson *et al.* [67]. They suggest that diabetes accounts for 14.8% (range of uncertainty 7.1–23.8%) of pulmonary tuberculosis and 20.2% (8.3–41.9%) of smear-positive tuberculosis, with an excess risk of the latter in urban areas. This can be compared to an overall estimate of 3.4% for the proportion of adult tuberculosis incidence ascribed to HIV/AIDS in India [68]. Extrapulmonary or unusual manifestations of tuberculosis are also more common in the context of diabetes. In pulmonary tuberculosis, the presence of diabetes, as well as being the most common underlying comorbidity, has also been reported to increase the risk of cavitary nodules [69].

In addition to the increased risk, there is also evidence that diabetes leads to worse tuberculosis outcomes and has adverse effects upon responses to treatment. A study from Indonesia indicated a doubling of the risk of remaining smear positive at the end of treatment for pulmonary tuberculosis in people with diabetes compared to those without diabetes [70]. The same group in Indonesia has also shown that the presence of T2DM may adversely affect the bioavailability of rifampicin and lead to an increase in dose requirement [71]. In Hong Kong, an area with much pioneering experience of tuberculosis treatment since the 1950s, the Centre for Health Protection recognizes the risk of a worse outcome, and its guidelines recommend a more prolonged period of treatment for people with diabetes compared to those without. For example, when treating pulmonary tuberculosis using a standard regimen of four drugs for the first 2 months followed by two drugs, a total treatment duration of 9 months, rather than 6 months, is recommended. Bidirectionality again needs to be remembered because the presence of tuberculosis is very likely to have a negative impact upon hyperglycemia. Two examples of individuals with tuberculosis in association with diabetes are shown in Figure 50.3. It is perhaps noteworthy that neither was receiving regular follow-up care for the diabetes.

**Figure 50.3** (a) A 49-year-old man with diabetes and obesity, not receiving regular follow-up, and presenting with hemoptysis, sputum smear positive for tuberculosis (TB). Chest X-ray shows extensive right upper lobe pneumonic changes. (b) A 30-year-old man with diabetes but no regular follow-up, presents with a cough for 4 months with weight loss, sputum smear positive for TB. Chest X-ray shows extensive bilateral and cavitary disease.

## Infections of the urinary tract

### Epidemiology and risk factors

Urinary tract infection (UTI) is frequently encountered in people with diabetes. Asymptomatic bacteriuria also occurs with a higher frequency. One study has demonstrated a prevalence rate for asymptomatic bacteriuria of 26% in women with diabetes, compared to 6% in women without diabetes, a threefold increase [72,73].

A randomized controlled trial of antibiotic treatment for asymptomatic bacteriuria revealed no differences in the development of symptomatic UTI, time to onset of symptoms, risk of pyelonephritis or need for hospitalization [72]. Thus, diabetes does not appear to warrant either screening for, or treating, asymptomatic bacteriuria. This remains a controversial issue and, from the practical standpoint of the physician, ascertaining “asymptomatic status” with confidence, particularly in older women with diabetes, can be difficult or impossible.

A number of studies confirm the increased risk of symptomatic UTI in association with diabetes. In one study of more than 600 women [74], those with T2DM had an overall risk of 20%. A recent study has extended the risk to include recurrence rates as well as risk to males [1].

Diabetes is a risk factor for cystitis in postmenopausal women, leading to a two- to threefold increase in risk [75]. An increased prevalence of asymptomatic vaginal *E. coli* colonization has also been reported in postmenopausal women with diabetes who are receiving insulin treatment. This vaginal colonization may be mediated by greater adherence of type 1 fimbriated *E. coli* to uroepithelial cells in women with diabetes, may be related to impaired cytokine secretion or may reflect a reduced polymorphonuclear inflammatory response [72,76].

Diabetes increases the risk of complications of UTI, serious or unusual forms of infection, and need for prolonged hospitalization [77]. It is a risk factor for acute pyelonephritis in women (odds ratio 4.1), and is the strongest of the various risk factors that have been examined. Among hospitalized patients, 16.7% reported having diabetes compared with 5.8% of non-hospitalized patients [72]. A three- to fivefold increase in risk exists in people with diabetes aged less than 44 years [74].

Diabetic autonomic neuropathy is an important predisposing factor to UTI. This affects the sympathetic and parasympathetic afferent fibers to the bladder and causes decreased reflex detrusor activity. Impaired bladder sensation results in bladder distension, increased residual urine volume, vesicoureteric reflux and recurrent upper UTI [78,79]. Some cases are urinary catheter or instrumentation related [72,78,79]. Additional host factors

predisposing to UTI include: glycosuria, sexual intercourse, history of previous UTI, obstruction, longer duration of diabetes, poor glycemic control, decreased urinary cytokine excretion, increased *E. coli* adhesion, macroalbuminuria and neutrophil dysfunction [78,79]. Renal papillary necrosis and chronic renal failure may also contribute to the complex array of risk to the urinary tract.

### Microbiology

*E. coli* is the most commonly reported organism. *Klebsiella* is also a problem, especially among patients with uncommon severe forms of UTI, such as emphysematous pyelonephritis. Other organisms include *Acinetobacter* species, group B streptococci and *P. aeruginosa* [72]. The latter should be suspected particularly if there is a history of recent instrumentation or hospitalization.

*C. albicans* in the urine can be associated with incomplete bladder emptying and high glucose concentrations in the urine. Diabetes has been shown to be present in 39% of hospitalized patients with funguria [72]. Candiduria may signify contamination of the urine specimen, benign saprophytic colonization ( $\pm$  catheter), or may be indicative of true invasive infection of the upper and/or lower urinary tract [80]. Diabetes is also a risk factor for multidrug-resistant UTI, perhaps related to recurrent or increased exposure to antibiotics [81].

### Clinical features of urinary tract infection in diabetes

Uncomplicated UTIs may be asymptomatic. Symptoms, when present, are generally similar to those experienced by the non-diabetic population. Infection of the lower urinary tract usually presents as dysuria, frequency or urgency. Fever, flank pain, chills and rigors, vomiting and costovertebral angle tenderness raise the suspicion of upper tract infection with renal involvement. Bilateral renal involvement is also more frequent and bilateral pyelonephritis is twice as common in people with diabetes. Bacteremia may be present.

A poor response to appropriate antibiotic therapy should raise the suspicion of the presence of complications. These may include renal papillary necrosis and perinephric abscess. The symptoms of renal papillary necrosis include flank and abdominal pain (which mimic both pyelonephritis and ureteric colic), together with fever. Renal functional impairment is commonly found. Features such as a persisting high fever despite antibiotic treatment, hypotension or septicemic shock, and a palpable tender renal mass may point to the presence of a perinephric abscess. In one series of patients with perinephric abscess, 36% had diabetes [82].

### Emphysematous cystitis and emphysematous pyelonephritis

Although uncommon, the severity of these infections warrants their special consideration. Emphysematous cystitis is an uncommon complication of lower UTI characterized by the presence of gas in the bladder wall (Figure 50.4). It presents with hematuria, pneumaturia and abdominal pain. Plain abdominal radiography

**Figure 50.4** Example of emphysematous cystitis in a 67-year-old woman with diabetes and end-stage renal disease (ESRD) requiring hemodialysis. She developed septic shock with lower abdominal tenderness. Blood and urine cultures show *E. coli*. Computed tomography (CT) scan shows air pockets inside the urinary bladder (arrows). From Sun JT, Wang HP, Lien WC. Life-threatening urinary tract infection. *Q J Med* 2009; **102**:223, with permission.

or CT scan are indicated to detect the presence of gas. Surgical intervention may be required in up to 20% of cases and mortality is reportedly up to 10%. Emphysematous cystitis requires aggressive treatment in hospital and intravenous antibiotic therapy [83].

Emphysematous pyelonephritis is an infection that is almost exclusively limited to people with diabetes, who account for 90% of cases (Figure 50.5). It predominantly occurs in females and carries a grave prognosis [84]. It is a necrotizing infection of the renal parenchyma and surrounding areas which can be focal or diffuse and may spread to the collecting system or perinephric tissues. The formation and presence of gas in the renal parenchyma, collecting system or perinephric area may be contributed to by fermentation of glucose when present at high concentra-

**Figure 50.5** Emphysematous pyelonephritis: computed tomography tomography (CT) scan demonstrating gas in the right ureter (indicated by arrow) and a moderate hydronephrosis in a 34-year-old woman with type 1 diabetes. The responsible organism was *E. coli*. She responded to antibiotics and drainage by nephrostomy, followed by ureteroscopy during which obstructing necrotic slough was removed. From Clark T, Abdalkareem M, Ali K. A case of emphysematous pyelonephritis. *J R Soc Med* 2009; **102**:75–77, with permission.

tions, by the presence of gas-forming organisms and by impaired renal perfusion. Mixed acid fermentation of glucose by Enterobacteriaceae has been suggested as a major pathway of gas formation [85].

A lengthy list of pathogens has been reported; however, as with other UTIs in the context of diabetes, the most common pathogens are *E. coli* (in 70%) and *Klebsiella* (in 30%). Vasculopathy of the renal circulation is believed to be a major factor in the pathogenesis, once again emphasizing the importance of vascular disease in the clinical manifestation of the more severe forms of infection related to diabetes.

Presenting features include fever, abdominal pain, nausea and vomiting and drowsiness or stupor. As a result of these non-specific symptoms the diagnosis is often delayed. The presence of features such as renal angle tenderness, pyuria or pneumaturia should lead to a high index of suspicion. A flank mass may be detected, often accompanied by crepitus. Disseminated intravascular coagulation, septicemic shock and acute renal failure are all associated with a poor prognosis.

The diagnosis is established by radiologic identification of gas in renal tissue. This is best demonstrated by CT. The plain abdominal X-ray sensitivity is lower. Ultrasonography can also be used, but CT should be regarded as the investigation of choice. In a report of 46 cases in Taiwan, 96% had diabetes with HbA<sub>1c</sub> higher than 8% (>64 mmol/mol), and 22% also had features of obstruction [86]. Mortality can exceed 50% in patients treated with antibiotics alone. Medical therapy alone is therefore not

recommended. Patients may require percutaneous drainage (for localized cases with abscess formation or obstruction) or nephrectomy (in extensive cases). The advent of CT has allowed a more rational approach to the use of these surgical interventions, by allowing more accurate delineation of factors such as gas distribution, obstruction and abscess formation [87].

### Diagnosis of urinary tract infection

A high index of suspicion is required, with particular attention in the presence of diabetic neuropathy, renal dysfunction or renal papillary necrosis. Microscopic examination of the urine may reveal leukocytosis and pyuria. Urine culture and sensitivity should always be carried out. In febrile patients or in suspected upper tract infection, blood culture is essential to detect bacteremia or Gram-negative septicemia.

Plain abdominal radiography is useful to help rule out obstructive uropathy, stones and emphysematous infection. Ultrasonography is a sensitive, safe and inexpensive technique for initial screening. Ultrasound or CT can confirm the diagnosis of renal abscess, mass, presence of air in the urinary tract and the extent of perinephric spread of infection. The diagnosis of renal papillary necrosis may require ultimate confirmation by retrograde pyelography.

### Treatment of urinary tract infection

Treatment should be tailored to take account of local antibiotic resistance patterns (if known), as well as previous history of UTI, previous antibiotic exposure (and possible allergies) together with other risk factors such as recent instrumentation or catheterization. Uncomplicated UTI may be treated with co-trimoxazole (if the local resistance rate is <15–20%), fluoroquinolones, nitrofurantoin, ampicillin, amoxicillin +/- clavulanate, or sulbactam. Increasing resistance to fluoroquinolones has been noted recently. Co-trimoxazole may potentiate the hypoglycemic effect of some oral antihyperglycemic agents and should be used with caution.

Complicated infections require hospitalization and parenteral antibiotics. Intravenous therapy is continued until fever resolves, following which oral antibiotics can be substituted to complete at least 2 weeks of treatment. Second or third-generation cephalosporins,  $\beta$ -lactam/ $\beta$ -lactamase inhibitor combinations, or fluoroquinolones may need to be considered in patients with risk factors, and the possibility of infection with *Pseudomonas* may influence this choice, particularly in the setting of nosocomial exposure or recent instrumentation.

Because upper urinary tract involvement with UTI may be up to 5 times more frequent in patients with diabetes compared with people without diabetes and may be unsuspected or asymptomatic. More prolonged courses of antibiotics (7–14 days) may be considered wise even in the context of apparently uncomplicated UTI [84]. This may also reduce the risk of subsequent relapse. Repeated urine culture to document bacteriologic cure 2–4 weeks post-treatment is advisable given high rates of relapse or treatment failure.

Distinguishing *Candida* infection from colonization is difficult. Removal of an indwelling catheter, if present, is recommended as an initial intervention. Antifungal agents such as fluconazole may be considered in patients with invasive disease.

## Intra-abdominal infections other than those within the urinary tract

### Emphysematous cholecystitis

Cholecystitis is probably no more common in patients with diabetes than in the general population; however, severe fulminating infection, especially with gas-forming organisms (enteric Gram-negative rods and anaerobes) is more common.

Emphysematous cholecystitis is a rare variant of acute cholecystitis caused by ischemia of the gallbladder wall and infection with gas-producing organisms. It is strongly associated with diabetes (35–55% of cases have underlying diabetes) [88].

Gangrene and perforation of the gallbladder are more frequent, and the overall mortality is substantially higher (at least 15% compared to less than 4%) when compared with acute cholecystitis.

*Clostridium perfringens*, *E. coli* and *Bacillus fragilis* are the most frequently encountered pathogens. Emphysematous cholecystitis is thought to result from acalculous cystic duct obstruction, associated with inflammatory edema, which can eventually lead to cystic artery occlusion. Colonization by gas-forming organisms contributes to necrosis of the mucosa, venous congestion, gangrene and, eventually, gallbladder perforation. Gallstones are present in only about half of patients.

The early clinical manifestations may be indistinguishable from those of acute cholecystitis. Right hypochondrial pain and fever are present in all cases, and other important features include nausea and vomiting, septic shock, jaundice and peritonitis. Toxicity is marked, and jaundice may develop in the later stages from biliary obstruction. The gallbladder may be palpable in 25–50% of patients. It should be remembered that Murphy sign (pain and inspiratory arrest on palpation of the right upper quadrant) may be absent in patients with underlying diabetic neuropathy. Crepitus on palpation is an ominous sign. Additional complications include pericholecystic abscess, gallbladder necrosis, generalized or biliary peritonitis, and localized perforation sealed by the omentum.

Plain abdominal X-ray or ultrasound can lead to diagnosis in 95% of cases. In a plain radiograph, gas may be visible in the gallbladder lumen or within the gallbladder wall as a gaseous ring. CT is the most sensitive modality for the detection of intraluminal or intramural gallbladder gas and also demonstrate local complications such as pericholecystic inflammatory changes, abscess formation or perforation.

Initiation of appropriate antibiotics and early cholecystectomy is crucial. Emergency surgery is needed because of the high incidence of gangrene and perforation [89,90].

### Liver and other intra-abdominal abscesses

Although liver abscesses may occur in many situations not involving diabetes, the issue is of sufficient importance to justify inclusion in this section.

In keeping with the susceptibility to *Klebsiella* infections described earlier, associations between diabetes and *K. pneumoniae* liver abscess have been reported, notably from Taiwan and Korea [91–93]. Examples from Hong Kong are shown in Figure 50.6.

In Korea, invasive liver abscess is particularly associated both with *K. pneumoniae* (78% of the total, 40% of whom have diabetes) and with the K1 serotype (60%) [27].

Diabetes is the most common underlying risk factor specifically for the virulent K1 serotype, but not for non-*Klebsiella* abscesses [94]. In a population-based series of pyogenic liver abscess reported from Taiwan and including 29 703 subjects [95], diabetes was a risk factor in 33% leading to an odds ratio of 9 and was associated with an increasing incidence. Liver abscess in people with diabetes was not, however, associated with increased mortality, particularly if therapeutic percutaneous drainage procedures are performed. Eighty percent were associated with *K. pneumoniae* and not as a mixed infection with other organisms. Primary liver abscess in other parts of Asia is also increasing in incidence [27], with 40% reportedly associated with diabetes. Bacteremia is present in 50%, and 8–10% of these cases have metastatic complications (e.g. endophthalmitis, meningitis, brain abscess, pneumonia, skin and soft tissue lesions).

In a series from Europe (n = 1448), the presence of diabetes was associated with a 3.6-fold increase in risk for pyogenic liver abscess, and also with a higher 30-day post-discharge mortality rate compared with patients who did not have diabetes [96].

In the context of the K1 serotype of *Klebsiella* species, a pathogenic role for the magA gene in the serotype-specific region of the K1 capsule gene cluster, together with a K1 capsular polysaccharide per se, is considered as one of the virulence determinants essential for the development of invasive liver abscess. MagA, an outer membrane protein contributing to capsular polysaccharide formation, coexists with serotype K1 and has been identified as the major virulence factor of *K. pneumoniae* [95]. Poor glycemic control also has a role by impairing neutrophil phagocytosis of K1/K2 type *K. pneumoniae*, whereas it does not significantly affect the phagocytosis of non-K1/K2 *K. pneumoniae*. An rmpA-associated hypermuco-viscosity phenotype has also been reported in invasive purulent diseases caused by *K. pneumoniae*.

Most isolates are susceptible to cephalosporins (especially third-generation agents) and fluoroquinolones; however, therapeutic drainage is also needed and also assists with obtaining specimens for culture and susceptibility testing.

Metastatic abscesses may occur elsewhere in the abdomen, either singly or in combination with other sites, as well as within the urinary tract. A notorious, although uncommon, example is psoas abscess where responsible organisms are likely to be *S. aureus*, *Mycobacterium tuberculosis*, *E. coli* or *Klebsiella*.

**Figure 50.6** (a) CT-scan of an 82-year-old man with fever and newly diagnosed diabetes. Blood culture grew *Klebsiella pneumoniae*. The scan shows an 8 × 8.2 cm heterogeneous lesion in the right lobe of the liver composed of multiple rim enhanced lesions, with septation and hypodense cystic components. A further three smaller similar lesions (1–2.5 cm) were also seen inferiorly. Overall features are suggestive of liver abscesses. The patient recovered with drainage and antibiotics. (b) CT-scan of a 77-year-old woman with underlying diabetes, fever and right upper quadrant pain. Both blood culture and pus (from

the liver abscess) grew *K. pneumoniae*. The CT scan shows an irregular ovoid lesion with multiple locules and thin intervening septations in the periphery of liver segment V and measuring 7.3 × 3.2 × 6.1 cm. The features suggest liver abscess with signs of early liquefaction. The patient recovered with drainage and antibiotics. The authors acknowledge the Department of Diagnostic Radiology and Organ Imaging, Prince of Wales Hospital, Chinese University of Hong Kong for kindly supplying the images and permitting their use.

## Skin and superficial soft tissue infections

### Skin and subcutaneous tissues

Infections involving the skin, nails and subcutaneous tissues are very common, and the skin and subcutaneous tissues are frequent targets of infection in diabetes, particularly in association with poor glycemic control. Candidal infections, bacterial infections such as furunculosis, dermatophycoses and onychophycoses are all commonly seen and may be the reason for diabetes being identified. Cutaneous forms of mucormycosis or other fungal infections may occur and be diagnosed following skin biopsy. More detailed consideration is given to these disorders in Chapter 47 and are not repeated here.

Sensory neuropathy, atherosclerotic vascular disease and hyperglycemia predispose patients with diabetes to skin and soft tissue infections. Additional risk factors for the development of cellulitis include a past history of cellulitis, edema, peripheral vascular disease, tinea infection and dryness of the skin. The predominant organisms involved are group A streptococcus (GAS) and *S. aureus*. Cellulitis can also occur in less usual settings. For example with *S. pneumoniae* (pneumococcal) infections, cellulitis may occur in association with extracutaneous foci of disease, the suggestion being that, in this setting, the cellulitis results from hematogenous spread rather than local infection [97].

People with diabetes, particularly those who inject insulin, often have asymptomatic nasal, mucosal and skin colonization with potential pathogens such as *S. aureus*. Nasal colonization may also contribute to increased risk of staphylococcal pneumonia, for example in association with influenza.

According to data from the National Health and Nutrition Examination Survey (NHANES), people with diabetes who are colonized with *S. aureus* are also more likely to have a methicillin-resistant *S. aureus* isolate than a susceptible one (odds ratio 2.6; 95% CI 1.1–6.1) [98]. A recent increase in community-associated methicillin-resistant *S. aureus* (CA-MRSA) gives additional cause for concern. A recent report evaluating CA-MRSA in three communities found that 77% of skin or soft tissue infections were methicillin-resistant [99]. The underlying conditions identified included smoking (35%), previous skin infection (21%) and diabetes (19%).

Mucosal and skin colonization with *C. albicans* is also common and may involve numerous sites including the genitalia of both sexes as well as the mouth, skin and nails [100]. Balanitis and vulval candidiasis are common presenting features of diabetes.

Colonization may predispose to cutaneous or incisional staphylococcal (or other bacterial) infections as well as transient bacteremia. Entry sites may also include areas of fungal skin infection (e.g. intertrigo). Infection at distant sites with abscess formation or septicemia may then ensue. In two relatively early

studies (each from the 1960s) older patients with diabetes were shown both to be at greater risk of staphylococcal septicemia and also to suffer a substantially higher mortality (69% in the diabetic patients compared to 42% overall) [101,102].

### Deeper soft tissue infections

Deeper soft tissue infections also occur with increased frequency in people with diabetes. Examples include pyomyositis, necrotizing fasciitis and Fournier gangrene. Pyomyositis, usually associated with infection by *S. aureus*, occurs in muscles that have undergone trauma, especially when associated with hematoma formation.

### Necrotizing fasciitis

Necrotizing fasciitis is a deep-seated life-threatening infection of subcutaneous tissue. Progressive destruction of fascia, fat and muscle ensues. Although relatively uncommon, necrotizing fasciitis is a life-threatening condition. Necrotising fasciitis and Fournier gangrene (a form of necrotizing fasciitis involving the perineum), as well as other necrotizing soft tissue infections resulting from a variety of organisms, all have reported associations with diabetes. Diabetes is the most common of a number of conditions predisposing to necrotizing fasciitis, all of which are associated with compromise to the immune system.

As its name indicates, necrotizing fasciitis spreads initially along fascial planes; however, as infection and inflammation progress, necrosis of muscle, subcutaneous tissues and overlying skin occurs. Necrotizing fasciitis usually follows identifiable episodes of trauma such as burns, insect bites or abrasions, or can result from exposure of non-intact skin to a source of infection. The most common sites are the limbs, abdominal wall and perineum. Involvement of the vulva in women with diabetes may begin as a Bartholin gland ductal abscess, usually associated with obesity [103].

Polymicrobial infection is most commonly observed, with streptococci and Enterobacteriaceae being the most common isolates. The great majority of cases result from infection with anaerobes together with one or more facultative aerobes, whereas about 10% are associated with GAS, with or without *S. aureus*. Thus, GAS is the most common cause of infection by a single organism and can also occur in combination with staphylococci, including CA-MRSA. A recent article describing necrotizing fasciitis caused by CA-MRSA showed that although current or past intravenous drug abuse underlay 43% of patients, 21% occurred in people with diabetes [104].

*Vibrio*, *Aeromonas*, *Haemophilus* and *Salmonella* infections have also been reported. An interesting example is infection by halophilic marine *Vibrios* either following exposure of non-intact skin to seawater [105] or following bites by marine organisms, such as crabs, and this should be considered when a history of appropriate exposure is present.

Necrotizing fasciitis carries a high mortality, particularly when affecting the lower extremities or perineum, and is rapidly fatal unless diagnosed promptly and treated aggressively. It may be

initially misdiagnosed as a benign soft tissue infection and a high index of suspicion is therefore required. Skin changes may be minimal in the early phase of infection.

Early disease may be characterized by severe local pain, which is either disproportionate to or precedes other clinical features such as local inflammation and cellulitis, fever and systemic toxicity. Cellulitis may spread rapidly, unseen in deeper fascial planes. Crepitus is present in about half of cases. Violaceous discoloration of the skin may be noticed and may progress into blistering and bullae. Thrombosis and vasculitis each contribute to necrosis of the superficial fascia and suppuration from liquefactive necrosis. Gangrene and ulceration can result. Anesthesia of overlying skin may indicate destruction of subcutaneous nerves.

Plain radiographs, ultrasound, CT and MRI scan can each assist in both diagnosis and management by identifying the presence of gas in the tissues and by delineating the extent of the disease. Aerobic and anaerobic cultures should be taken from within the lesion, as should blood cultures.

Surgical débridement and fasciotomy are the mainstays of therapy. The single most important issue influencing mortality is time to surgical débridement. Thus, timely diagnosis, empirical broad-spectrum antibiotic therapy (including anaerobic cover) and aggressive surgical débridement of affected tissue are crucial components of management. The antibiotic cover can subsequently be tailored according to culture and sensitivity results. Additional supportive therapy in an intensive care environment should be provided where possible and as necessary.

### Fournier gangrene

Fournier gangrene is a specific form of necrotizing fasciitis involving the perineum, scrotum and penis. Overall mortality is very high. As with other forms of necrotizing fasciitis, diabetes is the most common of a number of potential predisposing conditions with a reported presence ranging 32–60% of cases [106,107]. Infection is usually polymicrobial with a lengthy list of potential pathogens which is similar to that seen in other forms of necrotizing fasciitis (*E. coli*, *Bacteroides* spp, staphylococci, streptococci, *Proteus* spp, *Pseudomonas* spp, enterococci). *C. perfringens* is present in the great majority (>90%) of cases in which myonecrosis is present.

Initial malaise and scrotal discomfort or pain is followed by systemic toxicity. Blistering ulceration and necrosis of the skin occur and in the later stages progress to scrotal swelling and a foul purulent discharge. Crepitus may be present. Sources of infection include abnormalities of the urogenital system (most notably urethral trauma, instrumentation or a chronic indwelling catheter, scrotal abscess or injury, insect bite) and local gastrointestinal abnormalities (e.g. ischio-rectal or perianal abscess, incarcerated inguinal hernia).

Diagnosis is predominantly clinical. Radiologic imaging techniques may reveal subcutaneous gas and delineate the extent of involvement, as with other forms of necrotizing fasciitis.

Fournier gangrene is a surgical emergency, and extensive débridement is required. Urinary or faecal diversion may be

required, as may laparotomy. Broad-spectrum antibiotic therapies with anaerobic cover, as well as general supportive measures are indicated as with other forms of necrotizing fasciitis. The results of microbiologic investigation may allow subsequent tailoring of antibiotics.

### Infected diabetic foot

Foot infection is the most common soft tissue infection associated with diabetes and therefore is a topic of the utmost importance to all who deal with people with diabetes. Detailed coverage of this topic is provided in Chapter 44. In order to avoid duplication, the topic receives only brief discussion in this chapter.

Disease-related peripheral neuropathy and peripheral vascular disease are both important in the etiology of foot infections, although the clinical presentations of the “predominantly ischemic” and the “predominantly neuropathic” foot differ. Serious complications include osteomyelitis, amputation, or even death. Infection often begins after minor trauma, which may be unnoticed, especially in the presence of sensory neuropathy. Cellulitis, soft tissue necrosis and extension into bone, leading to osteomyelitis, may then follow. Involved organisms most commonly include GAS and *S. aureus*, as well as aerobic Gram-positive cocci, Gram-negative rods and anaerobes.

The mainstays of management include exploration and débridement of the necrotic tissue and administration of appropriate antibiotics. In moderate to severe cellulitis or in the presence of osteomyelitis that places the limb at risk, the patient should be hospitalized for broad-spectrum antibiotic therapy and surgical intervention.

As in most diabetes-related infections, poor glycemic control plays an important part, and foot infections remain a common presenting feature of newly diagnosed diabetes, particularly in less developed parts of the world. Prevention of foot ulcers involves a multidisciplinary team approach. Foot care is an essential component of all diabetes education programs and should include proper foot care habits, protective footwear and pressure reduction.

### Bone and joint infections

Bone and joint infections remain a significant problem for people with diabetes and can be very difficult to treat. Diabetes is a risk factor for both osteomyelitis and septic arthritis.

The different types of osteomyelitis require differing medical and surgical therapeutic strategies. The three main types, classified according to etiology, include osteomyelitis secondary to a contiguous focus of infection (e.g. after trauma, surgery or insertion of a joint prosthesis); osteomyelitis secondary to vascular insufficiency (e.g. diabetic foot infections); or osteomyelitis secondary to hematogenous spread of infection. The most common reason for septic arthritis is following insertion of joint prostheses. All are more common in people with diabetes, with osteomyelitis of the foot at the forefront. Taking, as an example, osteomyelitis of the spine, then a recurring theme occurs with a

combination of both increased risk of hematogenous vertebral osteomyelitis (two- to sixfold) and predisposition to infection involving unusual organisms [108]. Acute osteomyelitis can respond to antibiotics alone but prolonged courses are required for bone and joint infections given the physiologic and anatomical characteristics of the tissues involved. Early diagnosis, together with bone sampling for microbiologic and pathologic examination to allow targeted and long-lasting antimicrobial therapy, allows the best outcomes. As with the diabetic foot, a multidisciplinary approach is required for success, including expertise in orthopedic surgery and infectious diseases, together with vascular surgery. Surgical intervention should be considered if medical treatment fails, for diagnostic confirmation or in the presence of complications.

Chronic osteomyelitis may be associated with avascular necrosis of bone and formation of sequestrum (dead bone), and surgical débridement is then necessary for cure in addition to antibiotic therapy. It is important to remember the possibility of infection by *M. tuberculosis* [109].

### Iatrogenic and surgical site infections

#### Insulin injections

Infections at the site of insulin injections are very uncommon and remain so even when traditional hygienic practices are not applied. Although not advised, administration of insulin through clothing is also not associated with increased risk of infection. Abscesses at needle sites are occasionally seen in individuals receiving subcutaneous insulin infusions [110]. Likewise, pulp infection over the distal phalanges in association with self blood glucose monitoring is exceedingly unusual.

#### Surgical site infections

An association between diabetes and an increased risk of surgical site infections has been known to exist for many years. Most of the studies addressing this question have focused on the risk of postoperative infection following coronary artery bypass grafting (CABG). The association has been generally assumed to be causally related to the deleterious effect of hyperglycemia on immune function [111].

Three studies support an increased risk of postoperative infection associated with postoperative hyperglycemia among those with diabetes undergoing CABG [112–114]; however, whether or not hyperglycemia imposes an independent risk for infection remains controversial. In none of the studies was mortality increased and, in one, postoperative hyperglycemia was correlated with a higher risk of infection while an elevated HbA<sub>1c</sub> was not. The studies do demonstrate, however, that improved glucose control during the operative and perioperative period can reduce the risk of postoperative infections in people with diabetes undergoing cardiac surgery. One retrospective study of 1574 patients undergoing CABG at a single institution found no increase in mortality or rates of infection among those with higher postoperative glucose levels and 34.6% of patients in this series had a diagnosis of diabetes. Nevertheless, increased glucose concentra-

tions were associated with increased hospital charges and a longer postoperative stay.

Both allograft rejection and risk for infection appear to be higher in transplant recipients with diabetes. In one study, the risk of serious infection was higher in diabetic heart transplant recipients in the early postoperative period [115]. In another study, renal transplant recipients had a greater risk of both acute allograft rejection and infection when perioperative glycemic control was poor [116].

### Dialysis

Ambulatory peritoneal dialysis is a common form of treatment for end-stage renal disease in people with diabetes. For patients receiving continuous ambulatory peritoneal dialysis (CAPD), episodes of catheter-related peritonitis are common, although variable from patient to patient, with some developing multiple episodes. Overall, however, the rate of infection does not appear to be greater in patients with diabetes than patients without diabetes, perhaps reflecting impairment of immunity associated with end-stage renal disease per se.

The issue of peritonitis in patients receiving CAPD is an important one given the large number of people with diabetes receiving this treatment. It is well recognized that peritonitis, despite significant reductions in the last two decades, remains the most important complication of CAPD with an overall mortality of about 3.5%, irrespective of both the underlying cause of the infection and of the renal failure [117]. The degree to which the presence of diabetes adds to the already considerable infection risk remains uncertain. People with diabetes may, however, be generally more unwell and have additional factors and complications such as macrovascular disease, need for hospitalization and predilection to certain infections, such as candidiasis. All of these may, in principle, contribute to the already very considerable risk.

---

## Principles of treatment, prevention and general care

### General principles

A high level of awareness is required in people with diabetes and in all health care providers, both to allow prevention and early, prompt recognition and diagnosis. Education, good glycemic control and general measures to maintain health and nutrition are all important measures aimed at minimizing risk. Careful attention to foot care is particularly emphasized. Vigilant measures should be instituted to prevent infection in patients with diabetes. When infections do occur, evolving antibiotic resistance patterns and other local factors must be considered, with CA-MRSA and tuberculosis both providing obvious examples of the importance of this.

The choice of antibiotic therapy follows the same general principles as for any other individual. Use of empirical broad-spectrum antibiotics is generally recommended until microbiologic results can guide treatment. Due caution should be applied in the

presence of diabetic complications. For example, the use of potentially nephrotoxic agents in the context of diabetic nephropathy may aggravate renal dysfunction, and in turn impaired renal function requires caution with doses and monitoring of blood levels. The presence of gastroparesis or autonomic neuropathy may hinder, or render unreliable, the absorption of oral drugs. Patients who are blind or partially sighted as a result of eye complications may also be at increased risk, for example when exposed to drugs that impair hearing or balance. Longer courses of antibiotic therapy may be appropriate, for instance in treating UTI.

Antiviral agents are recommended in the setting of influenza, and a more aggressive treatment approach may be appropriate even when presentation is relatively late [62]. Responses to treatment should also be carefully monitored (e.g. in the case of tuberculosis) [70]. The importance of appropriate referral to surgical or other specialist colleagues has been stressed repeatedly. Examples include surgical débridement in the case of necrotizing fasciitis, and incision and drainage of abscesses.

People with diabetes generally have a normal response to vaccines and should receive immunizations according to established guidelines. None of the vaccines currently available are contraindicated on the basis of diabetes alone. Because of increased susceptibility to complications, routine immunization against pneumococcus and influenza is recommended, particularly for the elderly patient with diabetes or for those with additional comorbidity such as chronic respiratory disease. Influenza vaccination has been shown to reduce hospital admissions significantly during influenza outbreaks [118]. Hepatitis B vaccination is also important although some populations may require additional or booster doses over and above standard recommended regimens.

### Glycemic control

All physicians need to be aware of the importance of careful monitoring of diabetic control in the presence of infection and should be on guard against destabilization of control or development of complications. Interestingly, in people without diabetes following hospitalization, even mild degrees of hyperglycemia are associated with increased mortality in association with severe illness. Although depressed immune function correlates somewhat variably with traditional measures of glycemic control, there is sufficient evidence to indicate an inverse relationship between the two which is potentially reversible. Previously undiagnosed diabetes may also be first detected following hospitalization and then needs to be distinguished from hospital-related hyperglycemia which later reverts to normal.

Patients with T1DM or others receiving insulin need to be aware of the probability of changing insulin requirements in response to infection and to the risk of severe consequences such as diabetic ketoacidosis. Many patients with T2DM, who are not on insulin, need to be transferred temporarily to insulin therapy as the stress of illness frequently adversely affects glycemic control. Hospital admission is mandatory if severe destabilization of glycemic control occurs, or if symptoms such as nausea and vomit-

ing interfere significantly with oral food intake. In this situation, intravenous insulin-glucose regimens are recommended. While good glycemic control is important, it is also important to avoid hypoglycemia. Interaction between the diabetes care team and other involved specialists should be initiated as early as possible.

The importance of perioperative glycemic control in patients with diabetes undergoing surgery also needs to be emphasized in order to minimize negative impacts upon postoperative infection rates and wound healing (see Chapter 32).

Attention to other risk factors (e.g. neurologic and vascular complications) is also important in order to minimize the risk of infections and infection-related complications. The importance of the presence of microangiopathy and neuropathy in the risk of the more severe forms of infection is again emphasized.

For more detailed description of these aspects of care, readers are referred to clinical practice recommendations, for example those of the American Diabetes Association [119] or to other national or international guidelines, as well as to other relevant chapters in this book.

Awareness among physicians needs to be high, especially with regard to the unusual and severe forms of infection that may occur. The general approach to antibiotic treatment is the same as for patients without diabetes, but details may differ (e.g. doses and duration of therapy). Responses to vaccination are generally normal, and influenza and pneumococcal vaccination is recommended. Careful attention to glycemic control and to other underlying factors is essential.

# 10 Diabetes in Special Groups

# 51

## Diabetes in Childhood

**Christine Chan & Marian Rewers**

Barbara Davis Center for Childhood Diabetes, School of Medicine, University of Colorado Denver, Aurora, CO, USA

### Keypoints

- An estimated 700 000 children have diabetes worldwide; 100 000 new cases are diagnosed annually; the incidence has been increasing by up to 5% annually, over decades.
- Type 1a (autoimmune) diabetes mellitus (T1aDM) accounts for almost all cases in children younger than 10 years, for >90% among older children of European ancestry and for 20–70% of diabetes in children older than 10 years from other ethnic groups.
- The presence of two or more of the islet autoantibodies predicts the development of diabetes in those less than 10 years, in most cases; despite enormous research effort, prevention of T1aDM is still elusive.
- Diabetes in children is diagnosed based on polyuria, polydipsia, weight loss, fatigue and random blood glucose >200 mg/dL (11.1 mmol/L). Oral glucose tolerance testing is rarely needed.
- Diabetic ketoacidosis (DKA) in a thin dehydrated child with Kussmaul breathing, abdominal pain, vomiting and impaired neurologic status is present at diagnosis in fewer than 30% of cases in developed countries today.
- There are significant differences in management of DKA in children, compared with adults, with the primary focus on prevention of cerebral edema.
- After diagnosis, childhood diabetes is managed in the outpatient setting by a team including a pediatrician specializing in diabetes, a diabetes nurse educator, a dietitian, a pediatric social worker and/or a pediatric psychologist trained in childhood diabetes.
- In-depth initial and continuing education of parents and patients in the self-management of diabetes is the cornerstone of lowering the risk of acute and long-term complications.
- Insulin pump or basal bolus multiple daily injections are the standard of insulin therapy in children.
- Nutrition planning should be based on carbohydrate counting or exchange system; the macronutrient and micronutrient composition of the diabetic diet is similar to that for healthy children without diabetes.
- While regular exercise is recommended for all children with diabetes, it requires careful planning of insulin and nutritional management to prevent severe hypoglycemia.
- Severe hypoglycemia is largely preventable, but is still the most common serious complication of childhood diabetes.
- Health care providers should equip families with the tools necessary to avoid dehydration, uncontrolled hyperglycemia or DKA, and hypoglycemia during routine infections.
- HbA<sub>1c</sub> levels below 58 mmol/mol (<7.5%) are the target currently recommended and achievable by most children and adolescents; the gap between recommended and actual HbA<sub>1c</sub> levels is the widest among adolescents.
- Age-specific psychologic care should include screening for and treatment of family dysfunction, developmental maladjustments, communication problems, disordered eating and sleep patterns, as well as psychiatric disorders both in the patients and their care providers.
- All children with diabetes should be screened at an appropriate age and duration of diabetes for dyslipidemia, microalbuminuria, elevated blood pressure, retinopathy, celiac, thyroid and Addison disease.

### Spectrum of diabetes in children

In Europe and North America, 1 in 300 children develops diabetes by the age of 20 years. While the rates are lower elsewhere, there are an estimated 700 000 children with diabetes worldwide and 100 000 new cases are diagnosed annually. Diabetes is a heterogeneous disease at any age. Newborn babies and infants rarely

develop the disease (1 in 250 000 in those younger than 6 months) and the etiology is not autoimmune, but usually monogenic (see Chapter 15). From the age of 9 months to 10 years, almost all diabetes is caused by islet autoimmunity (see Chapter 9). Type 1a (autoimmune) diabetes mellitus (T1aDM) accounts also for more than 90% of the cases among older children of European ancestry, but in other ethnic groups 20–70% of older children may have type 2 diabetes mellitus (T2DM; Figure 51.1). With the increasing prevalence of obesity in the general population, a significant proportion of children with T1aDM present with a phenotype that masquerades for T2DM. Measurement of autoantibodies to insulin, GAD<sub>65</sub>, IA-2 and ZnT8 at diagnosis, C

**Figure 51.1** Type-specific proportions of prevalent cases of diabetes in the US population, according to age group (a, 0–9 years; b, 10–19 years) and race/ethnicity. **Figure 51.2** Incidence of T1DM has been rising about 3–5% per year.

peptide after the initial metabolic stabilization and HLA-DR,DQ typing may be necessary to assess appropriate long-term treatment.

This chapter focuses on the practical aspects of the management of T1aDM in children, while Chapter 52 addresses management of diabetes in adolescents and transition to adult care. For type 1b diabetes (clinical presentation as in T1aDM, but absent islet autoantibodies) and monogenic diabetes see Chapters 9b and 15, respectively. The epidemiology and etiology of diabetes are addressed in Chapters 3 and 9, respectively. Briefly, T1aDM is caused by the interplay of genetic and environmental factors. The initial step – development of islet autoimmunity marked by the presence of islet autoantibodies – is believed to be driven by one or more environmental triggers [1]. Over the past 40 years, the incidence of childhood T1DM worldwide has increased by 3–5% annually (Figure 51.2). Elimination of the environmental trigger(s) responsible for this epidemic would be the most efficient approach to primary prevention; however, there is lack of consensus about which environmental factors initiate and promote islet autoimmunity. Efforts to prevent T1DM have been

recently reviewed elsewhere [2]. After the initiation of islet autoimmunity, most patients have a long preclinical period that offers an opportunity for secondary prevention of the progression to clinical diabetes. The presence of more than one of the autoantibodies combined with susceptibility HLA-DR,DQ genotypes identifies those at high-risk of developing diabetes. There may be a “point of no return” in the autoimmune destruction of the islets, rendering some interventions effective only at the earlier stages of the process. Once tolerance is broken to more than one of islet autoantigens, most individuals progress to diabetes within 10 years. A period of mild asymptomatic hyperglycemia, detectable by oral glucose tolerance testing (OGTT) [3] or HbA<sub>1c</sub> [4], may precede by months or years overt insulin dependence among persons with islet autoantibodies. Intervention at this “dysglycemic” stage may also theoretically preserve endogenous insulin secretion and prevent the acute and long-term complications of T1DM. Preservation or regaining of residual insulin secretion after diagnosis of diabetes might also help, but the immunomodulatory agents used so far in tertiary prevention may carry unacceptable long-term risks.

## Manifestation, diagnosis and initial treatment

### Clinical presentation and diagnosis

The cardinal symptoms at the diagnosis of diabetes include polyuria (96% of children, often with nocturia or bed-wetting), polydipsia, weight loss (61%) and fatigue [5]. The classic presentation of diabetic ketoacidosis (DKA) in a thin dehydrated child with Kussmaul breathing, abdominal pain, vomiting and impaired neurologic status affects fewer than 30% of cases presenting in developed countries today [5,6]. With the increasing community recognition of diabetes, most children present with milder hyperglycemia of shorter duration; however, 75% of the children (63% below age 5) have the symptoms for more than 2 weeks, suggesting that the diagnosis could be made earlier in many cases. A young child may have a less specific presentation, for example with vomiting or rapid breathing during the course of an infection. Diabetes should always be considered in ill children; urine or blood testing for glucose and ketones leads to an early diagnosis and may prevent DKA and hospitalization. Nearly all patients admitted with severe DKA have been seen hours or days earlier by health care providers who missed the diagnosis.

While most children do not require intravenous fluids or insulin infusion at the diagnosis of diabetes, many are hospitalized for a few days. These hospitalizations could be avoided if safe outpatient alternatives and adequate reimbursement existed for this initial care. For instance, the availability of an outpatient care center has helped to decrease hospitalization at diagnosis from 88% in 1978–1982 to 46% in 1998–2001, with the proportion of hospitalizations secondary to DKA increasing from 44% to 63% [6].

The diagnostic criteria are the same in children and adults (see Chapter 2); however, most children are quite symptomatic and do not require an extensive work-up. In a symptomatic child, plasma glucose  $\geq 11.1$  mmol/L (200 mg/dL) at any time of day, without regard to time since the last meal, or fasting plasma glucose  $\geq 7.0$  mmol/L (126 mg/dL) is diagnostic. Blood glucose results obtained using a glucose meter should be immediately confirmed in a laboratory, before the initiation of insulin treatment. By contrast, if marked hyperglycemia and blood or urinary ketones are present, treatment is urgent; waiting another day to confirm the diagnosis may be dangerous if DKA is allowed to develop. In a well child, the diagnosis must not be based on a single plasma glucose test or borderline results obtained using a glucose meter. In such cases, the authors check the HbA<sub>1c</sub> level; if this is normal, further monitoring of the fasting and/or 2-hour post-prandial blood glucose is recommended for several days. In children progressing to overt diabetes, hyperglycemia after dinner is usually the initial abnormality detectable by self-monitoring of blood glucose at home. OGTT should not be performed if fasting, random or post-prandial criteria are met as it is unnecessary and excessive hyperglycemia can result.

Hyperglycemia detected incidentally or during acute infection, trauma or other illness may be transient, especially if typical

symptoms of diabetes are absent or equivocal. Children with transient hyperglycemia may be more likely to develop diabetes, but the reported progression rates vary from 0 to 32%. Testing for islet autoantibodies helps to rule in diabetes in cases with mild presentation; however, it is important to consider that the quality of commercial assays for islet autoantibodies varies widely and testing for at least three autoantibodies (to insulin, GAD<sub>65</sub> and IA-2) provides 80% predictive value.

Impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) may also be detected in a child with islet autoimmunity progressing to overt diabetes [3]. OGTT is rarely needed in pre-pubertal children, however, except to reassure the family that a metabolic decompensation is not imminent. In older children, especially obese teenagers with equivocal symptoms, the OGTT may have a role in the earlier diagnosis of T2DM, IGT and IFG.

### Diabetic ketoacidosis

The clinical presentation of DKA includes abdominal pain, nausea and vomiting which can mimic an acute abdomen. The patients are mildly to moderately dehydrated (5–10%), may have Kussmaul respiration and become progressively somnolent and obtunded.

DKA results from absolute or relative deficiency of circulating insulin and a corresponding increase in the levels of counter-regulatory hormones, such as catecholamines, cortisol, glucagon and growth hormone (see Chapter 34). This combination leads to a catabolic state with increased glucose production by the liver and kidneys, increased lipolysis, ketogenesis with ketonemia and metabolic acidosis. Absolute insulin deficiency occurs in patients with previously undiagnosed T1DM or in established patients with omission of or inadequate insulin regimens. Relative insulin deficiency occurs during acute illness and stress if the increase in counter-regulatory hormones is not balanced by an appropriate increase in insulin dosage. The severity of DKA is categorized by the degree of acidosis:

- Mild: venous pH 7.2–7.3 or bicarbonate  $< 15$  mmol/L
- Moderate: venous pH 7.1–7.2 or bicarbonate  $< 10$  mmol/L
- Severe: venous pH  $< 7.1$  or bicarbonate  $< 5$  mmol/L

### Diabetic ketoacidosis at diagnosis of diabetes

In the USA, patients younger than 20 years with a clinical diagnosis of T1DM and T2DM presented in DKA in 29% and 10% of the cases, respectively [6]. In Europe, the rates for T1DM cases ranged 15–67% correlating inversely with the local incidence of T1DM [7]. DKA is more often found among younger children and in children with lower socioeconomic status who encounter barriers in accessing medical care [6]. Intensive community intervention to raise awareness of the signs and symptoms of childhood diabetes among school teachers and primary care providers may help to reduce the prevalence of DKA at diagnosis [8].

### Diabetic ketoacidosis in established patients

In a large cohort of children with established T1DM, on average, eight patients per 100 developed DKA every year [9]; however,

nearly 60% of the DKA episodes occurred in 5% of children with recurrent events. Recurrent DKA was predicted by poor metabolic control, previous episodes of DKA, psychiatric and eating disorders, difficult family or social circumstances or limited access to medical care.

### Treatment of ketoacidosis

Hydration status should be assessed and fluid deficit and osmolality calculated to help guide fluid and electrolyte replacement. Serum electrolytes, glucose, blood urea nitrogen (BUN), creatinine, calcium, magnesium, phosphorous and blood gas testing should be repeated every 2–4 hours or more frequently in severe cases. The calculations are shown below.

$$\text{Anion gap} = \text{Na} - (\text{Cl} + \text{HCO}_3)$$

$$\text{Corrected Na} = \text{measured Na} + [(\text{plasma glucose} - 100 \text{ mg/dL})(1.6)/100]$$

$$\text{Serum osmolality} = 2(\text{Na} + \text{K}) + \text{glucose}/18 + \text{BUN}/2.8 \text{ (mOsm/L)}$$

Patients with DKA have a 5–10% deficit in extracellular fluid volume which has developed slowly. Avoid rapid or overzealous fluid replacement. Initial volume expansion should occur over the first 1–2 hours with IV infusion of 10–20 mL/kg normal saline (0.9%) or Ringer solution. The bolus rarely needs to be repeated and should not exceed a total of 40 mL/kg over the first 4 hours of treatment. Subsequent fluid deficit replacement should occur over the next 48 hours using 0.5–0.75 normal saline 0.9%. Once blood glucose concentrations reach 250 mg/dL (14 mmol/L), 5–10% dextrose should be added to the IV solution to maintain the blood glucose concentration between 150 and 250 mg/dL (8–14 mmol/L) and avoid saline overload and hyperchloremic acidosis.

Continuous IV infusion of soluble human insulin at a dose of 0.1 units/kg/hour should commence after the patient has received initial volume expansion. An IV bolus of insulin is unnecessary and may increase the risk of cerebral edema [10]. The insulin infusion should allow for a gradual decrease in blood glucose concentration by 50–100 mg/dL/hour. If the blood glucose levels decrease too quickly or become too low before acidosis has resolved, IV dextrose concentration may be increased to 12.5% to prevent hypoglycemia while continuing to correct the metabolic acidosis with insulin. Unless the patient is truly hypoglycemic, the insulin infusion rate should not be decreased to less than 0.05 U/kg/hour as this is likely to prolong the time needed to suppress ketogenesis. Bedside monitoring of blood ketones ( $\beta$ -hydroxybutyrate) is more helpful than blood gases in adjusting insulin and glucose infusion rates.

Total body potassium is usually depleted, but serum levels at presentation may be normal or high secondary to efflux of intracellular potassium into the extracellular space in the presence of acidosis. Once the serum potassium is found to be normal or low, and urine output is confirmed, IV fluids should include 20–

40 mEq/L potassium in the form of K acetate,  $\text{K}_2\text{HPO}_4$  or a combination of these. No more than half of the potassium replacement should be given as  $\text{K}_2\text{HPO}_4$  because excessive phosphorous administration may result in hypocalcemia following the suppression of parathyroid hormone.

Similar to serum potassium levels, serum phosphorus levels may be initially elevated only to fall rapidly during treatment of DKA. Clinical problems resulting from low phosphorus levels have not been substantiated; however, severe hypophosphatemia ( $<1 \text{ mg/dL}$ ) should be treated. If hypocalcemia develops, administration of phosphate should be decreased or stopped.

Severe acidosis is reversible with fluid and insulin replacement. Bicarbonate therapy may paradoxically cause CNS acidosis and hypokalemia from rapid correction of acidosis and is a risk factor for cerebral edema. Bicarbonate therapy is not recommended unless the acidosis is profound ( $\text{pH} < 6.9$ ) and likely to interfere adversely with the action of epinephrine during resuscitation. If bicarbonate is considered necessary, 1–2 mmol/kg can be cautiously administered over 60 minutes.

### Cerebral edema

Neurologic status must be monitored at frequent and regular intervals. Subclinical cerebral edema occurs in most children with DKA. Severe clinical edema affects 0.5–1% of the children and is fatal in over 20% [10]. Typically, cerebral edema occurs at 4–12 hours, but has been reported as late as 24–28 hours after the initiation of IV fluid treatment. Potential risk factors for symptomatic cerebral edema in children include:

- More profound dehydration, hyperventilation and acidosis at presentation;
- Bicarbonate therapy;
- Excessive and rapid fluid administration, especially if initial serum osmolality is  $>320 \text{ mOsm/L}$ ;
- Failure of serum sodium to rise as hyperglycemia resolves; and
- Initial IV insulin bolus or too early initiation of insulin infusion.

Signs and symptoms of cerebral edema include headache, change in mental status or behavior, incontinence, focal neurologic findings, sudden normalization of heart rate in a previously tachycardic dehydrated patient or a worsening clinical course in a patient with improved laboratory values. Bradycardia, hypertension and irregular respiration (Cushing triad) are signs of greatly increased intracranial pressure. Early intervention is essential. Treatment includes administration of mannitol (1 g/kg over 30 minutes), decreasing fluid rate to 75% or less of maintenance rate, and elevation of head of bed. Mannitol therapy may need to be repeated. Intravenous hypertonic saline has also been used as an alternative to mannitol. Radiographic studies (such as head CT) should be obtained after rather than during treatment of cerebral edema.

Frequent monitoring of blood glucose levels should prevent hypoglycemia. For acute hypoglycemic episodes while on continuous insulin infusion, the insulin infusion may be temporarily discontinued for up to 15 minutes if necessary.

**Transition to subcutaneous insulin regimen**

Patients may be transitioned to an appropriate subcutaneous insulin regimen once DKA has resolved and they are able to eat. To prevent rebound hyperglycemia, the insulin infusion should not be discontinued until 15–30 minutes after the first subcutaneous injection of rapid-acting insulin has been administered. Long-acting insulin analogs achieve therapeutic levels able to replace insulin infusion 4–6 hours after the subcutaneous injection. Bedside monitoring of blood ketones helps to titrate insulin dose and prevent a relapse.

**Pediatric ambulatory diabetes care**

Diabetes is primarily managed in the outpatient setting by a team including a pediatrician specializing in diabetes, a diabetes nurse educator, a dietitian, a pediatric social worker trained in childhood diabetes and/or a pediatric psychologist with knowledge of childhood diabetes and chronic illness. In communities with low population density and low prevalence of childhood diabetes, such a care team may not be available and care will primarily be provided by the child's primary care physician. In these instances, these physicians should work closely with and have access to a regional diabetes care team.

Health care providers and the diabetes care team must always be cognizant of and sensitive to the cultural needs and barriers to care that may arise with minority children of recent immigrants. Interpreters should be utilized when needed.

**Initial education**

Initial education should provide a basic understanding of the pathophysiology of diabetes and its treatment to ensure that families feel confident in providing diabetes care at home (Table 51.1) [11].

At many institutions, initial education at time of diagnosis occurs in an inpatient setting regardless of whether or not the child presents acutely ill in DKA. In some centers with appropriate outpatient resources, initial diabetes education and initiation of insulin therapy can occur in the ambulatory setting which has been shown to be cost effective.

**Table 51.1** Initial education curriculum.

An explanation of how the diagnosis was made and reason for symptoms  
 Discussion regarding normal blood glucose levels and targets, the need for immediate insulin treatment and its mechanism of action  
 Practical skills including how to draw up and administer insulin, blood glucose testing, blood and urine ketone testing  
 Basic dietary guidelines  
 Simple explanation of symptoms and management of hypoglycemia  
 Diabetes at school  
 Importance of medical alert identification  
 Psychologic adjustment to the diagnosis  
 Emergency telephone contacts

**Continuing education**

In the first 6 months following diagnosis, close contact in the form of frequent outpatient visits, home visits, telephone communication and other methods of communication is essential for addressing the frequently changing requirements during this time (Table 51.2) [11].

Diabetes education is a continuous process and must be repeated to be effective. It must be adapted and appropriate to the age of the child. Infants and toddlers often have unpredictable eating and activity patterns. There is often more difficulty in distinguishing normal behavior from mood swings related to hypoglycemia or hyperglycemia. Needle phobia can present a significant issue with the perception of pain inflicted by the caregiver. Hypoglycemia is more common in this age group and the prevention, recognition and management of hypoglycemia is a priority. School-aged children will have increased understanding and involvement with their diabetes management. Providers should address school-aged children directly in addition to speaking with their parents or care providers. Education includes monitoring of blood glucose levels and injections at school, particularly during meal times, exercise and extracurricular activities. There should be increased recognition and awareness of hypoglycemic symptoms. Education should also focus on age-appropriate stepwise handover of diabetes responsibilities. This becomes particularly important in adolescence during which there is a critical balance between promoting independent responsible management of diabetes while maintaining parental involvement.

Once established, it is common practice for children to be seen in the ambulatory setting at least every 3 months; visits should be more often if the patient does not meet the treatment goals or intensifies treatment, for example if insulin pump treatment is initiated. During these visits, overall health and well-being is assessed, growth and vital signs are monitored, and a physical

DKA, diabetic ketoacidosis

examination is performed. There should be routine screening for diabetes-associated complications and co-morbidities. Blood glucose records, including a check of HbA<sub>1c</sub>, medications and school plans are reviewed. This will allow for the insulin doses to be adjusted and provide a template for continued diabetes education.

The dietitian may review dietary habits and provide ongoing nutrition education as needed. The social worker or psychologist assesses and monitors psychosocial problems and family dynamics and the impact of diabetes care. At the conclusion of these visits, an individualized plan should be developed for each child and their family and a written copy of this plan should be provided.

The advent of new technology including downloadable glucometers, insulin pumps and continuous glucose sensors has made it increasingly possible for the diabetes care team to gain insight into home management of diabetes; however, this should not replace self-monitoring and regular review of blood glucose data at home by the patient and their family.

### Diabetes management in school

Children with diabetes spend a significant portion of their day in school; therefore, diabetes management in school is a critical portion of their diabetes management plan [12]. The child has the right to receive adult support for diabetes care from school personnel during school hours, outdoor school activities and school-sponsored events away from school. School personnel must be trained to provide or supervise all diabetes care prescribed by the diabetes team and be supportive of providing diabetes care and encourage diabetes management during school hours, including:

- Insulin administration by injection or with an insulin pump;
- Testing blood glucose in young children and older, newly diagnosed children and adolescents until they are capable of performing the task independently; and
- Identification and treatment for hypoglycemia, both mild-moderate and severe.

Children with diabetes should have a school health plan in place. The health plan should include contact information for the child's family as well as their diabetes care providers. It should also contain information regarding routine management of diabetes (blood sugar monitoring, insulin administration and dosing, snack times) and an emergency plan for management of hypoglycemia and hyperglycemia. Issues specific to insulin pumps include remembering to activate insulin bolus with food, disconnecting the pump during vigorous exercise or in the event of severe hypoglycemia, pump failures and pump alarms.

Extracurricular activities are an important component of a child's school experience and children with diabetes should be allowed to participate and their needs accommodated accordingly. Field trips, field days and overnight trips often require advanced planning, but a child's diabetes should never be a cause for exclusion from any school-sanctioned activity.

---

## Insulin treatment

The overarching goal of insulin replacement is to provide just enough insulin at an appropriate time to provide sufficient basal insulin levels as well as higher insulin levels after meals [13]. The choice of insulin regimen depends on the individual's age, duration of diabetes, dietary and activity patterns, ability to cope and metabolic targets. Patient and family preferences should also be respected.

### Insulin pump therapy

Insulin pump therapy is the best way to restore the body's physiologic insulin profile. The pump delivers a variable programmed basal rate that corresponds to the diurnal variation in insulin needs. Prepubertal children require a higher basal rate in the early part of night, while post-pubertal patients who experience the "dawn phenomenon" require higher rates in the morning.

The user initiates bolus doses before meals and to correct hyperglycemia. Most pumps can receive wireless transmission of test results from glucose meters, but the patient or caregiver must still manually enter the amount of carbohydrate being consumed. The pump calculates the amount of insulin needed for a meal or correction based on previously entered variables which include: insulin:carbohydrate ratios, insulin sensitivity factor, glycemic target and duration of insulin action (set at 2–8 hours to protect from accumulating too much insulin). The user may override the suggestion or press a button to initiate the bolus.

Rapid-acting insulin analogs perform better in pumps than regular insulin, both in terms of mimicking the first-phase insulin release after meal and avoidance of post-prandial hypoglycemia. Even with the analogs, however, insulin has to be administered at least 10–15 minutes before meal to reach effective levels in time. A longer lead time may be needed if preprandial blood glucose is higher than 150 mg/dL. Young children, picky eaters and disorganized patients may struggle with these requirements. In addition, they are often unable to predict the size of the meal. In these cases, one may administer half of the usual meal bolus in advance, with the other half, if needed, after meal. Compliance problems include infrequent blood glucose testing, not reacting to elevated blood glucose, incorrect carbohydrate counting or missing the boluses altogether.

Patients and their families must be instructed on troubleshooting and treatment of hyperglycemia, particularly if ketones are present, as this may be an indication of a pump malfunction. If the flow of insulin becomes interrupted, ketonemia will develop within 4 hours; this is particularly dangerous at night as there is no long-acting insulin on board. Syringes should always be available so that insulin may be administered via injection in the event of a pump failure.

Most clinical trials have demonstrated better HbA<sub>1c</sub> and less severe hypoglycemia with pump therapy, compared with multiple daily injections (MDI). Pump therapy can improve the quality

of life in children who have trouble with or fear of injections or who desire greater flexibility in their lifestyle (e.g. with sleeping in, sports or irregular eating). Insulin pumps can be particularly helpful in young children or infants who have multiple meals and snacks and require multiple small doses of rapid-acting insulin. The newer generation of insulin pumps can deliver as little as 0.025 U/hour, but higher rates using diluted insulin may be needed for uninterrupted flow.

Disposable pumps are already available and much smaller “patch” pumps are in development. In the near future, one may expect a “closed-loop” system allowing the insulin pump to be directed automatically by a continuous glucose sensor with minimal human input; however, a number of issues remain to be solved, including the biocompatibility of the sensors and infusion sets, limitations of the systemic versus intraportal administration of insulin, lack of counterbalancing delivery of glucagon and optimal delivery algorithms for various meals and activities.

Currently, the most frequent complications of insulin treatment include failures of insulin delivery because of a displaced or obstructed infusion set, local skin infections and DKA. Insulin pump treatment is significantly more expensive than regimens based on injections. For some patients, pumps may be too difficult to operate or comply with the multiple testing and carbohydrate counting requirements, or may be unacceptable because of body image issues or extreme physical activity (e.g. swimming, contact sports).

### Subcutaneous insulin injection regimens

Injections regimens, in order of worsening HbA<sub>1c</sub> outcomes, include:

- Basal bolus regimen: 40–60% of the total daily dose as basal insulin analog (glargine, detemir) in 1–2 doses a day with rapid-acting insulin analog 10–15 minutes before each meal; soluble human insulin is less preferable and requires administration at least 20–30 minutes prior to each meal.
- Intermediate-acting human insulin twice daily and soluble human insulin 20–30 minutes prior to each meal.
- Two injections daily of a mixture of short or rapid and intermediate-acting insulin before breakfast and before the evening meal.
- Three injections using some variation of the following: a mixture of short or rapid and intermediate-acting insulin before breakfast, rapid or soluble human insulin before the afternoon snack or evening meal, and intermediate or basal/long-acting insulin before bed.

Intermediate-acting insulins such as NPH are often mixed with soluble human (regular) or rapid-acting analogs (aspart, lispro or glulisine). Patients and families should be taught how to mix the insulin properly to avoid contamination. It is generally taught to draw up clear (regular or short-acting) insulin prior before drawing up cloudy insulin (NPH). Per the manufacturer’s instructions, glargine or detemir insulins should not be mixed with any other insulin.

Premixed insulins contain a mixture of regular (or rapid-acting) insulin and NPH insulin in various fixed ratios. These preparations may be useful for children who do not want to draw insulin from separate vials prior to injecting. They may also be useful in reducing the number of injections when compliance is an issue, especially among teenagers. Premixed insulins are also available for use in pen injector devices. The main disadvantage to using premixed insulin preparations is the lack of flexibility in adjusting the separate insulin doses, which is often necessary with varied food intake or during illness or exercise.

---

## Nutrition

Nutritional management in children with diabetes remains a key component of diabetes care and education; if available, a pediatric dietitian should be a part of the diabetes care team. The management does not require a restrictive diet, just a healthy dietary regimen that the children and their families can benefit from. Current guidelines target optimal glycemic control, reduction of cardiovascular risk, psychosocial well-being and family dynamics [14,15]. A thorough dietary history should be obtained including the family’s dietary habits and traditions, the child’s typical meal times and patterns of food intake.

Insulin pump and MDI therapy utilize carbohydrate counting in which the grams of carbohydrate to be eaten are counted and a matching dose of insulin is administered. This plan allows for the most freedom and flexibility in food choices, but it requires expert education and commitment and may not be suitable for many families or situations (e.g. school lunches, teenagers). Exchange planning teaches that it is not necessary to count precise grams. Exchanges are taught as either 10 or 15-g servings of carbohydrate. The exchange plan can enable a more consistent daily intake of carbohydrate. The constant carbohydrate meal plan was used often in the past with insulin regimens based on NPH and regular insulin, where carbohydrate intake and the amount of insulin were kept relatively constant from day to day. It has been perceived as too restrictive and a potential source of conflict.

The use of the glycemic index has been shown to provide additional benefit to glycemic control. Low glycemic index carbohydrate foods, such as wholegrain breads, pasta, temperate fruits and dairy products may lower post-prandial hyperglycemia. A glycemic load approach to predicting the post-prandial blood glucose response, based on the glycemic index of the food and the portion size, has not been fully explored in children. Regardless of which meal plan is chosen, helpful principles are shown in Table 51.3.

### Age-specific advice

Breastfeeding in infants should be encouraged. Insulin pump therapy should be considered, particularly in patients who require very small doses of insulin. Toddlers are often picky eaters and are more likely to eat frequent smaller meals throughout the day; their insulin regimen should match this eating pattern. Food

**Table 51.3** Principles of dietary planning in children with diabetes.

- 1 Eat a well-balanced diet, with daily energy intake distributed as follows:
  - Carbohydrate 50–55% (sucrose intake up to 10% total energy)
  - Fat 30–35% (up to 20% monounsaturated fat; <10% polyunsaturated fat; <10% saturated fat and trans fatty acids; n-3 fatty acids 0.15 g/day)
  - Protein 10–15%
- 2 Eat meals and snacks at the same time each day, if possible
- 3 Use snacks to prevent and treat hypoglycemia, but avoid overtreatment:
  - Young children often have a mid or late morning snack
  - Most people will have a mid or late afternoon snack
  - Many children require a bedtime snack, particularly if the bedtime blood glucose is below 130 mg/dL (7 mmol/L) or if they have been active during the day
- 4 Gauge energy intake to maintain appropriate weight and body mass index:
  - Overinsulinization, “forced” snacking and excess food intake to prevent or treat hypoglycemia promote excessive weight gain and should be avoided
  - Eating disorders are common in teenagers with diabetes, particularly girls
- 5 Recommended fiber intake for children older than 1 year: 2.8–3.4 g/MJ; children older than 2 years should eat = (age in years + 5) g/day fiber
- 6 Avoid foods high in sodium that may increase the risk of hypertension; target salt intake – to less than 6 g/day (sodium chloride)
- 7 Avoid excessive protein intake (athletes should not require protein supplements)
- 8 Children with diabetes have the same vitamin and mineral requirements as other healthy children; however, hypovitaminosis D is common and screening and supplementation are recommended
- 9 There is no evidence of harm from an intake of artificial sweeteners in doses not exceeding acceptable daily intakes
- 10 Specially labeled diabetic foods are not recommended because they are not necessary, are expensive, are often high in fat and may contain sweeteners with laxative effects. These include the sugar alcohols such as sorbitol
- 11 While alcohol intake is generally prohibited in youth, teenagers continue to experiment with and sometimes abuse alcohol. Alcohol may induce prolonged hypoglycemia in young people with diabetes (up to 16 hours after drinking). Carbohydrate should be eaten before, during and/or after alcohol intake. It may be also necessary to lower the insulin dose, particularly if exercise is performed during or after drinking (e.g. dancing)
- 12 Approximately 10% of patients with type 1 diabetes have serologic evidence of celiac disease. Those with positive intestinal biopsy or symptomatic have to be treated with GFD. Products derived from wheat, rye, barley and triticale are eliminated and replaced with potato, rice, soy, tapioca, buckwheat and perhaps oats. While most of the children are asymptomatic, the long-term consequences of untreated celiac autoimmunity may warrant GFD

GFD, gluten-free diet.

refusal can be a significant source of distress, particularly if an insulin dose has already been administered. In school-aged children, meal plans may need to be adjusted depending on the school schedule. Food intake among teenagers is often chaotic. Breakfasts are skipped and binges may happen at any time of day or night. Weight loss or failure to gain weight may be associated with insulin omission for weight control and may be indicative of a disordered eating behavior. While insulin pump or MDI treatment may help some, simplification of the management plan to avoid extreme mismatches between food intake and insulin are sometimes the only viable option.

## Exercise

Children with diabetes derive the same health and leisure benefits from exercise as children without diabetes and should be allowed to participate with equal opportunities and equal safety [16]. Physiologically, during exercise in children without diabetes, there is a decrease in pancreatic insulin secretion and an increase in counter-regulatory hormones resulting in an increase in liver glucose production (see Chapter 23). This matches skeletal muscle uptake of glucose during exercise, maintaining stable blood glucose concentrations under most conditions. In children

with T1DM, there is no pancreatic regulation of insulin in response to exercise and there may be impaired counter-regulation. These factors combine to increase the risk of hypoglycemia and hyperglycemia during exercise. It is helpful to keep an exercise record noting the most recent insulin dose, timing and type of exercise, blood glucose levels before and after exercise, snacks eaten and the time of any episode of hypoglycemia.

Factors affecting a child’s response to exercise include:

- Duration, type, timing and intensity of activity;
- Overall metabolic control and ambient blood glucose level;
- Type and timing of insulin injections and its absorption;
- Type and timing of food;
- Muscle mass and conditioning; and
- Degree of stress.

## Preventing hypoglycemia

Blood glucose levels should be checked before, during and after the exercise. Children should consume carbohydrates prior to exercise, with the amount depending on the blood sugar level prior to exercise and the duration and intensity of exercise. For short duration activity, sports drinks with simple sugars provide optimal absorption and usually prevent hypoglycemia for the next 30–60 minutes. For activity of longer duration, solid foods containing carbohydrates are digested more slowly and should be

consumed in addition to a liquid with simple sugars. Extra snacks should always be available to the child during exercise. The child's coaches and teammates or other responsible adult and peers should be aware of the signs and symptoms of hypoglycemia. Often, children will require adjustments to their insulin dosing when exercise is anticipated. The site of insulin injection should also be taken into account. Exercise increases blood flow in the part of the body being used, increasing insulin absorption if that area is where the insulin injection was administered. For example, prior to running the insulin dose should not be administered in the legs.

### Insulin adjustments

For exercise anticipated within the first hour after eating, the dose of rapid-acting insulin before the meal may need to be decreased by 25–75% (depending on the intensity of the exercise) in addition to consuming 10–15 g of fast-acting carbohydrate prior to exercise. For day-long activities (such as camps, hiking or skiing), consider a 30–50% reduction in the long-acting insulin dose (or in the basal rate if using an insulin pump) the night before and on the day of the activity. For children using insulin pumps, there are numerous options for insulin adjustments with exercise. If the pump will be worn during exercise, the basal rate can be reduced by 30–50% beginning 30–90 minutes prior to exercise and continuing for up to 30 minutes or longer after the exercise. For some types of activities (e.g. contact sports), children may need to disconnect from the pump and do one of the following:

- Bolus part of the basal insulin to be missed prior to exercise (particularly if the pre-exercise blood sugar level is elevated) and the remainder after exercise;
- Bolus half of the insulin missed while disconnected after exercise;
- Bolus all of the insulin missed while disconnected after exercise.

In general, the pump should not be disconnected for longer than 2 hours. If necessary, the pump should be reconnected briefly and a bolus administered prior to reconnecting again.

### Delayed hypoglycemia

Hypoglycemia can occur several hours after exercise secondary to increased glucose transport into the skeletal muscle, the late effect of increased insulin sensitivity, and the delay in replenishing liver and muscle glycogen stores. Blood glucose levels must be monitored for several hours following exercise, at bedtime and sometimes during the night on days with strenuous exercise. Consider a longer lasting snack (containing a solid carbohydrate, protein and fat) at bedtime and reducing the insulin dose as discussed above.

### Ketones and exercise

In situations of underinsulinization, whether it be from poor glycemic control or from illness, exercise may be dangerous because of the effect of uninhibited action of the counter-

regulatory hormones. Children with diabetes should not participate in strenuous exercise if the pre-exercise blood sugar level is high and urine ketones (small or more) or blood ketones (0.5 mmol/L or more) are present.

## Hypoglycemia

Hypoglycemia is the most common acute complication in the treatment of T1DM and responsible for a significant proportion of deaths in people with diabetes aged under 40 years of age (see Chapter 33) [17]. While hypoglycemia in persons with diabetes is defined as plasma glucose below 70 mg/dL (4 mmol/L), severe hypoglycemia (seizure or loss of consciousness) usually does not occur until prolonged exposure to levels of 40–50 mg/dL (2.2–2.7 mmol/L) or lower. Severe hypoglycemia happens to one in five children every year on average, but 80% of the events occur among the 20% of children who have recurrent events [6]. Younger age, longer diabetes duration, barriers in access to care and presence of psychiatric disorders or chaotic family environment increase the risk. While lower HbA<sub>1c</sub> is generally a risk factor for hypoglycemia, appropriate intensive insulin treatment can lower the risk by improving timing of insulin in relationship to food intake and exercise [18].

### Signs and symptoms

- *Autonomic signs and symptoms:* trembling, pounding heart, cold sweatiness, pallor;
  - *Neuroglycopenic signs and symptoms:* difficulty concentrating, blurred or double vision, disturbed color vision, difficulty hearing, slurred speech, poor judgment and confusion, problems with short-term memory, dizziness and unsteady gait, loss of consciousness, seizure, death;
  - *Behavioral signs and symptoms:* irritability, erratic behavior, nightmares;
  - *Non-specific symptoms:* hunger, headache, nausea, tiredness;
- Early warning signs and symptoms of hypoglycemia are much more difficult to identify in young children.

### Treatment

In mild or moderate symptomatic hypoglycemia, after documenting a blood glucose of  $\leq 70$  mg/dL (3.9 mmol/L):

- Provide immediate oral, rapidly absorbed 5–15 g glucose or sucrose: glucose tablets, “Smarties” or 4 oz (100 mL) of sweet drink (juice, soda).
- 1 g glucose should raise the blood glucose by 3 mg/dL (0.17 mmol/L) for the average adult and proportionally more in a child; target the rise of blood glucose level to 100 mg/dL (5.6 mmol/L).
- Retest blood glucose in 10–15 minutes, if no response or inadequate response – repeat as above.
- For initially lower glucose values, as symptoms improve and euglycemia is restored, ingest solid snack or meal (e.g. fruit, bread, cereal) to prevent recurrence.

- Retest blood glucose in 20–30 minutes to confirm that target glucose has been maintained.

In severe hypoglycemia, where the child has an altered mental status and is unable to assist in their care, may be unconscious and/or seizing, urgent treatment with parenteral glucagon or dextrose is required.

### **Glucagon**

Glucagon is given intramuscularly or subcutaneously (10–30 µg/kg body weight):

- 0.3 mg for children younger than 6 years
- 0.5 mg for those 6–12 years
- 1 mg for those older than 12 years or heavier than 100 lb (45 kg)

Glucagon injection may be repeated in 5–10 minutes, if response was inadequate; however, it is likely to be ineffective after prolonged fasting. Side effects include vomiting and tachycardia.

### **Dextrose**

Dextrose can be given intravenously by trained medical staff if glucagon is unavailable or recovery is inadequate in a hospital setting or by paramedics:

- Intravenous dextrose should be administered slowly over several minutes (e.g. dextrose 10–30% at a dose of 200–500 mg/kg; dextrose 10% is 100 mg/mL).
- Rapid administration or higher concentration may result in an excessive rate of osmotic change, phlebitis and extensive tissue damage, if extravasated.

Close observation and monitoring of blood glucose is essential because vomiting is common and hypoglycemia may recur. If recurrent hypoglycemia occurs, the child may ultimately require an IV infusion of dextrose 10% at 2–5 mg/kg/minute until stable.

Severe headache and transient paresis lasting up to 24 hours are not uncommon and generally do not require radiologic work-up.

### **Hypoglycemia unawareness**

Hypoglycemia unawareness occurs when there is reduced awareness of the onset of hypoglycemia. A single hypoglycemic episode can lead to hypoglycemia unawareness secondary to a decrease in counter-regulatory responses, but it is usually seen in patients who have multiple periods of blood glucose <70 mg/dL. Avoiding subsequent hypoglycemia for 2–3 weeks may reverse this loss of awareness.

### **Prevention**

Hypoglycemia occurs more frequently:

- When the treatment regimen or lifestyle is altered (increased insulin, less food, more exercise);
- In younger children;
- With lower HbA<sub>1c</sub> levels;
- When there are frequent low blood glucose levels;
- When there is hypoglycemia unawareness;

- During sleep; or
- After alcohol ingestion.

Patients and families should be aware of the above risk factors so that glucose monitoring and insulin regimens can be changed accordingly. There is an increased risk for hypoglycemia during, immediately after and up to 2–12 hours after exercise. Untreated celiac disease and Addison disease may also increase the risk of hypoglycemia.

Nocturnal hypoglycemia is often asymptomatic and should be suspected if the morning blood glucose is low and/or there are episodes of confusion, nightmares or seizures during the night, or if there is impaired thinking, altered mood or headaches upon awakening. Nocturnal hypoglycemia can be confirmed with blood glucose monitoring during the night and may be prevented by including more protein and fat in the bedtime snack. Care should be taken that this does not occur at the expense of high overnight blood glucose levels.

Studies have shown an association between hypoglycemia and decrease in cognitive functioning in children with T1DM, particularly in children diagnosed before the age of 5–6 years. More recently, there has been increased interest in the potential role of chronic hyperglycemia on cognitive functioning in young children. Even mild–moderate hypoglycemia may impair school functioning and overall well-being. A reduced awareness of hypoglycemia and the risk of injury or accident often lead to a significant fear of hypoglycemia and decreases in insulin dosing, which in turn results in increased HbA<sub>1c</sub>. Severe hypoglycemia can increase parental and patient's worry, poor sleep, emergency room visits, hospitalizations, excessive lowering of insulin doses and subsequent worsening of glycemic control. Long-term follow-up of the Diabetes Control and Complications Trial (DCCT) participants has been reassuring that there was no evidence for permanent neurocognitive changes related to hypoglycemia in adolescent and young adult individuals, suggesting that the effect of severe hypoglycemia on long-term neuropsychologic functioning may be age-dependent [19].

Ultimately, hypoglycemia is frequently predictable and should be prevented. Children and their caregivers must be taught to recognize the symptoms of hypoglycemia and treat this immediately and appropriately. Children with diabetes should always carry around a source of rapid-acting glucose and should wear identification noting that they have diabetes. The diabetes care provider should be notified if a child is having recurrent episodes of symptomatic hypoglycemia or if there is hypoglycemia unawareness. This will facilitate discussions to adjust insulin regimens, food intake patterns, blood glucose goals and monitoring. Continuous glucose monitoring helps to detect and to avoid hypoglycemia.

---

## **Sick day management**

Children with diabetes in good metabolic control should not experience more illness or infections than children without dia-

betes; however, they will go through their share of routine infections which can be challenging for their caregivers. The influenza vaccine and other routine childhood immunizations are recommended for all children with diabetes.

Health care providers should equip families with the tools necessary to avoid dehydration, uncontrolled hyperglycemia or ketoacidosis, and hypoglycemia. Face to face education and written instructions are important, but most parents require telephone advice when first facing sickness in their child and some may need repeated support. Over time, most parents should be able to manage sick days independently as well as identify appropriate times when to seek help from their diabetes provider or emergency services. Patients should immediately seek medical attention if:

- Blood glucose concentrations continues to rise despite extra insulin;
- Blood glucose concentrations remains persistently below 3.5 mmol/L (70 mg/dL);
- Blood ketones are higher than 1.5 mmol/L or ketonuria is severe and persistent; or
- The child becomes exhausted, confused, dehydrated or develops difficulty in breathing, severe abdominal pain or a severe hypoglycemic reaction.

Missed insulin injection, inactivated insulin or interruption of insulin delivery from pump may lead to “sick days” as well, especially in older children. While treatment is essentially the same as for hyperglycemia in the course of an infection, the differential diagnosis is important for prevention of recurrent events.

Hyperglycemia is seen in many illnesses, particularly those associated with fever, as a result of elevated levels of stress hormones, which promote gluconeogenesis and insulin resistance. Severe illness increases ketone body production secondary to inadequate insulin action or insufficient oral intake of carbohydrates. By contrast, illnesses associated with vomiting and diarrhea can lead to hypoglycemia secondary to decreased food intake, poor absorption and slower gastric emptying.

In general, during illness, blood glucose concentrations must be monitored more frequently – at least every 3–4 hours and more often when blood glucose concentrations are outside the target range (e.g. 80–200 mg/dL). Urinary or blood ketones must be checked at least twice daily and always when blood glucose concentration exceeds 300 mg/dL (17.6 mmol/L). If available, the authors recommend testing blood ketones ( $\beta$ -hydroxybutyrate, using Precision Xtra/Exceed meter) over urine ketone testing as a more specific and timely marker of ketosis:

- The presence of ketones when blood glucose concentrations are persistently elevated above 200 mg/dL (11.1 mmol/L) indicates the need for supplemental insulin and fluids.
- The presence of ketones when blood glucose concentrations are low or normal, especially during gastrointestinal illness, indicate insufficient oral intake of carbohydrates (starvation ketones). In this case, ketones do not reflect insulin deficiency, but rather a physiologic response and may protect the patient from severe

hypoglycemia as  $\beta$ -hydroxybutyrate is the only alternative fuel to glucose for the brain. Supplemental insulin is contraindicated as it will likely cause hypoglycemia; the correct treatment includes fluids with glucose.

Insulin therapy must never be stopped during a sick day, although the dose may need to be decreased if the child is vomiting or eating less than usual. A fasting patient still requires approximately 40% of the usual daily insulin dose, as long-acting basal insulin, to cover basic metabolic needs and prevent ketoacidosis; however, infections associated with normal food intake often require an increase of basal insulin by 10–15%. In addition, extra doses of rapid-acting insulin are usually needed to correct hyperglycemia, prevent ketoacidosis and avoid hospital admission. These doses may be repeated every 2–4 hours as needed based on the results of blood glucose and ketone monitoring.

With blood glucose concentrations greater than 200 mg/dL (11.1 mmol/L), the authors recommend:

- Usual high blood glucose correction (e.g. 1 unit of rapid-acting insulin for each 50 mg/dL above 100 mg/dL, if blood ketones <0.6 mmol/L or urine ketones negative/small;
- Injection of rapid-acting insulin in the amount of 10% of the total daily dose, if blood ketones 0.6–1.5 mmol/L or urine ketones are moderate or large;
- Injection of rapid-acting insulin in the amount of 10–20% of the total daily dose if blood ketones >1.5 mmol/L or urine ketones are moderate or large;
- As acidosis is present in most patients with hyperglycemia and blood ketones >3.0 mmol/L, this warrants referral to an emergency department.

Patients using insulin pumps who develop hyperglycemia and moderate or large urine ketones (or greater than 1.0 mmol/L blood ketones) must always take into consideration the possibility of an interruption in insulin delivery. If blood glucose levels do not decrease appropriately after an insulin bolus from the pump, the correction bolus of short-acting insulin should be given as injection by pen or syringe and the pump infusion set should be changed. A temporary increase in the basal rate by 20% or more may be required until blood glucose concentrations begin to normalize and ketones clear.

If hypoglycemia <70 mg/dL (<3.9 mmol/L) persists and the patient is unable to tolerate any oral intake, an injection of low dose glucagon may reverse the hypoglycemia and enable oral fluid intake to resume. Glucagon is mixed as usual but given using an insulin syringe with the dose being one unit per year of age up to 15 years [20]. Upon mixing with water, glucagon remains stable for at least 48 hours at 4°C. The small dose of glucagon can be repeated every 2–4 hours; however, it is likely to be less effective with prolonged fasting. This dose of glucagon is not to be used for the emergency treatment of severe hypoglycemia.

Hydration status must be followed closely. Fever, hyperglycemia with osmotic diuresis, and ketonuria all increase fluid losses. Households should maintain a supply of sugar and electrolyte containing fluids:

- Oral water is sufficient to prevent dehydration in uncomplicated cases of hyperglycemia.
- If there is an ongoing fluid loss from diarrhea or vomiting, hydration liquids should contain salt in addition to water (e.g. Pedialyte, Rehydralate). These preparations contain 25–30 g/L glucose, 45–90 mEq/L sodium, 30 mEq/L bicarbonate and 20–25 mEq/L potassium. Oral rehydration fluid can be made at home by mixing half of a flat teaspoon of salt (~3 g of NaCl = ~50 mEq sodium), 7 teaspoons of sugar (28 g) and (optionally) 100 mL (4 oz) of orange juice into 1 L water.
- If there is difficulty eating or keeping food down and the blood glucose is falling below 200 mg/dL (11.1 mmol/L), sports drinks should be administered. They contain less electrolytes but higher amounts of glucose (e.g. Gatorade contains 255 g/L glucose, 20 mEq/L sodium, 3 mEq/L bicarbonate and 3 mEq/L potassium).
- If the blood glucose is falling below 100 mg/dL (5.6 mmol/L), fluids with higher concentration of sugar are recommended (e.g. juice or non-carbonated regular soda containing approximately 70 g glucose per 100 mL. These fluids contain almost no sodium and are not appropriate in large amounts for children with diarrhea.

The required volume of oral fluid replacement is the sum of maintenance volume, deficit and ongoing losses. In practical terms, infants and toddlers with diabetes who vomited more than twice or have multiple loose stools should be referred to an emergency department for evaluation and intravenous fluids. Those with milder symptoms can be given oral fluid therapy at home; small amounts (5 mL) of cold fluids every 5 minutes. Most children with vomiting can be successfully orally rehydrated with persistent gentle encouragement of parents.

Antiemetic medication at home is generally contraindicated, especially in young children, as it may mask acute abdominal

processes such as appendicitis, volvulus or intussusception and may have significant adverse effects. Ondansetron (Zofran) can be used to contain vomiting in patients properly evaluated by a physician and selected older children presenting without abdominal pain.

### Monitoring and goals of diabetes management

Hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) is the only measure of mid to long-term glycemic control for which robust outcome data are available (see Chapter 25). Elevated HbA<sub>1c</sub> predicts long-term microvascular and macrovascular complications but has its limitations. In the DCCT, an HbA<sub>1c</sub> of 53 mmol/mol (7.0%) corresponded to a higher average blood glucose concentration (measured seven times a day) of 192 mg/dL in the conventionally treated patients compared with 163 mg/dL in the intensively treated patients. Consequently, the same HbA<sub>1c</sub> level conferred significantly higher risk of microvascular complications and hypoglycemia in the conventionally treated patients compared with intensively treated patients [21]. HbA<sub>1c</sub> can only be one of the measures of optimal glycemic control, along with documented hypoglycemia and quality of life. Ideally, there should be four to six measurements per year in younger children and three to four measurements per year in older children.

Self-monitoring of blood glucose (SMBG) provides immediate and daily documentation of hyperglycemia and hypoglycemia, helps to determine immediate and daily insulin requirements and detects hypoglycemia and assists in its management. Blood glucose is best measured during the night, after the overnight fast, at anticipated peaks and troughs of insulin action, 2 hours after a meal and in association with vigorous sport or exercise – typically 4–6 times a day. The frequency of SMBG is associated with improved HbA<sub>1c</sub> in patients with T1DM [21]. Patient acceptance of SMBG may be enhanced by including the opportunity for testing alternative sites in addition to the fingertips (e.g. the palm of the hand or the forearm); however, alternative sites may be slower to reflect falling blood glucose.

A logbook or some type of electronic memory device has to be used to record patterns of glycemic control and adjustments to treatment. The record book is useful at the time of consultation and should contain time and date of blood glucose reading, insulin dosage, together with a note of special events (e.g. illness, parties, exercise, menses, hypoglycemic episodes and episodes of elevated blood or urinary ketones).

At present, the safest recommendation for glycemic control in children is to achieve the lowest HbA<sub>1c</sub> that can be sustained without severe hypoglycemia as well as frequent moderate hypoglycemia or prolonged periods of significant hyperglycemia where blood glucose levels exceed 250 mg/dL (14 mmol/L). Each child should have targets individually determined. Targets for HbA<sub>1c</sub> and SMBG recently proposed by the International Society for Pediatric and Adolescent Diabetes (ISPAD) [21] are summarized in Table 51.4.

#### Estimate of 24-hour maintenance fluid volume

Estimation based on age:

- 0–2 years = 80 mL/kg
- 3–5 years = 70 mL/kg
- 6–9 years = 60 mL/kg
- 10–14 years = 50 mL/kg
- >15 years = 35 mL/kg

Estimation based on body weight:

- 100 mL/kg for the initial 10 kg body weight, plus
- 50 mL/kg for the next 10 kg body weight, plus
- 20 mL/kg for each additional kg body weight

For example, a child weighting 30 kg needs 1000 + 500 + 200 = 1700 mL maintenance water for 24 hours or 70 mL/hour, not counting past or ongoing losses

**Table 51.4** Biochemical targets of glycemic control. These targets are intended as guidelines, each child should have their targets individually determined.

Level of control	Optimal	Suboptimal	High risk
<b>HbA<sub>1c</sub></b>			
DCCT standardized (%)	<7.5	7.5–8.9	≥9.0*
IFCC (mmol/mol)	<58	58–74	≥75
<b>SMBG mmol/L (mg/dL)</b>			
Fasting or preprandial BG	5–8.3 (90–150)	>8.3 (>150)	>11.1 (>200)
Post-prandial BG	5–10 (90–180)	10–13.9 (180–250)	>13.9 (>250)
Bedtime BG	6.7–10 (120–180)	<6.7 (<120) or 10–11 (180–200)	<4.4 (<80) or >11.1 (>200)
Nocturnal BG	4.4–9 (80–160)	<4.4 (<80) or >9 (>162)	<3.9 (<70) or >11.1 (>200)

BG, blood glucose; DCCT, Diabetes Control and Complications Trial; IFCC, International Federation of Clinical Chemistry; SMBG, self-monitoring of blood glucose.

\* DCCT conventional adult cohort had a mean HbA<sub>1c</sub> value of 8.9% (74 mmol/mol), both DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) have shown poor outcomes with this level.

### Continuous glucose monitoring

Sensors are available and in development that measure interstitial fluid glucose every 1–20 minutes (i.e. “continuously”). Currently, these devices are expensive and insurance coverage is limited. Over time, it is anticipated that these devices will become the standard of care in children with T1DM. The continuous glucose results are available to the user in real-time and are stored in the receiver device or pump for downloading to a computer at a later time. The download allows the patient and health care professional to review the results and make appropriate and educated insulin dosage adjustments. This much more sophisticated approach to SMBG may allow targets to be determined so that an alarm will alert the wearer to a glucose value projected to fall below or above the preset target and inform insulin delivery from a pump. As continuous glucose monitoring becomes more widely available, decreased blood glucose targets may be more safely achieved in children with diabetes.

The average HbA<sub>1c</sub> is lowest in the youngest age group, perhaps reflecting the more complete caregiver involvement at younger ages. Of all age groups, adolescents are currently the farthest from achieving HbA<sub>1c</sub> 58 mmol/mol (<7.5%), reflecting the diabetes mismanagement that frequently accompanies the increased independence in diabetes care during the adolescent years, as well as the effect of psychologic and hormonal challenges of adolescence. Too ambitious goals may lead to an unwarranted sense of failure and alienation on part of a teenage person with diabetes. As diabetes technology improves, especially continuous glucose monitoring, recommended target indicators for glycemic control will likely decrease to reflect a new balance of benefits and risks.

Health care providers should be aware that achieving an HbA<sub>1c</sub> consistently below the target range without extensive personal and national health care resources and outside of a clinical trial structure may be very difficult. As a benchmark, intensively treated adolescents in the DCCT achieved a mean HbA<sub>1c</sub> of 65 mmol/mol (8.1%), compared to 54 mmol/mol (7.1%) in adults. Older well-educated DCCT participants with excellent

access to the newest diabetes technology maintained HbA<sub>1c</sub> of 62–66 mmol/mol (7.8–8.2%) during 12 years of follow-up in the Epidemiology of Diabetes Interventions and Complications (EDIC) study [22].

### Psychologic care

The diagnosis of T1DM brutally changes the lives of affected families and poses relentless challenges. It is impossible to take a “vacation” from diabetes without some unpleasant consequences. It is no wonder that children with T1DM and their parents are at risk for adjustment problems. Persisting adjustment problems may mark underlying dysfunction of the family or psychopathology of the child or caregiver. Young people with T1DM are more frequently diagnosed with and treated for psychiatric disorders, disordered eating, neurocognitive and learning problems, family dysfunction and poor coping skills than the general population. The psychologic care recommendations of the ISPAD [23] are summarized in Table 51.5.

### Screening and early treatment of risk factors for complications and associated conditions

#### Dyslipidemia

Cardiovascular disease (CVD) is a leading cause of morbidity and mortality in adults with T1DM. Preclinical atherosclerosis often starts in childhood. While children with T1DM have generally a favorable lipid profile, this remains a major modifiable CVD risk factor in this population. Screening for dyslipidemia in children with T1DM should commence after the age of 2 years if there is a family history of hypercholesterolemia or CVD or this is unknown, or otherwise at age 12 years, and should be repeated every 5 years thereafter if normal [24]. Glycemic control should be established in newly diagnosed patients prior to screening. Children with low density lipoprotein (LDL) levels 130–159 mg/dL (3.4–4.1 mmol/L) should obtain glucose control, dietary and exer-

**Table 51.5** Psychologic care recommendations for families of children with T1DM.

- 1 Mental health professionals with training in diabetes should be available to interact with patients and families at clinic visits to conduct screening and more complete assessments of psychosocial functioning as well as support the diabetes team in the recognition and management of mental health and behavior problems
- 2 There should be easy access to consult psychiatrists for cases involving severe psychopathology and the potential need for psychotropic medications
- 3 Diabetes health care providers should strive to maintain regular, consistent and uninterrupted contact with patients and their families
- 4 Developmental progress in all domains of quality of life (i.e. physical, intellectual, academic, emotional and social development) should be monitored routinely
- 5 Routine assessment should be made of developmental adjustment to and understanding of diabetes management, including diabetes-related knowledge, insulin adjustment skills, goal-setting, problem-solving abilities, regimen adherence and self-care autonomy and competence. This is especially important during late childhood and prior to adolescence
- 6 Psychosocial adjustment problems, depression, eating disorders and other psychiatric disorders should be ruled out or treated, if present, in patients not achieving HbA<sub>1c</sub> goals or having recurrent severe hypoglycemia or DKA
- 7 General family functioning needs to be assessed (conflict, cohesion, adaptability and parental psychopathology) and diabetes-related functioning (communication, parental involvement and support, and roles and responsibilities for self-care behaviors) especially when there is evidence of cultural, language or family problems
- 8 Training parents in effective behavior management skills, especially at diagnosis and prior to adolescence, should emphasize appropriate family involvement and support, effective problem-solving and self-management skills, and realistic expectations
- 9 Motivational interviewing may be useful in counseling young people and parents regarding intensification of insulin regimens. This may help in clarifying patient and parental goals and resolve ambivalence about regimen intensification. Patients should not be denied access to regimen intensification based on perceptions of limited competence
- 10 Adolescents should be encouraged to assume increasing responsibility for diabetes management but with continuing, mutually agreed parental involvement and support. The transition to adult diabetes care should be negotiated and carefully planned between adolescents, their parents and the diabetes team well in advance of the actual transfer to adult care

cise counseling for 6 months with consideration of pharmacologic therapy if this fails; pharmacotherapy in addition to diet and lifestyle changes is recommended if LDL is >160 mg/dL (4.1 mmol/L). The treatment goals are LDL <100 mg/dL (2.6 mmol/L), high density lipoprotein (HDL) >35 mg/dL (0.9 mmol/L) and triglycerides <150 mg/dL (1.7 mmol/L).

The use of lipid-lowering drugs in children has been the subject of much discussion. Bile acid sequestrants and statins are currently approved medications [25]. Bile acid sequestrants are not well tolerated and therefore compliance is poor. Several short-term trials of statins have confirmed their safety and efficacy in children and adolescents with familial hypercholesterolemia. The American Heart Association recommends initiating therapy with statins at the lowest dose with emphasis on appropriate patient selection criteria including the presence of other cardiovascular risk factors, age >10 years in boys, Tanner stage II or higher, preferably after menarche in girls. Patient and family preferences should be considered and there should be no contraindication to statin therapy (e.g. hepatic disease) [26]. If therapy with statins is undertaken, regular monitoring of liver function and screening for symptoms of rhabdomyolysis should occur. Appropriate contraceptive advice should be given to girls receiving statins.

### Microalbuminuria

Microalbuminuria is the first clinical manifestation of diabetic nephropathy and may be reversible with diligent glycemic and blood pressure control. Microalbuminuria is defined as any of the following [27]:

- Albumin excretion rate 20–200 mg/min, or 30–300 mg/24 hours in 24-hour urine collections.

- Albumin concentration 30–300 mg/L (in early morning urine sample).
- Albumin:creatinine ratio 2.5–25 mg/mmol or 30–300 mg/g (spot urine) in males and 3.5–25 mg/mmol in females (because of lower creatinine excretion).

Screening for microalbuminuria with a random spot urine sample should occur annually in children once they are 10 years of age and have had diabetes for more than 5 years. If values are increasing or borderline, more frequent screening should occur. A timed overnight or 24-hour collection can be obtained for follow-up if needed. Abnormal results should be repeated. The diagnosis of microalbuminuria requires documentation of two abnormal samples out of three samples over a period of 3–6 months. Once persistent microalbuminuria is confirmed, non-diabetes-related causes of renal disease should be excluded. Following this evaluation, treatment with an angiotensin-converting enzyme (ACE) inhibitor should be started, even if the blood pressure is normal. Patients should be counseled about the importance of glycemic control and smoking cessation if applicable.

### Elevated blood pressure

Hypertension in adults with diabetes is associated with the development of both microvascular and macrovascular disease. Treatment of blood pressure is critical in reducing these complications in adults and presumably in children and adolescents as well. Blood pressure should be checked and reviewed at each clinic visit. Hypertension is defined as systolic or diastolic blood pressure (measured on at least three separate days) above the 95th percentile for the child's age, sex and height. Care should be taken to ensure use of the appropriate-sized cuff in children

to avoid inaccurate readings. If elevated blood pressure is confirmed, non-diabetes causes of hypertension should first be excluded.

### Retinopathy

The first dilated ophthalmologic examination should be obtained by an ophthalmologist, optometrist or other health care professional trained in diabetes-specific retinal examination once the child is  $\geq 10$  years old and has had diabetes for 3–5 years [24]. The frequency of subsequent examination is generally every 1–2 years, depending on the patient risk profile and advice of an eye care provider.

### Celiac disease

The prevalence of biopsy-confirmed celiac disease (CD) in patients with T1DM ranges from 3% to 7%, compared to  $< 1\%$  in the general population [28]. Many children with diabetes are asymptomatic but are positive for specific serologic markers of CD such as autoantibodies to tissue transglutaminase. Most of the children with diabetes and CD still remain undiagnosed, despite intestinal symptoms and/or short stature in about half of the cases.

Clinical manifestations of CD are diverse, vary with age and may overlap with functional disorders. Some of the manifestations, such as delayed growth and puberty, decreased bone mineralization, abdominal pain and abnormal liver function tests, may overlap with those of poorly controlled diabetes. Therefore, physicians and other health care providers need to consider CD in the differential diagnosis and many have argued for a routine transglutaminase screening in children with T1DM.

T1DM and CD share HLA and non-HLA susceptibility genes. The prevalence of transglutaminase autoimmunity is highest in those with the HLA-DR3,DQB1\*0201 haplotype. One in four children with diabetes homozygous for this haplotype and 12% of the heterozygotes are positive for transglutaminase autoantibodies.

Most patients with T1DM with CD are transglutaminase-autoantibody-positive at the initial screening, although new cases develop during follow-up. All patients should be screened for immunoglobulin A (IgA) transglutaminase-autoantibodies at onset of diabetes and, if negative and asymptomatic, rescreened every other year. If the transglutaminase-autoantibodies are negative, but the patient has symptoms and/or signs consistent with CD, other causes (e.g. poor glycemic control, or intolerance of milk, soy or salicylates) should be explored. HLA-DQB1 typing and total IgA level measurement may be helpful; if DQB1\*0201 is present, IgA  $< 10$  mg/dL and, if symptoms persist, biopsy is recommended. Positive transglutaminase autoantibody findings have to be confirmed on another occasion, because transglutaminase autoantibody levels can fluctuate. If transglutaminase autoantibodies are strongly and persistently positive (radioimmunoassay index  $> 0.5$  or ELISA  $> 60$ ), biopsy is recommended even in a completely asymptomatic patient. By contrast, patients with low to moderately positive transglutaminase autoantibody

levels may have false-negative biopsy and may be falsely reassured that they do not have CD and forego further follow-up. The authors recommend repeating transglutaminase autoantibody testing every 3–6 months as long as the levels are positive.

Untreated CD may pose problems with diabetes management, including increased risk of hypoglycemia and chronic diarrhea which is difficult to differentiate from that caused by autonomic neuropathy in adult patients. It is an open issue whether treating silent CD improves diabetes-related outcomes. To date, results suggest small benefit in growth and bone mineralization, excess weight gain but no diabetes control benefit, or a slight decrease in HbA<sub>1c</sub>. Gluten-free diets may prevent some of the episodes of hypoglycemia. The benefit of early detection and treatment remains unproven, but is the subject of ongoing investigation.

### Thyroid disease

Hypothyroidism is present in 4–18% of children with T1DM. Long-term follow-up suggests that as many as 30% of people with T1DM develop autoimmune thyroiditis [29]. The presence of hypothyroidism has been associated with thyroid autoantibodies, increasing age and diabetes duration and female gender. Hyperthyroidism is not more common in patients with T1DM than in the general population (1%). With follow-up of 20 years, 80% of people with T1DM and thyroid peroxidase (TPO) autoantibodies develop hypothyroidism.

The presence of autoimmune thyroiditis in the population with T1DM has the potential to affect growth, weight gain, diabetes control, menstrual regularity and overall well-being. All children with T1DM should be screened for elevated levels of the thyroid-stimulating hormone after stabilization at onset of diabetes and every 1–2 years thereafter, or sooner if symptoms of hypothyroidism or hyperthyroidism are present. We also recommend measuring TPO and free T4 at the time of thyroid-stimulating hormone screening. Subjects with positive TPO autoantibodies and normal thyroid function should be screened on a more frequent basis (every 6–12 months).

### Addison disease

Addison disease affects approximately 1 in 10000 of the general population and in 1% of subjects with T1DM [29]. The autoimmune process resulting in Addison disease can be identified by the detection of autoantibodies reacting to 21 hydroxylase (21-OH). The presence of this autoantibody in the general population is very rare, in contrast to 1–2% in subjects with T1DM. Of those with positive antibodies but as yet free of Addison disease, 15% develop Addison disease within a few years. Progression to adrenal insufficiency begins with elevated plasma renin activity and then progresses to increased adrenocorticotrophic hormone, decreased stimulated cortisol, and eventually abnormalities of basal cortisol. The authors' current practice is to screen all children with T1DM for the presence of 21-OH autoantibodies. Those positive are followed for adrenal insufficiency by plasma

renin activity and adrenocorticotrophic hormone stimulation testing. Most subjects who develop disease are mildly symptomatic with decreasing insulin doses and HbA<sub>1c</sub>.

### Keypoints

- Adolescence is characterized by significant and complex biological, social and psychologic changes that occur during the teenage years.
- Adolescents with diabetes establish a long-term positive bond with their pediatric health care team. Consequently, the transition to an adult diabetes service provider is a significant event.
- Adolescents are at risk of dropping away from health care professional contact and follow-up during the time of transition, which may be detrimental to their physical and psychologic well-being.
- Adolescents need support to anticipate the issues they may face when preparing to move from children's services and to identify the solutions that may be available to them.
- The transition must be carefully managed so that the adolescent does not need to make an abrupt adaptation in their move from an environment that is very supportive to one where they are expected to be more independent.

### Introduction

Adolescence is a life stage characterized by transition and change regardless of health status. Diabetes in adolescence is a life-changing condition requiring diligent and consistent management by a multidisciplinary team of clinicians in addition to comprehensive care and support provided by the family unit. Many young people with diabetes establish a long-term positive bond with their pediatric health care team. Consequently, the transition to an adult diabetes service provider is a significant event. The seamless transfer of adolescents with diabetes from pediatric to adult services can also be a challenge for health services and clinicians. Young people may mourn the loss of the relationships they had with the pediatric health team and can become distressed about learning to trust new staff [1]. There is evidence to suggest that during the time of transfer, adolescents are at risk of dropping away from health care professional contact and follow-up which may be detrimental to their physical and psychologic well-being [2]. As a result, it has been estimated that 10–60% of adolescents do not make the transition successfully from pediatric to adult health services [3,4]. The purpose of this chapter is to enhance understanding of the key issues presenting for adolescents and clinicians, and to consider effective models of care that will facilitate seamless transition from pediatric to adult diabetes care.

### Transition

Transition is the reorientation that people experience to a change event [5]. Events that change our lives occur constantly, but they often go unnoticed, unless we are disrupted by them. These are “change events” that produce an end to one's familiar way of living and require the individual to find new ways of being in the world that incorporate those changes. Change is situational, such as a move to a new job, a new city or a new school. Transition is the way people respond to the changes that are occurring in their lives.

Transition involves moving through the change situation and negotiating one's sense of self in an altered world [6]. Transition is the movement people make through a disruptive life event so that they can continue to live with a coherent and continuing sense of self [7]. Understanding transition involves exploring the person's responses to a passage of change. Health care professionals are frequently in the position of supporting people who are in transition because of the changes associated with the impact of illness.

During the last three decades, the concept of transition has evolved in the social sciences and health disciplines, with nurses contributing to more recent understandings of the transition process as it relates to life and health [8–15]. Transitional definitions alter according to the disciplinary focus, but there is broad agreement that transition involves the way people respond to change. Transition occurs over time and entails change and adaptation, for example developmental, personal, relational, situational, societal or environmental change, but not all change

engages transition. Transition is not an event, but rather the inner reorientation and self-redefinition that people go through in order to incorporate changes into their lives [5].

The transition focused on here when discussing adolescent transfer to adult services is when one “chapter” of life is over and the person is unable to go back to the way life was before the change event occurred. The change event under particular focus is the shift to a new and unfamiliar service environment. To enable a “new chapter” to begin these adolescents will need to respond to the changes in their lives, sorting out what can be retained of their former way of living and what has to be released, in order to move forward [15]. This is often the experience of the adolescent moving from child to adult health services. Understanding transition theory will enable health care professionals to assist young people to make this transition during a life stage that is characterized by constant change.

### Transition as a process

The terms “transition” and “transfer” have been used interchangeably in the literature when referring to adolescents moving between diabetes services. As a consequence, transition may be interpreted as simply a process of physical transfer to a different service with a failure to acknowledge the psychosocial needs of the adolescent and family members. This oversight may have resulted in a lack of resources to assist the adolescent and parents to make the psychosocial transition between children’s and adult services [1]. A clear distinction between the concepts of transition and transfer is needed.

When people experience transition, they look for ways to move through the unfamiliar to create some order in their lives so they can reorient themselves to the new situation [5]. Transition can involve much trial and error, as people work out ways of living and being in their changing world. When young people are learning to live with a chronic illness such as diabetes they are involved in that transitional process. Over time these people redefine their sense of self, redevelop confidence to make decisions about their lives and to respond to the ongoing disruption that so often accompanies chronic illness. When undertaking the work of reclaiming their sense of self and identity, they come to an understanding of what is changing, or has changed in their lives and how this reality is shifting key values and identity markers.

The transitional process takes time, however, as the adolescent will disengage with what was known and familiar and look toward the altered and new situation that lies ahead. At this point it can be helpful for the person to connect with others they can trust. A familiar health professional, support group, a friend or a family member who is a good listener becomes an important asset in the sense-making process. Without such examination of the change event or events, people’s understanding of what is changing may be limited. This is particularly the case for adolescents who are engaged in major change in all areas of their lives. For many adolescents, leaving the care of their pediatrician and other familiar health care professionals is a passage from security to uncertainty [16]. These young people need time to examine their

perceptions and experiences and to consider the actions that they need or want to take. Adolescents will need support to anticipate the issues they may face when preparing to move from children’s services and to identify the solutions that may be available to them. This is a key point in enabling successful transition for adolescents moving to adult diabetes care.

---

## Adolescence as a time of transition

Adolescence is a transitional stage of human development that occurs between childhood and adulthood. This transition is characterized by significant and complex biologic, social and psychologic changes that occur during the teenage years. During this time the adolescent is developing a sense of self and identity, establishing autonomy and understanding sexuality. Adolescence is a stage of life where control–autonomy–dependence are pertinent issues in the lives of young people [16]. There is often anxiety experienced by the adolescent regarding acceptance by peers which may also impact self-care behaviors.

The events and characteristics that mark the end of adolescence and the beginning of adulthood can vary by culture as well as by function. Countries and cultures differ at what age an individual can be considered to be mature enough to undertake particular tasks and responsibilities such as driving a vehicle, having sexual relations, serving in the armed forces, voting or marrying. Adolescence is usually accompanied by an increase in independence allowed by the parents or legal guardians and generally less supervision in daily life. This is true too of adolescents transferring to an adult care service. The intention is to ensure that the adolescent has the practical and cognitive skills required for diabetes self-care and has developed the capability to interact with others such as health care providers; however, age itself may not be a reliable indicator, as adolescents may have different needs and developmental issues at different stages and mature at different rates. The parents of the adolescent must also be prepared to relinquish some of the responsibility for diabetes care which they may have undertaken with a high degree of vigilance for many years. For some parents, this shift in responsibility can be a time of high anxiety. Fundamental to any successful transition program is the work with parents to help them find a balance between shifting the responsibility to the adolescent and continuing to maintain an appropriate level of interest and family cohesion [4].

---

## Adolescence and diabetes

Type 1 diabetes mellitus (T1DM) is the most common metabolic disease that affects children [17]. It occurs when the pancreas is unable to produce insulin. Treatment consists of at least twice daily insulin injections in order to prevent serious short and long-term complications. In addition, children and their families need to ensure that an appropriate diet and lifestyle is followed and blood glucose levels are closely monitored [17].

For an adolescent with diabetes, the rapid changes in physical, sexual, psychologic, social and cognitive function that occur with adolescence can often lead to a decline in self-care behaviors. Glycemic control during adolescence can be suboptimal [18] because of a number of factors such as the physiologic changes associated with puberty [19], a desire to be perceived the same as peers, poor adherence to insulin regimens and decreased attendance at diabetes care clinics [2]. Irregular attendance at clinics has been associated with poor glycemic control and increased rates of diabetes-associated complications [20].

Adolescents who live with T1DM may experience the transition from the children's to the adult health service as an additional burden over and above the everyday challenges of becoming a young adult because achieving glycemic control may have a significant impact on daily life [21–24]. Clinicians working in both children's and adult services have raised concerns that young people transferring between services often fall through service gaps. Scott *et al.* [4] found that 90% of adolescent survey respondents had felt “lost in the shuffle” when making the transition from pediatric to adult diabetes services.

Adolescence is a time when many young people have not received adequate follow-up until a crisis has forced them back into the system [1,3,21]. Transition in this context was defined by Blum *et al.* [25] as “the purposeful, planned movement of adolescents with chronic physical and medical conditions from child-centred to adult-orientated health care systems.” This definition has been widely applied within a wide spectrum of clinical practice, guidelines and research studies and focuses on the passage between two points within the health care system. The authors contend, however, that a broadening of this definition is needed because the adolescent's transitional process of inner re-orientation also has to be considered in order to provide holistic care.

A systematic review conducted by Fleming *et al.* [21] highlighted the need for collaboration between children and adult services, particularly in light of the well-documented differences between these services [22,26–28]. Some of the differences between services have been identified as decreased parental involvement in adult services and significant differences in clinical practice and culture [29]. While it has been acknowledged that it is necessary for the children's and adult services to have different foci, it is argued that collaboration is needed to help bridge the gap so that transition is experienced by the adolescent as a smoother process [21,22].

---

## Transition in the diabetes care setting

The process of transition in the diabetes care setting involves both the physical transfer of an adolescent from one health care setting to the other (pediatric to adult) as well as the acquisition and practice of self-management skills and the shift of responsibility of care from parent to adolescent. Transition therefore is not only the physical transfer of an individual moving between health

services, but also the environmental, emotional and psychologic factors that are encompassed in this process. Transition is a progressive process that involves patient, health care provider and family or carer and effectively commences, in one dimension or another, once a child is diagnosed with diabetes.

### Components of transition

It is useful for the purpose of understanding the complexities of transition to investigate the tasks that are accomplished when transition is successfully achieved. Successful transition involves the accomplishment of a number of tasks, as follows.

**1 Acquisition and practice of self-management skills.** The pediatric model of care assumes that young people lack the necessary practical and cognitive skills to undertake some of the tasks imperative to daily diabetes management, such as managing food intake, as well as the broader diabetes management tasks such as interacting with relevant health care professionals and keeping up-to-date with current knowledge. The process of transition involves the acquisition and practice of these skills by the patient, independent of parent or carer.

**2 Acquisition of skills necessary to maximize utility of the adult health care system.** Skills such as self-advocacy, the ability to find and negotiate services and knowledge about general young adult health issues such as substance abuse, mental health, exercise and sexual health prepare the adolescent for self-care [30].

**3 Shift of responsibility of care from parent to individual.** Responsibility of T1DM management must shift from the parent to the adolescent while maintaining an appropriate degree of parental interest and family cohesion [21,31]. Pediatricians who inappropriately foster persistent parental involvement risk promoting dependency in the patient [32]. It is important to note, however, that a shift of responsibility in diabetes management may be perceived as threatening by parent and patient and may result in feelings of neglect and anxiety. Therefore, both too much parental focus and too early a dismissal of parental responsibility can be disadvantageous to the transition process.

**4 Internalization of concept of illness.** Prior to transition, it is likely that responsibility of T1DM management belonged to one or both parents of the young person. Transition involves the shift of responsibility of care from parent to individual, and this shift may trigger or complete the process of internalization (consolidating and accepting illness), offsetting the degree of displacement that is implicit when responsibility of care does not belong to the patient themselves. Consequences of internalization can include loss of identity and subsequent reframing of identity at a time when identity is fluid and in the process of development, and loss of control and personal power, which is important for self-esteem. Again, this occurs during a developmental period when the individual may be struggling with self-esteem issues, because of physical changes and changes in peer significance.

**5 Integration of T1DM management tasks into emerging lifestyle.** In general, the period during which transfer occurs is a time when the adolescent or young adult is adopting a new lifestyle, for

example, leaving secondary school, moving – economically, geographically and emotionally – from the parental home, entering the workforce, attending university or traveling [31]. The adolescent or young adult must learn how to integrate their daily T1DM management tasks into their emerging new lifestyle.

**6 Physical transfer to an adult health care system.** The physical transfer to adult health care services requires the implementation of a specific set of diabetes management skills and knowledge as well as negotiation and self-advocacy skills that are not assumed in the pediatric health care system.

---

## Adolescent needs during transition

Rarely have young people been asked what their needs are during transition. This is surprising given that the transition between diabetes services often occurs concurrently to the time of significant change in the adolescent's life.

A qualitative study undertaken by Visentin *et al.* [33] found that adolescents focused on the medical transfer of care during transition. The focus on medical care may be because many adolescents had not regularly seen any other health care professional. Adolescents stated they were interested in being introduced to the diabetes nurse educator and dietitian at the adult services [33]. Kipps *et al.* [3] reported a higher rate at attendance of adult services when the adolescent had met a member of the adult team before transfer which signifies the importance of prior contact and collaboration.

The precise needs of adolescents will vary according to culture and circumstances [34] and so research at the service level will be required to ensure services are tailored to need. Flexibility seems to be the key, because young people may be ready to transfer to adult services at different times, dependent on their cognitive and physical development, emotional maturity and general health [34]. The role of health professionals in this process is to tailor advice to young people based on their developmental and cognitive level [29].

During this transitional process, adolescents with diabetes need a shared understanding of their needs from their health care provider. This requires consultation with adolescents themselves [33], planning, ongoing contact and feedback between care providers in the two health care systems, and evaluation of services [35].

### Promoting self-care

Promoting better management for adolescents with T1DM by developing their capacity to self-care through healthy choices prior to transition to adult services is an optimal goal. Gradual and early promotion of self-care is particularly important during adolescence when young people may try to act out behaviors in order to demonstrate independence. A cross-sectional multisite study of adolescents was conducted with 130 young people, studying factors that affect blood glucose control, such as how they care for themselves, eating problems, relationships, depression

and health issues [36]. The research found that poor self-care, disturbed eating behavior, depression and peer relations were all associated with poor blood glucose control. Where there were good family relationships and support from parents, girls achieved better control than boys. The researchers suggest that further research should look at the reasons behind these relationships. The authors propose that monitoring of diabetes knowledge and promotion of self-efficacy from late childhood may optimize the transfer of self-care knowledge and behaviors from parents to adolescents [36].

Adolescence and young adulthood is characterized by a number of cognitive, emotional, behavioral and social changes that can present as barriers to effective self-management, including engagement with health care services. Cognitive changes include a shift in thinking from concrete to abstract and the ability to engage in introspection. These new cognitive skills give the ability to reflect on self-identity (self-concept and self-esteem). Adolescence is also a time of experimenting with new behaviors and, in particular, risk-taking behaviors. Socially, the importance of peers significantly increases at this time and concerns with being accepted by peer group are strong.

Successful transition can only be facilitated by provision of appropriate services, programs and resources. Long-term success is heavily dependent on instilling adequate self-care behaviors and self-advocacy skills so that adolescents can deal appropriately with external factors such as home, school and work life which may present as obstacles to effective diabetes management.

### Education programs to promote self-care

A powerful predictor of good self-care is self-efficacy. For the purposes of this chapter, self-efficacy can be seen when adolescents have confidence in their capability to make decisions and take actions that demonstrate diabetes self-care. Education programs that enhance self-efficacy by incorporating personal health care goals and social and peer support have been shown to improve health outcomes and facilitate smooth transition in adolescents and young adults with T1DM [30]. Cook *et al.* [37] describe a pilot study demonstrating how the problem-solving behavior of adolescents with T1DM was improved through participation in a workshop style education program. The Choices Program consisted of six small weekly group workshop style sessions where adolescents came together to discuss major diabetes management problems, including psychosocial issues, and work together to identify solutions. This program demonstrated an increase in the practice of diabetes health care behaviors such as blood glucose monitoring and exercise. Cook *et al.* [37] identified three principles that are key to the success of an education program: parental involvement, integration with clinic (e.g. to allow implementation of regimen changes) and six or more sessions plus multiple follow-up and review sessions.

Education programs should be based on current learning and behavior change theories and should be developed with these key principles in mind. Furthermore, education programs should be

part of standard care as well as specific elements in formal transition care programs.

---

### **Barriers and facilitators to successful transition**

Many authors emphasize the need for collaboration between pediatric and adult diabetes services so as to create a smooth transition for adolescents [1,21,23,28,32]. These authors recommended that transition should be planned and coordinated [21,23,28,32]; however, the reality is that unless there is a transition program in place, adolescents transfer to adult services in an ad hoc manner with little planning, consultation or case management [33]. Hence, the absence of guidelines for the development, implementation and evaluation of transition programs must be viewed as a significant barrier to successful transition. Authors from Australia, the UK and the USA have called for the development of national policies that inform transition for adolescents with chronic conditions [1,21,23,28,32]. More recently, countries such as the UK, Australia and Canada either developed or made progress around developing standards and guidelines for policies in order to improve transition outcomes and experiences. For example, Diabetes Australia – Victoria is undertaking a project to develop a state-wide coordinated transition system for individuals living with T1DM. In addition, some professional organizations have developed best practice guidelines to inform the care of adolescents transferring to adult services. The successful translation of these guidelines into practice, however, remains unclear.

It has been acknowledged that transition to adult services can be difficult for a myriad of reasons. The most reported concern is the notable differences in the approach to care between children's and adult diabetes services. Children's services focus on the whole family and assume the child has little or no knowledge about diabetes and management. The adult sector take a more individual approach and assumes the patient has decision-making capacity and is knowledgeable about diabetes and has the necessary skills to navigate the complex health system [26,28]. In addition, adult services expect a much greater degree of independence from young people and encourage communication without parents being present. It may be difficult for adolescents to adapt to this type of relationship, particularly when they have had a long-standing relationship with their pediatrician [22]. The adolescent may experience significant difficulty if the pediatric health care provider has not recognized the need to up-skill the adolescent in self-care behaviors before transfer to an adult service. A helpful approach to assist adolescents to transition is to focus on the location of the actual aspects that are changing, then to explore how the changes are being experienced by the individual, followed by consideration of how the person is responding or may respond [15].

Adult service staff may make the assumption that the adolescent has the necessary skills and maturity to be able to plan their future and have the insight to understand the consequences if they choose not to undertake diabetes self-care [21,22]. Viner [1] argued that

adolescents are not served well by either model of diabetes care because the children's clinic may not acknowledge their growing independence while the adult clinic may not acknowledge their growth, development and family concerns. It has been recommended that transition be "a family affair" [27] and that transition in health care is acknowledged as only one aspect of a broader life transition that adolescents move through [1].

If the transition process is not meeting the needs of adolescents then they may choose to drop out of the system. While adolescents may continue to access a primary care physician for the prescription of insulin, it is thought that a multidisciplinary approach to diabetes care provides optimal management [38,39]. If diabetes is poorly managed, young adults are at an increased risk of microvascular and macrovascular complications as well as life-threatening acute complications such as diabetic ketoacidosis (DKA) [40].

The demands of diabetes may be experienced as difficult during the adolescent years and it has been documented that glycemic control at this life stage often deteriorates [21,22,41,42]. The deterioration in glycemic control is thought to be related to an increase in insulin resistance that relates to physiologic changes in puberty coupled with the psychosocial pressures associated with this period [41,42]. Of further concern, glycemic control in young people in the 16–25 year age group was found to be poorer than at other times during the lifespan [43].

The health professionals participating in the study of Visentin *et al.* [33] expressed concern about exposing adolescents to older people with type 2 diabetes, particularly if those older patients had obvious complications of diabetes such as amputations. Interestingly, adolescents claimed that such exposure was not an issue for them.

The experiences of adolescents with diabetes living in rural or remote areas have been rarely reported. There appears to be an assumption that adolescents have easy access to services; however, this may not be the case in many counties. In a study by Cameron *et al.* [44], adolescents in rural areas were found to have poorer outcomes than young adults from metropolitan areas, particularly in the areas of mental health, self-esteem and family cohesion. The authors considered a major factor in the differences in these outcomes was a lack of transition programs and other support services. Another factor was that adolescents with diabetes living in rural and remote areas may have less access to peers who also have diabetes, leading to a lack of peer support.

---

### **Models of transition care**

While the literature has outlined principles for successful transition and made suggestions for model development, there is limited research that provides outcome data to support one model over another [1,3,30]. A study undertaken in the UK compared different models of transfer within one region using data generated through interviews and retrospective casenote review [3]. The models evaluated were:

- 1 Direct transfer to an adult clinic;
- 2 Transfer to a young adult clinic in a different hospital;
- 3 Transfer to a young adult clinic within the same hospital; and
- 4 Transfer to an adolescent clinic that was jointly operated by pediatricians and adult physicians.

The most significant declines in clinic attendance were observed when adolescents were either transferred to a young adult clinic in a different hospital or were transferred directly to an adult service. These adolescents were also the most dissatisfied with their care. Consistent with others studied, those adolescents lost to regular follow-up had higher mean HbA<sub>1c</sub> levels. Variables such as socioeconomic status and geographic location were not included in the analysis. The authors concluded that transfer to a young adult clinic was preferable to direct transfer to an adult-only clinic and providing the opportunity to meet with staff from the adult service prior to transfer may improve outcomes [3].

Another UK-based study [26] surveyed adolescents who were attending an under 25-year-old-clinic. Interestingly, a high number of adolescents in this study did not report difficulties with transition; however, they did feel it would be helpful to have visited the clinic prior to transfer.

A study undertaken in Australia [45] surveyed adolescents aged between 15 and 18 years. The author concluded that a specific transition clinic can provide an important link and that transition needs to be a gradual process. Another study in Australia reported increased effectiveness when a coordinator worked with adolescents during the transition to adult care [46]. Schidlow and Fiel [27] discussed a transition clinic established in the USA where the pediatrician and adult physician conducted joint clinics in pediatrics as a stepping stone to the adult clinic. Unfortunately, there was no reported evaluation of this service.

There has been little qualitative research that has explored how adolescents experience transition. One recent Australian study researched the experiences of six young adults with cystic fibrosis using in-depth interviews [47]. The aim was to reveal the factors that contributed to the experience of transition and potential outcomes. A number of strategies were outlined that may improve the transition process with this patient group. These included a familiar face at adult clinics, orientation tours and the provision of written and verbal information as part of the transition program.

Table 52.1 provides a summary of the recommended stages of transition and includes specific recommendations for improving outcomes at each stage. Seven out of the eight stages of transition identified in Table 52.1 occur prior to transfer to an adult service and constitute the preparation phase (Phase 1). They focus largely on promoting self-care behaviors through education and practice. The stages are sequential, beginning at diagnosis and followed with a detailed introduction of the concepts of transition, assignment of a transition case manager, an assessment of the patient's diabetes and health knowledge, commencement of an education program, demonstration of learned skills and transfer to an adolescent/young adult transition clinic, where the young

person is given the opportunity to practice learned skills before transfer to an adult service.

### Transition case coordinator

There is sufficient evidence to suggest that successful transition can be facilitated by utilizing a transition case coordinator (TCC) and that the cost benefits from reduced hospital admissions otherwise secondary to preventable complications can cover the cost of establishing and running a TCC program [30,46]. TCCs have also been successfully utilized within juvenile idiopathic arthritis transition programs. An evaluation of a transition program delivered to adolescents and young adults with juvenile arthritis revealed that TCCs are highly valued by both patient and parent [30].

TCCs can be any health care professional with a high level of knowledge of T1DM and its complications as well as knowledge and experience in dealing with adolescents. This includes diabetes nurse educators, diabetes educators, primary care physicians or diabetes specialists such as endocrinologists. One of the most important characteristics of a TCC is the ability to communicate effectively with adolescents and young adults, and one might suggest this as a priority over in-depth knowledge of the condition itself. Research has demonstrated that positive results can be obtained through administrative non-medical case management [48].

The fundamental role of the TCC is to support the adolescent or young adult in becoming their own effective lifelong case manager, by ensuring that an increase in the patient's confidence and skills is a priority of the health care system in which the patient resides. In order to improve health outcomes, TCCs need to be clinically sophisticated advocates of evidence-based care. The tasks of the TCC are to coordinate clinic appointments, follow-ups and appointments with allied health professionals and to ensure accurate adequate information is provided to the patient in a timely manner. TCCs are also responsible for facilitating the patient's engagement with relevant community health organizations. It is the role of the TCC to attempt to re-engage "drop-outs" by identifying barriers to engagement and offering to reactivate and facilitate a referral to an appropriate health care professional or diabetes clinic.

A recent 5-year evaluation of a transition care program in a Sydney-based hospital demonstrated that a TCC program can increase clinic attendance and reduce HbA<sub>1c</sub> and DKA-related hospital admissions [46]. The transition care program consisted of a TCC (a diabetes educator) who followed up bookings and missed appointments and provided an after-hours sick day phone service. The program also involved a primary care physician and a diabetes specialist. The cost savings from reduced hospital admissions covered the costs of the program. Interestingly, the evaluation revealed that the potential to lose contact with adolescents and young adults is greatest in the first few months after referral; 9 out of 10 young adults (mean age 18) lost to follow-up only attended one appointment.

The effectiveness of an administrative-based non-medical TCC has been demonstrated through evaluation of the Maestro Project, an administrative support and systems navigation service

**Table 52.1** Recommended stages of transition.

Action	Description	Stage	Age	Practical and psychosocial achievements	Factors that facilitate success
Diagnosis	Introduction of concepts of illness and care to patient and family/carer Mental health support Introduction of concepts of transition (if age-appropriate) Mental health review	1	NA	Patient and family/carer progress effectively through stages of grief Patient and family/carer understand physical and psychosocial effects of illness Patient and family/carer have a broad notion of the concepts of transition	Information provided at diagnosis should be thorough and of immediate relevance Delivery of information should be by a health professional who is contactable for questions at a later time Incorporate a mental health professional into the diabetes management team who can facilitate understanding of psychosocial impact of illness
Introduction	Introduction of concepts of transition Interactive discussion with input from adolescent and parent, and case manager (see below)	2	12*	Dissemination of patient information First draft transition care plan	Transition care plan should consider and address age, gender and cultural issues
Case coordinator	Appoint a transition case coordinator to coordinate aspects of the process and act as key contact	2	12*	Professional relationship with adolescent and parent	Case coordinator should have significant knowledge of mental health and adolescent-specific issues
Knowledge assessment	Assessment of diabetes knowledge and self-management skills Mental health review	3	12–13*	Second draft care plan, incorporating outcomes of assessment, education goals and mental health review Address any mental health concerns	Transition care plan should consider and address age, gender and cultural issues
Education program	Basic diabetes management Skills development Advanced diabetes management Adolescent-specific and general health issues Dietary review Solo consultations (in part)	4a	13–15*	Learning Self-efficacy, problem-solving	Group education including peers and family/carer
		4b	13–15*	Gaining independence Active participation in care with parents/carer Solo consultations with parent/carer involvement at end of consultation	Parental/peer involvement Integration with clinic Six or more sessions plus multiple follow-up and review sessions

*Continued on p. 882*

Table 52.1 Continued.

Action	Description	Stage	Age	Practical and psychosocial achievements	Factors that facilitate success
Demonstration	Demonstration of learning outcomes	5a	15–17*	Internalization of concept of illness is complete Adolescent is self-managing Adolescent is self-advocating Solo consultations (with parent/carer involvement at end of consultation if deemed necessary) Responsibility of care has shifted from parent to adolescent/young adult	
	Decide on suitable model of transfer, i.e. private vs. public, transition clinic vs. adult clinic Establish adult diabetes management team	5b	15–17*	Third draft care plan incorporating developed skills and health care goals with patient input Professional relationship with adolescent/young adult transition clinic staff, implying multiple visits to transition clinic	Final diabetes management plan should align health care goals with other life goals
Transfer to adolescent/young adult clinic	Physical transfer to adolescent/young adult transition clinic to enable patient to practice acquired skills	6	15–25*	Solo consultations Demonstration of acquired skills	Transition clinic staff met prior to transfer First appointment arranged by transition case manager and followed-up Any issues identified addressed immediately
Transfer to adult service	Physical transfer to chosen adult care provider	7	*	Physical transfer to chosen adult care provider	Adult staff met prior to transfer First appointment arranged by transition case manager and followed-up Any issues identified addressed immediately
Support, follow-up and evaluation	Transition case manager provides support and follows up with adolescent/young adult to discuss transition, concerns, etc.	8	*	Minimum 6-monthly follow-ups (2 per year) for 2 years post-transfer	Use multiple vehicles for follow-up, including formal letters via post, telephone calls and SMS reminders

\*Age is indicator only. Progression to subsequent stage should occur when it is deemed appropriate by health professional, patient and family/carer.

available to adolescents and young adults aged 18–35 years with T1DM in the province of Manitoba, Canada [49]. The program, Building Connections: The Maestro Project, commenced in 2002 and consists of biannual telephone and email contact by the Maestro, a non-medical TCC who facilitates connections and appointments with relevant health care professionals and follows up bookings and missed appointments. The program also consists of a website through which program participants can locate local services and other relevant educational materials, an e-newsletter, a casual evening drop-in support group and evening group educational dinner events.

The Maestro Project's 2007 Annual Report reveals that the program has significantly increased engagement with health care services. Of the 101 young adults who were referred to the Maestro Project after they had been transferred to an adult service, medical engagement increased from 59.4% having had one or more visits to an endocrinologist to 73.3% after 1 year in the program. Engagement with a diabetes educator also increased, from 25.7% having had one or more visits, to 41.6%. The program has dramatically reduced drop-out rates in the province, from 40.6% to 10.9% [49]. The Maestro Project is one example of how even basic administrative non-medical transition case management can improve outcomes for adolescents and young adults, in terms of increasing their engagement with the adult health care system.

### Successful transition: an adolescent perspective

Many studies have identified factors expressed by adolescents and young adults as important for successful transition. A study by the Royal District Nursing Service Research Unit in South Australia [33] revealed that factors most important to adolescents and young adults include feeling secure, safe and trusting (of health care professionals), gaining independence and being able to access accurate and up-to-date information easily. Additionally, earlier discussions on transition and meeting adult staff prior to transfer are two steps that have been consistently reported by adolescents and young adults, not only in the diabetes health care sector but across many chronic illnesses including cystic fibrosis, juvenile rheumatoid arthritis and sickle cell disease [50]. Studies by Court [45] and Scott *et al.* [4] identified several factors as important to adolescents and young adults progressing through transition (Table 52.2). Furthermore, study participants have identified that endocrinologists, dietitians and primary care physician were the top three most important health professionals to have at a transition clinic [4].

### Transition in practice

The most effective approach to the transition process is one that is organized and sensitive to the needs of the individual adolescent and family. There is evidence to suggest that a health worker dedicated to facilitate transition between services can have a positive impact on young people [29]. Adolescents in transition from

**Table 52.2** Factors that facilitate transition to adult services.

#### Preparation process

- Earlier discussions surrounding transition
- Autonomy and self-direction – 71% of study respondents wanted to set goals with their adult health care team [4]
- Important education topics
- Research
- Stress management
- Financial assistance
- Cooking
- Complications (without direct exposure, as occurs in adult clinics)

#### Consultation and staff issues

- Visits to adult clinic prior to transfer
- Longer initial meetings with adult center staff
- Ability to talk about personal issues
- Continuity of care

#### Transfer and clinic environment

- Clinics not located in a hospital setting
- Ideal young adult clinic ages 18–30 years and separate from adult clinic
- Evening clinics and opportunities for “drop-in” appointments
- Interaction with peers and peer support

children's to adult diabetes services are involved in a period of critical but forced change. There are variations in the way adolescents engage or fail to engage in transitional processes. For example, adaptation to change often involves undertaking a process of trial and error [10] so that individuals can determine and understand the ways they are responding to change. Sometimes when young people undertake a process of trial and error, health workers may consider that they are engaging in risky behaviors. This may create a problem-orientated approach for adolescents rather than a preventive model of care that may inhibit the promotion of self-care.

Dalton and Gottlieb [51] explored the concept of readiness to embrace change, which they argued was often linked with a person's compliance to a medical regimen. By contrast, previous research revealed that living with long-term illness appears to be about incorporating the consequences of illness into everyday life [10,52]. Dalton and Gottlieb [51] provided an alternative view that conceptualized readiness as a process of *becoming* ready over time. Readiness to change was embedded within a process of learning. Baker and Stern [53] described a process of readiness that involved making the illness a part of life and coming to terms with self-care teaching and having a sense of control. Relationship-building between health care professionals and adolescents, as a means for mapping individual context and identifying shifting values over time, dealing with difference and miscommunication, is perhaps the first step to facilitating this transition.

There have been a number of studies that found that adolescents were keen to receive written and verbal information about transition and that they wanted to be provided with opportunities to meet the new team prior to transition [3,26,45,47]. It is neces-

sary for a transition model to take into account the stakeholders' views (professional, parents and clients). Transition literature from the diabetes and cystic fibrosis fields agree that there is a lack of outcome data that can clearly support one model over another [1,21,32]. Suggestions such as young adult clinics, stepped transition, joint clinics with pediatricians and adult physicians and transition nurses have all been described in the literature.

Health professionals and adolescents in the study by Visentin *et al.* [33] highlighted that transition is frequently focused on the medical transfer of care with the allied health teams having a minor role. Of the four children's services participating in their study, only one had a recall system established to offer adolescents regular education updates at designated intervals. Similarly, only one of the adult services had an established pathway in place to ensure that all of the adolescents were offered dietitian and diabetes nurse educator appointments at the time of the transition. Furthermore, health care professionals reported a poor uptake of these appointments. The ramifications of these findings, which have been replicated in other studies, are that adolescents are not receiving holistic preparation for transition in terms of developing self-management skills required for adaptation to an adult health setting. Adolescents in Visentin *et al.*'s [33] study were keen to be given opportunities to meet staff prior and receive written information. Transition might be easier if adolescents were involved in early planning and informed about what to expect from the adult service and how it may differ to the pediatric service.

Research studies have revealed that transition to adult services is often based on the medical model. Transition needs to be viewed holistically as opposed to focusing solely on the referral from one medical doctor to another. A problem-focused or reactive approach to diabetes care effectively relinquishes the potential for independence and control for the adolescent. If nurses and dietitians are only involved during periods of diabetes instability, then adolescents may not be provided opportunity to learn self-care skills. T1DM is often a family issue with reliance upon parents for information and advice. It is important that diabetes nurses and dietitians become involved in working with adolescents towards self-care as many were diagnosed as children and may never have received first-hand information about diabetes.

The role of diabetes nurse educators in preparation and facilitation of the transition process and follow-up has not been fully realized. Preparation needs to be expanded so that there is a larger focus on developing self-care skills. This approach would assist individuals in taking on the extra responsibilities expected by adult services. Frank [22] stated that a gradual preparation of both youth and parents is an important principle for transition. Blum *et al.* [25] argued that the notion of transition should be discussed as early as diagnosis. One of the transition principles advocated by Rosen *et al.* [32] is to have a designated health professional to coordinate the transition process between children's and adult diabetes services. Diabetes nurse educators are in an excellent position to undertake this role.

Care plans to facilitate a coordinated and planned transition process have been proposed by Weissberg-Benchell *et al.* [31]. The care plans should be developed in consultation with the adolescent and parents, and incorporate all aspects of the transition process such as identifying information regarding specific health services, appointments, and health and education goal planning; however, the effectiveness of the use of care planning as a process to facilitate seamless transition and improve outcomes for adolescents does not appear to have been evaluated.

The optimal goal of transition between services is to provide health care that is uninterrupted, coordinated and developmentally appropriate. The value of early preparation in late childhood from a multidisciplinary team is important for transition. To summarize the evidence, it is proposed that transition programs contain the following elements:

- Early introduction to adolescents of the concept of transition;
- Based on capacity building principles and promotion of confidence and independence and self-advocacy skills;
- Both the pediatric and adult diabetes services have a documented transition program for adolescents;
- Transition care plans incorporating all elements of the transition process;
- Timing of the transition based on maturity and skill rather than age;
- A senior member of the clinical staff from each service is responsible for the successful implementation and maintenance of the transition program;
- A designated professional, who collaborates with the adolescent and family, takes responsibility for the transition of each adolescent;
- The transition program has a multidisciplinary focus with input from consumers, primary care and allied health professionals;
- Adolescents are encouraged to develop a relationship with their primary care physician;
- The transition program should include the details of the process of transition, the expected outcomes and evaluation processes;
- The transition program should promote individualized plans for each adolescent inclusive of expected outcomes and time-frames, opportunity for the adolescent to have a voice in articulating their needs, early involvement with the adult team, opportunity for adolescents and their families to meet with new carers, opportunities to meet with other adolescents who have successfully transitioned to adult services, and access to psychosocial support for adolescents experiencing difficulty in the transition;
- All staff, including clerical and administrative staff as well as clinicians, should be educated in the philosophies and features of the transition program. Parents and children should also have the purpose and principles of structured transition explained and have access to details of the program well before transition commences;
- Include opportunity to address common concerns of adolescents such as growth and development, sexuality, mood and mental health, substance misuse and other high risk behaviors.

### Information and communication technology

Modern information and communication technologies such as the Internet and mobile phones have the capacity to provide a unique and effective method of delivering support to adolescents and young adults with chronic illness. Adolescents and young adults are at the developmental age where new technologies are quickly and easily integrated into peer culture and daily life. A study by Rasmussen *et al.* [54] revealed that young women with T1DM use the Internet not only as a means of obtaining information and communicating with others, but also as a means by which to achieve a sense of autonomy and stability.

Text messaging has been recently used in the UK as a way to support young adults with diabetes to achieve goals [55]. The text message provides a weekly reminder of the goal set during clinic, with follow-up messages that reinforce the goal by providing information and reminders. The aim of the program is to optimize self-efficacy and motivate health enhancing behaviors. The program is based on the principles of social cognitive theory and has demonstrated improved metabolic control among participating adolescents [55].

The Internet offers many communication forums that adolescents will be familiar with. Websites, chat forums and various messaging systems are popular and have enormous potential for information sharing and education. For example, Twitter is a free social networking forum that enables users to send and read other users' updates known as "tweets." Tweets are text-based posts and could be used to support self-care and goal achievement for adolescents with diabetes.

There is also major potential for modern technologies such as advanced videoconferencing to provide isolated patients, including those in rural areas, with convenient access to specialist health professionals. The Centre for Online Health commenced a research project in 2000 that aimed to establish and evaluate a telepediatric service in Queensland, Australia [56]. The service operates using a centralized coordination unit, and services regional and remote hospitals. The telepediatric service provides access to specialist pediatric services. A response to the referring clinician is guaranteed within 24 hours. In the first 6 years, more than 4000 consultations were coordinated through the telepediatric service. The consultations have concerned a wide variety of fields including diabetes, endocrinology, burns, cardiology, dermatology, oncology, orthopedics, gastroenterology, neurology and pediatric surgery. A range of communication techniques are used for communicating including email, telephone and videoconferencing. Approximately 90% of referrals result in a consultation via videoconference. The service has demonstrated a significant increase in the number of children accessing specialist services. This type of technology also has significant potential to support adolescents living in rural and remote areas through transition to adult services.

### Quality processes

Key performance and clinical indicators developed locally have been identified as being essential for the governance of transition

processes [34]. For example, the Australian Clinical Practice Guidelines: Type 1 Diabetes in Children and Adolescents [57] described three phases of transition: preparation, formal transition and evaluation. The guidelines recommend that the preparation phase commences from 12 years of age; however, it is unclear if such early planning actually takes place because evaluation of transition programs has rarely been reported. The findings from studies such as Visentin *et al.* [33] indicated that the three stages of transition programs are often not being fully implemented in health units.

Evaluation of transition programs may include but not be limited to undertaking a satisfaction survey of adolescent clients and their parents, to determine if they are happy with the service, they were able to adopt the treatment regimen, felt involved in and informed about the transition process and attended follow-up appointments [34]. When auditing, it is recommended to consider the availability and effectiveness of policy detailing transition processes and principles, a multidisciplinary education program, processes to enhance coordination between programs and administration and documentation [34]. In summary, some key evaluation measures include:

- Development and documentation of a structured transition program with established review dates;
- Percent of adolescents transitioning with an individualized plan;
- Adolescent and parental satisfaction; and
- Percent of adolescents attending follow-up after 12 months.

---

### Future research

A body of knowledge has developed that has focused on the transition processes, models and adolescent experiences; however, further research is required to enhance our understanding of how best to serve adolescents with diabetes. For example, several studies have explored how developmental stage and lifestyle impact an adolescents' transition and outcomes but research exploring factors such as ethnicity, socioeconomic status, geographic location (e.g. rural and remote) and gendered experiences have not been reported. Rigorous evaluation of variations in transition programs is also needed to inform future program development that promotes long-term engagement with the health system. The promotion of self-care for adolescents with diabetes is an area that would benefit from focused research. There is currently little understanding of care approaches that increase the effectiveness of self-care strategies in adolescents. In addition, research into how to access and re-engage adolescents who drop out of the health care system is urgently needed.

Further research into how modern technologies, resources and networks can be exploited to provide support to adolescents in transition is also necessary. For example, there is potential for developing and implementing an online transition resource that can be integrated into service coordination tools used by health care providers.

## Conclusions

Adolescents in transition from pediatric to adult diabetes services are experiencing forced change. Adolescents with diabetes establish a long-term positive bond with their pediatric health care team, so that the transition to an adult diabetes service provider is a significant event in their lives. Evidence has revealed the major elements of successful transition programs; however, there is a need to evaluate the effectiveness of the various transition models. Promoting better management for adolescents with T1DM by developing their capacity to self-care prior to transition to adult services is an optimal goal. There is significant potential to improve practice and outcomes through establishment of transition programs for adolescents with diabetes.

## Diabetes in Pregnancy

Anne Dornhorst<sup>1</sup> & Anita Banerjee<sup>2</sup>

<sup>1</sup>Department of Medicine, Imperial College Healthcare NHS Trust, Hammersmith Hospital, London, UK

<sup>2</sup>Diabetes and Endocrinology, Princess Royal University Hospital, London, UK

### Keypoints

- The number of women with diabetes becoming pregnant is increasing, in line with the increase in type 2 diabetes (T2DM) among women of reproductive age. Rising obesity levels are also contributing to the increasing number of women developing glucose intolerance during pregnancy.
- Perinatal mortality and morbidity is increased in diabetic pregnancies, mainly through increased stillbirths and congenital malformations rates, which are three- to fivefold higher than in non-diabetic pregnancies.
- Metabolic changes occur in pregnancy to facilitate nutrient transfer to the fetus. Maternal insulin resistance helps divert glucose to the fetus. Women with pre-gestational diabetes have insufficient insulin to counter the rise in insulin resistance and require increasing insulin therapy during pregnancy. Women without diabetes before pregnancy become glucose intolerant in pregnancy if they have insufficient insulin reserves.
- Maternal diabetes affects all aspects of pregnancy from conception to the timing and mode of birth. The major early effects are on embryogenesis and the risk of malformations. Glycemic control is critical at this time as glucose is teratogenic to the developing embryo.
- Maternal diabetes affects fetal pancreatic islets and  $\beta$ -cell development which may be a factor in the increased risk of diabetes among children of mothers with diabetes.
- Fetal insulin is an important fetal growth factor and accelerated fetal growth occurs in many diabetic pregnancies as a consequence of maternal hyperglycemia causing fetal hyperinsulinemia. This metabolic environment in later pregnancy may render the fetus susceptible to hypoxia and acidosis and ultimately stillbirth. It also increases the risk of transient neonatal hypoglycemia.
- Good maternal diabetic control lessens the risk to the fetus of malformations, accelerated fetal growth, stillbirth and neonatal hypoglycemia as well as the risk of future obesity and diabetes for the child.
- Pregnancy poses certain risks for the mother with diabetes. Any detrimental effects on retinopathy and nephropathy, however, are limited to those women with significant clinical disease beforehand and are usually self-limiting.
- Proteinuria and microalbuminuria are risk factors for pre-eclampsia and preterm birth.
- Pregnancy in women with underlying cardiovascular disease (CVD) is associated with maternal morbidity and mortality. CVD is likely to increase as more older women with T2DM give birth.
- The increasing prevalence of maternal obesity is having an increasing impact on maternal and fetal pregnancy outcomes.
- The clinical care of women with pre-gestational diabetes and those with previous gestational diabetes mellitus (GDM) should begin before pregnancy. Women who receive pre-pregnancy care have better pregnancy outcomes and it remains a major clinical challenge to ensure that more women with diabetes are properly prepared for pregnancy.
- Preparations include the need to optimize glycemic control, to ensure folic acid supplementation and to stop all unsafe medications for pregnancy. Women should be screened for retinopathy and nephropathy before pregnancy and given relevant information concerning risks to themselves and any unborn child.
- Antenatal management should focus on achieving maternal glucose levels as near to normal as safely possible and close maternal and fetal surveillance for medical and obstetric complications. National evidence-based clinical guidelines for diabetes in pregnancy should be followed to ensure all women have access to the best available care.
- Women at risk of GDM should be screened at 28 weeks' gestation using a 75-g oral glucose tolerance test (OGTT) and the World Health Organization criteria for impaired glucose tolerance.
- Treatment for GDM includes diet and exercise and the use of metformin, glibenclamide or insulin if glucose values cannot be maintained with diet and exercise alone.
- Both women with pre-gestational diabetes and GDM should be offered induction of labor at 38 completed weeks' gestation to reduce the risk of a late stillbirth and the risk of birth injury in a large for gestational age infant. Insulin requirements fall to pre-pregnancy values in the immediate postpartum period and should therefore be reduced.
- The use of insulin pumps, continuous glucose monitors and the basal analog insulin is increasing in clinical practice; however, their use still needs to be fully evaluated in pregnancy.

- Following birth, early breastfeeding reduces the risk of neonatal hypoglycemia and all mothers with diabetes should be encouraged to breastfeed within 30 minutes of birth and then every 3–4 hours until a regular feeding pattern is established.
- Women with GDM should be screened for diabetes before leaving hospital, 6 weeks postpartum and then annually. In low risk

populations, a fasting blood glucose value is sufficient and is likely to be associated with greater long-term compliance than an OGTT. All women with a history of GDM should receive lifestyle advice to lessen their long-term risk of future diabetes.

## Introduction

Diabetes in pregnancy poses serious problems for both mother and fetus and has long-term health implications for the child. The number of pregnant women with pre-gestational and gestational diabetes mellitus (GDM) is increasing, mainly because of the increasing prevalence of obesity in women of childbearing age.

Despite advances in our scientific knowledge and understanding of the effects of diabetes on fetal growth and development, and improvements in fetal and maternal care, pregnancy outcomes are broadly similar to 1989, when the St. Vincent Declaration pledged to improve pregnancy outcomes to those of women without diabetes [1]. Even in highly developed health care systems, stillbirths and congenital malformations remain three- to fivefold higher than in non-diabetic pregnancies.

Improving pregnancy outcomes depends on improving glycemic control from conception to birth. Newer technologies involving glucose monitoring and insulin pumps may bring promise for the future, but the real challenge today is to ensure all women with diabetes begin their pregnancies well prepared and with optimal glycemic control.

The largest audit of diabetic pregnancies including all 3808 pregnancies of women with type 1 (T1DM) and type 2 diabetes mellitus (T2DM) who delivered or booked in 231 hospitals in England, Wales and Northern Ireland from March 1, 2002 to February 28, 2003 was published in 2005 [2]. These women accounted for 0.38% of all births at this time and provide much of the epidemiologic data in this chapter.

A confidential enquiry reviewing the demographic, social and lifestyle factors and clinical care in 521 pregnancies to women in the original audit was published subsequently [3]. This enquiry included 127 pregnancies with a fetal congenital anomaly, 95 pregnancies with fetal or neonatal death of a normally formed baby, 220 pregnancies with a good outcome and 79 pregnancies in women with T2DM and provides valuable clinical data pertaining to pregnancy outcomes.

The American Diabetic Association (ADA) [4] and the National Institute for Health and Clinical Excellence (NICE) [5] published guidelines on the clinical management of women with pre-existing diabetes in pregnancy in 2008. The clinical guidelines in this chapter are based on these two consensus evidence-based guidelines.

## Clinical science and epidemiology of diabetes in pregnancy

### Classification of diabetes in pregnancy

The classification of diabetes is discussed in Chapter 2. A uniform classification of diabetic pregnancies is still needed for both epidemiologic and clinical purposes.

Diabetes is recognized as a heterogeneous condition [6] and while most women with pre-gestational diabetes in pregnancy will have T1DM or T2DM, a few will have monogenetic and mitochondrial forms of diabetes, while others will have secondary causes, such as cystic fibrosis. Correctly identifying the type of diabetes during pregnancy can be difficult, especially when the woman is diagnosed with diabetes during pregnancy, as some may be in the early phases of T1DM [7,8], others may have previously undiagnosed T2DM [9], while the most of the remainder have diabetes induced by pregnancy.

Pregnancy may be the first time that asymptomatic forms of monogenetic diabetes are diagnosed, as they are often present in the second and third decade [10,11]. This is true for maturity-onset diabetes of the young (MODY) caused by a mutation in the glucokinase gene (see Chapter 15). While the prevalence of this form of MODY may be less than 2% for the total antenatal population, screening selected women can increase the likelihood of finding a glucokinase gene mutation to approximately 80% in a white population. Clinical features that may suggest MODY includes a combination of:

- Fasting hyperglycemia outside pregnancy (5.5–8 mmol/L);
- A small blood glucose rise (<4.6 mmol/L) during a 2-hour oral glucose tolerance test (OGTT);
- A requirement for insulin treatment during one or more earlier pregnancies but controlled on diet subsequently;
- A first-degree relative with a history of T2DM;
- GDM or fasting hyperglycemia during pregnancy (>5.5 mmol/L) [11].

Many of the fetal complications of a diabetic pregnancy are a direct result of maternal hyperglycemia and therefore are more dependent on glycemic control than the type of maternal diabetes. By contrast, the medical, obstetric and social risk factors differ between women with T1DM and T2DM. Understanding these differences is important for optimizing pregnancy care [3].

The CEMACH audit assessed the outcomes of 3808 pregnancies in 2767 (73%) women with T1DM and 1041 (27%) women with T2DM. Perinatal mortality, stillbirth, neonatal mortality and congenital anomaly rates were similar for both types of diabetes [2]; however, there were significant differences in pre-pregnancy planning, obesity, social deprivation, risks of recurrent and severe hypoglycemia and retinopathy, all of which may affect clinical care before and after pregnancy. Less than 1% (0.73%) of pregnancies were in women identified as either having MODY or another or unknown cause for their diabetes [2].

GDM is defined as glucose intolerance occurring or first recognized during pregnancy [12]. In the general non-diabetic antenatal population, there is no cut off between adverse pregnancy outcomes and either fasting or the 1 or 2-hour OGTT blood glucose values. The Hyperglycemia and Adverse Pregnancy Outcomes study (HAPO) performed 25 505 75-g OGTTs at 24–32 weeks' gestation in women without diabetes and found a continuous relationship between maternal glucose concentrations and increased birth weight and increased cord-blood serum C-peptide levels; both of these measures are surrogate markers for fetal exposure to maternal glucose [13]. These associations occurred at glucose levels below those currently used to diagnose GDM.

Women who develop impaired glucose tolerance (IGT) during pregnancy, share common diabetic risk alleles [14] and have similar insulin secretory defects [15] to women with T2DM. Many of these women develop T2DM in later life [16]. For these reasons, GDM can be considered a forerunner of T2DM, with the caveat that some women diagnosed with GDM are in the preclinical phase of T1DM or have other rarer forms of diabetes.

Historically, the best known classification for diabetes in pregnancy was a Boston classification, named after Priscilla White who published it in 1949 [17]. The White classification was based on maternal and obstetric risk factors, graded from A (best) to F (worst) designed to predict pregnancy outcomes. Subsequent modifications to this classification were introduced in 1965 and 1971 and further updated in 1980 to incorporate ischemic heart disease and renal transplantation [18]. The White classification, like others based on purely pregnancy-related risk factors, "Prognostically Bad Signs in Pregnancy" [19], are no longer used in clinical practice.

---

## Metabolic adaptation to pregnancy

### Metabolic changes in normal pregnancy

Metabolic changes occur in pregnancy to ensure sufficient maternal fat deposition in the first half of pregnancy to sustain fetal growth in the second half of pregnancy. By the eighth week of pregnancy, fasting plasma glucose concentrations start to fall and reach a nadir by 12 weeks; by contrast, post-prandial glucose levels rise [20,21]. Fasting and glucose-stimulated insulin concentrations rise throughout pregnancy [22,23]. The fall in fasting glucose precedes changes in insulin secretion or sensitivity, and

is partly caused by an increase in renal clearance of glucose early in pregnancy [24].

Maternal insulin sensitivity is reduced in late pregnancy by approximately 50%, becoming comparable with levels seen in T2DM [25–27]. For glucose tolerance to be maintained, maternal  $\beta$ -cells must compensate for this fall in insulin sensitivity by increasing first and second-phase insulin responses approximately threefold by the last trimester [15]. In human pregnancy, increased insulin secretion is associated with morphologic changes in the pancreas, including marked  $\beta$ -cell hypertrophy and hyperplasia [28].  $\beta$ -Cells are dynamic and increase in both function and mass in rodent pregnancies. Whether this occurs in human pregnancy is unclear [29]. This capability is presumably decreased in women with diabetes [30].

Pregnancy-related maternal insulin resistance benefits fetal growth, because a rise in post-prandial glucose concentration aids glucose transfer to the fetus, a process termed "facilitated anabolism" [31]. Maternal to fetal glucose transfer in the fasting state is enhanced by maternal lipolysis, which occurs in late pregnancy, with free fatty acids becoming the main maternal fuel substrate and diversion of glucose to the fetus. The ability of insulin to suppress lipolysis (via inhibition of hormone-sensitive lipase in adipose tissue) is severely impaired in late pregnancy, when maternal free fatty acid release and fatty acid oxidation are increased in parallel with reduced carbohydrate oxidation [32–34]. This process of enhanced lipolysis has been termed "accelerated starvation" [35] and is attributed to the actions of human placental growth hormone and other placental hormones [36–41]. These metabolic changes facilitate the transfer of glucose and amino acids to the fetus. An increase in hepatic glucose output in late pregnancy, owing to hepatic insulin resistance, ensures that maternal glucose is available to the fetus between meals [26].

Transgenic mice that overexpress human placental growth hormone develop severe peripheral insulin resistance, similar to that found in the third trimester of pregnancy, confirming its importance in the insulin resistance of late pregnancy. This increase in insulin resistance is accompanied by an increase in expression of the p85 regulatory subunit of phosphatidylinositol kinase (PI<sub>3</sub>-kinase) and a decrease in insulin receptor substrate 1 (IRS-1) associated PI<sub>3</sub>-kinase activity in skeletal muscle [42].

The cytokine tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) impairs insulin signaling *in vitro* and is increased in the second and third trimester of human pregnancy. In late pregnancy, circulating TNF- $\alpha$  levels are inversely correlated with insulin sensitivity [43].

The role, if any, of other adipokines including leptin, adiponectin, interleukin-6 (IL-6) and resistin in insulin resistance in pregnancy still needs to be defined. Adiponectin secretion and mRNA levels in white fat decline with advancing gestation in association with decreased insulin-stimulated glucose uptake rather than altered lipid metabolism [44]. Plasma leptin doubles in pregnancy, being produced by both maternal adipose stores and the fetoplacental unit but its role in maternal metabolism is uncertain [45].

### Metabolic changes in pregnancy in women with diabetes

Carbohydrate tolerance deteriorates in women with diabetes by the second trimester, in parallel with the physiologic decrease in insulin sensitivity. Women with T1DM therefore need increased insulin to maintain glycemic control from the mid-second trimester [15,46]. By contrast, in the first trimester, insulin sensitivity increases and insulin requirements at 14 weeks' gestation are less than the start of pregnancy for well-controlled women with T1DM [46]. In 237 pregnancies in women with T1DM in Scotland, the rise in insulin requirements was associated with maternal weight at booking and weight gain between 20 and 29 weeks while inversely related to duration of diabetes [47].

The added demand on  $\beta$ -cell secretion may account for the increased presentation of T1DM during pregnancy [7,8]. Women in the prolonged but subclinical phase of T1DM characterized by an active insulinitis may have sufficient  $\beta$ -cell function to prevent overt hyperglycemia before pregnancy but insufficient insulin reserve to maintain euglycemia in pregnancy.

Pregnancy-induced lipolysis makes women with T1DM more susceptible to diabetic ketoacidosis (DKA). This can develop rapidly and at relatively low levels of hyperglycemia [48]. If left untreated DKA is associated with high fetal mortality [49].

Women with pre-gestational T2DM are characteristically insulin-resistant before pregnancy with relative insulin deficiency. Further demands on their  $\beta$ -cells often results in a treatment escalation from diet to insulin early in pregnancy to maintain glycemic control. High doses of insulin are frequently needed, and it is not unusual for women to require in excess of 300 U/day by late pregnancy, only to be well controlled with no insulin postpartum [50]. The combination of insulin resistance, decreased insulin secretion and increased lipolysis can precipitate DKA in ketosis-prone obese pregnant women with diabetes, especially among black Afro-Caribbean women, with pre-gestational T2DM or GDM [51,52].

### Glucose intolerance in pregnancy

Glucose intolerance in pregnancy as defined by the WHO 1999 criteria [6] develops in a small but increasing percentage of pregnancies. These women have insufficient  $\beta$ -cell capacity to maintain euglycemia and are typically obese and insulin-resistant before pregnancy. They have lower insulin responses to oral glucose at 30 and 60 minutes than glucose-tolerant control subjects [53,54]. Differences in insulin sensitivity between glucose intolerant and glucose-tolerant women are less marked as pregnancy progresses [26].

Glucose intolerance in pregnancy is a continuum [13] and the higher the fasting blood glucose and 2-hour glucose value on an OGTT, the greater the underlying  $\beta$ -cell dysfunction and metabolic derangement. Even lesser degrees of glucose intolerance are accompanied by abnormal glycerol and free fatty acid metabolism [55] and higher circulating pro-insulin concentrations [56].

Women with a history of GDM, who become glucose-tolerant postpartum, continue to have  $\beta$ -cell dysfunction, reduced glucose-stimulated insulin release and impaired suppression of lipolysis [57–61]. As many of these women are obese and insulin-resistant, the persistence of decreased  $\beta$ -cell function postpartum increases their susceptibility to future diabetes [62–64]. Both obesity and increasing weight gain postpartum are major determinants for the development of diabetes [65].

### Effect of maternal diabetes on pregnancy

Maternal diabetes influences all aspects of pregnancy, from fertility through to birth, and subsequent health of the child and adult. While hyperglycemia is the most obvious metabolic abnormality of a diabetic pregnancy, other metabolic abnormalities can also influence outcome as implied by the term “fuel-mediated teratogenesis” [31]. In addition, diabetic complications, such as microalbuminuria, can influence the risk of obstetric complications, including hypertension and pre-eclampsia.

### Placenta

A healthy pregnancy depends on a healthy placenta but maternal diabetes can cause functional and structural changes in the placenta [66–69]. Insulin receptors are highly expressed in the trophoblast and endothelial cells of the placenta and maternal and fetal insulin regulates nutrient transfer between the maternal and fetal circulation [70]. Placental insulin-binding capacity is increased in macrosomic diabetic pregnancies compared to non-diabetic placentas [71].

### Fertility

Before the availability of insulin, most women with diabetes died within 2 years of diagnosis, and pregnancy was rare. In the 1920s, only one diabetic-related pregnancy was recorded in 35 000 deliveries at two London teaching hospitals [72]. Among those women who became pregnant approximately half of mothers and babies died [73].

Nowadays, although most young women with T1DM can be reassured about their fertility, delayed menarche in girls diagnosed before puberty is common, especially if diabetic control is poor [74,75]. More relevant to fertility is the association between T1DM and early menopause [76]. The mean self-reported age at menopause in an USA study of 143 women with T1DM diagnosed before the age of 17 years was 41.6 years, compared to 49.9 years for 186 sisters without diabetes and 48.0 years for 160 unrelated control subjects [76].

Other potential causes of infertility in women with T1DM are weight-related amenorrhea and primary ovarian failure. Eating disorders are more prevalent among young women with T1DM and are commonly associated with anovular cycles and amenorrhea [77]. Premature ovarian failure can have an autoimmune etiology but is seldom associated with T1DM [78].

Obesity and polycystic ovarian syndrome occur more commonly in women with T2DM and both are risk factors for anovulatory cycles and infertility [79–81].

### Miscarriage

Obtaining precise data on miscarriage rates is difficult because of selection bias, recall bias and the exact definition of the upper time limit. In the UK, miscarriage is defined as the spontaneous ending of a pregnancy before viability (currently taken as 24 weeks' gestation). Spontaneous miscarriage rates among women with diabetes are broadly similar to the general population, which is 12–15%, although the risk is increased when diabetic control is poor [82–86].

Early fetal loss in non-diabetic pregnancies is often attributable to lethal chromosomal abnormalities and once a viable fetus is confirmed by ultrasound at around 8 weeks, the miscarriage rate falls and continues to fall with increasing gestational age [87,88]. Diabetic pregnancies are not at increased risk of chromosomal abnormalities but non-viable congenital malformations are more common than in non-diabetic pregnancies. These contribute to the early miscarriage rates in women with poorly controlled diabetes.

An observational UK study of 185 pregnancies in women with T1DM found a fourfold increased risk of spontaneous miscarriage when women had a glycated hemoglobin (HbA<sub>1c</sub>) level >7.5% (58 mmol/mol) compared to those with a HbA<sub>1c</sub> level <7.5% (58 mmol/mol) (7/48 vs 4/110) [89].

Maternal age and obesity are risk factors for first trimester miscarriage. A threefold increase in recurrent early miscarriage (defined as more than three successive miscarriages before 12 weeks) was found in an UK study of 1644 pregnant obese women (body mass index [BMI] >30 kg/m<sup>2</sup>) compared with 3288 age-matched normal weight control subjects (BMI 19–24.9 kg/m<sup>2</sup>) [90]. As the number of older obese women with T2DM become pregnant, miscarriage rates are likely to rise.

### Embryogenesis and malformations

Maternal hyperglycemia is a major cause of fetal malformation. Clinical and animal studies implicate a combination of metabolic, maternal and fetal factors in the etiologies of diabetic-related malformations [91]. Improved identification and classification of monogenetic and mitochondrial forms of diabetes have shown that some of these rarer forms of diabetes are associated with fetal structural abnormalities, and distinct phenotypes that are independent of maternal glycemic control have been identified (see Chapter 15).

MODY 5 diabetes, which arises from a mutation in the transcription factor hepatocyte nuclear factor-1 $\beta$ , exemplifies this. It is not only associated with early-onset diabetes and renal cysts, but also with a variety of other urogenital and pancreatic anomalies in the offspring [92]. There are well-documented genetic susceptibilities to glucose-mediated malformations in rodents which are likely to occur in human pregnancies [93].

Following improvements in obstetric and neonatal care, congenital malformations now represent the major cause of diabetes-related perinatal morbidity and mortality. Over the last 40 years, diabetes-related congenital malformations rates have been 4–10%. This high rate is especially poignant as good metabolic

control around the time of organogenesis lessens this risk [86,94–106].

Multiple anomalies are more common in diabetic pregnancies than in non-diabetic pregnancies. This suggests the teratogenic insult occurs early in embryologic development [107,108]. While heart and CNS congenital abnormalities are the most common diabetes-related abnormalities [106], the caudal regression syndrome (sacral agenesis) is the most pathognomonic of diabetes, being 200 times more common in diabetic pregnancies [109]. A greater than threefold excess of severe cardiac anomalies including transposition of the great arteries, truncus arteriosus and tricuspid atresia occurs in diabetic pregnancies [110].

The prevalence of major congenital anomalies in the CEMACH audit of women with pre-gestational diabetes was 41.8/1000 births [106]. This rate was twofold higher than the rate of major congenital anomalies from non-diabetic pregnancies reported as 21/1000 births in the European Surveillance of Congenital Anomalies (EUROCAT) data for 2002–2003. Anomalies of the circulatory system and neural tube were threefold higher than expected among the diabetic pregnancies.

### *Congenital malformations – lessons from animal studies*

Rodent studies show diabetes-associated fetal malformations that are broadly similar to those of humans, although the susceptibility to particular different diabetes-related malformations depends on the maternal species and strain [93,111].

Apoptosis in the mammalian pre-implantation blastocyst is a natural process that eliminates abnormal cells. Hyperglycemia modifies the expression of key apoptotic regulatory genes and normalizing hyperglycemia in mice during the periconception period normalizes the expression of these genes [112]. In rodents, maternal hyperglycemia reduces the number of blastocysts formed and the total cell mass of those that survive. In a hyperglycemic environment, blastocyst cell mass is reduced predominantly from the inner cell layer and insulin treatment of hyperglycemic female dams, starting at the time of conception protects the blastocyst from these changes [113]. Insulin may act as a growth factor during early mammalian embryogenesis, influencing mitosis, apoptosis and differentiation through insulin receptors expressed on blastocysts [114]. Other growth factors and cytokines expressed in early blastocysts that may be involved in embryo development are the insulin-like growth factors (IGFs) and TNF- $\alpha$  [115].

Animal studies, predominantly in the rodent, implicate glucose as the major teratogen in diabetic pregnancies. Many of the cellular processes induce oxygen-derived free radical production and increased oxidative stress which provide a plausible unifying mechanism by which supraphysiologic concentrations of metabolic substrates, including glucose, pyruvate and hydroxybutyrate, could be teratogenic [91,116–118]. Hyperglycemia at the time of embryogenesis exposes the fetal mitochondria to a high influx of glucose-generated pyruvate that, by overwhelming the immature mitochondrial electron transport chain, may result in an excess of reactive oxygen species (mainly superoxide) being

generated. The subsequent formation of hydrogen peroxide and hydroxyl radicals in turn leads to increased lipid peroxidation, mitochondrial swelling, DNA damage and altered expression of key genes [91]. Antioxidative agents such as N-acetylcysteine (NAC) and the vitamins E, C and folic acid protect against diabetes-induced malformations in rat embryos [27,119,120].

Myoinositol has an important role as a precursor for a number of secondary messengers and may contribute to diabetic teratogenesis. Cultured rodent embryos in high glucose concentrations have decreased inositol uptake and become inositol deficient [121–125]. Inositol supplementation to embryos cultured in high glucose media or dietary addition to diabetic pregnant rodents protects against glucose-mediated malformation [126,127]. By contrast, the addition of an inositol uptake inhibitor to the culture medium of rodent embryos causes inositol deficiency and embryonic dysmorphogenesis, which is reversible if inositol is added to the culture [128]. Antioxidants diminish both embryonic dysmorphogenesis induced by hyperglycemia and inositol uptake inhibitors, suggesting a possible link between malformations and oxidative stress [129].

Decreased arachidonic acid and several prostaglandins, in particular PGE<sub>2</sub>, in diabetic embryogenesis have been implicated as a cause of malformations. Hyperglycemia during the period of neural tube closure reduces embryonic prostaglandin levels secondary to altered arachidonic acid metabolism and phosphatidylinositol turnover, and the downregulation of the embryonic COX-2 gene [130]. Inhibition of rostral neural tube fusion by high glucose concentrations in rat embryos is prevented by the addition of either myoinositol or PGE<sub>2</sub>, but not if indometacin, a prostaglandin synthesis inhibitor, is also added to the culture [121]. Intraperitoneal injections of arachidonic acid to diabetic rats reduce the rates of neural tube defects (NTDs) [131]. Reduced yolk sac PGE<sub>2</sub> concentrations have been reported from human pregnancies terminated at 8–10 weeks [132].

There is a possible link between decreased prostaglandin synthesis and oxidative stress in cultured diabetic rat embryos; the reduced PGE<sub>2</sub> concentration seen in day-10 rat embryos and membranes exposed to high glucose concentrations can be restored when the antioxidant NAC amide is added to the culture medium. Superoxide dismutase and NAC can prevent malformations when added to the medium of rat embryos cultured in COX inhibitors, acetylsalicylic acid or high glucose concentrations [118].

NTDs in diabetic pregnancies are 2–5 times higher than in non-diabetic pregnancies [106]. Both genetic and environmental factors are involved in NTD development [133]. Although folic acid supplementation can prevent many cases of NTDs, the cellular mechanism for this protection and the relationship between maternal folate status and genetic susceptibility to NTDs are not known. Low dietary folate is an environmental factor for NTD and the 1996 dietary fortification of enriched grain products with folic acid in the USA coincided with a 20% reduction in NTDs by 1998–1999 [134]. Human studies have not shown any evidence for abnormal folate metabolism in pregnant women with

diabetes [135]. In rodent studies, folic acid supplementation protects against diabetes-induced malformations [120].

### **Diabetic control and malformations**

There is a clear association between congenital abnormalities and maternal glucose control in early pregnancy as assessed by HbA<sub>1c</sub> [2,85,89,95,101,102,136–141]. Despite the evidence that diabetic fetal malformation rates approach those of the general antenatal population when glycemic control from conception through to the end of organogenesis is tightly controlled [142–144], the incidence of serious birth defects has changed little over the last few decades [103,140,145].

In a systematic review of seven cohort studies between 1985 and 2006 that examined 1977 diabetic pregnancies with 117 anomalies, the odds ratio for a congenital malformation increased by 1.2 (95% CI 1.1–1.4) for each one standard deviation (SD) unit rise in HbA<sub>1c</sub> level at the time of conception [144]. When the pre-conceptual HbA<sub>1c</sub> concentration was at the mid-normal non-diabetic range, the absolute risk of a congenital anomaly was approximately 2% (95% CI 0.0–4.4) and rose to a risk of 3% (95% CI 0.4–6.1) and 10% (95% CI 2.3–17.8) when the HbA<sub>1c</sub> levels were 2 and 8SD above normal range, respectively.

In the CEMACH audit of pre-gestational diabetic pregnancies, 25% of women with a malformation had a first trimester HbA<sub>1c</sub> level below 53 mmol/mol (7.0%) [2]. This would suggest that at the lower levels of HbA<sub>1c</sub> this measurement of glycemic control does not assess malformation risk as well as it does at higher HbA<sub>1c</sub> values, a finding that is supported from continuous glucose monitoring studies [146].

Intensive glycemic management at the time of conception improves malformation rates [142]. In the randomized Diabetes Control and Complication Trial (DCCT), there were 191 live births from 270 pregnancies. HbA<sub>1c</sub> level at conception was significantly lower in women in the intensive treatment group than in the conventional group (57 ± 9 mmol/mol [7.4% ± 1.3%] and 65 ± 5 mmol/mol [8.1% ± 1.7%], respectively; *P* = 0.0001). There were 92 births (one set of twins) to women in the intensive glycemic management arm and 99 births (two sets of twins) to women in the conventional arm. One (0.7%) congenital malformations occurred in a woman assigned to intensive therapy compared with eight in women in the conventional arm (5.9%; *P* = 0.06).

### **Fetal pancreatic and β-cell development**

Understanding the genetic and intrauterine environmental factors that influence fetal pancreatic and β-cell development and the contribution of maternal diabetes will provide insight into the trans-generational etiology of T2DM.

Immunoreactive insulin is detectable in the human fetal pancreas by 7 weeks after conception and primitive islets by 12–13 weeks, with evidence of functional fetal β-cells by the end of the first trimester [147]. Increased fetal β-cell stimulation and hyperinsulinemia in response to maternal hyperglycemia occurs in

early pregnancy and may persist throughout human pregnancy. This early priming of  $\beta$ -cell function may explain why accelerated fetal growth patterns occur even with good metabolic control later in pregnancy [148,149].

$\beta$ -Cell function and insulin sensitivity in children and young adulthood are influenced by intrauterine growth restriction [150,151]. There are critical spatiotemporal windows in embryonic and fetal life when maternal diet and placental function affects expression of key developmental pancreatic genes through epigenetic modifications of DNA methylation [152]. While most work has centered on models of growth restriction and subsequent  $\beta$ -cell development, *in utero* exposure to hyperglycemia also affects fetal, neonatal and adult  $\beta$ -cell number and function in rodents [153]; however, these experimental models may be less relevant to human pancreatic  $\beta$ -cell development than those in larger mammals, as the rodent fetal endocrine pancreas is more immature *in utero* and  $\beta$ -cells continue to proliferate postnatally.

The molecular changes linking growth restriction and  $\beta$ -cell mass in the sheep include a normal  $\beta$ -cell mass in fetal and early adult life, corresponding with upregulation of the genes for IGF-II and insulin gene as well as their receptors. By late adult life, however, male sheep have reduced  $\beta$ -cell mass and develop diabetes having lost their ability to upregulate these genes and maintain an adequate  $\beta$ -cell mass [154].

Pancreatic duodenal homeobox-1 (Pdx1) is a pancreatic transcription factor that regulates pancreas development and  $\beta$ -cell differentiation. Decreased Pdx1 expression in humans is associated with T2DM in adulthood. Reduced fetal Pdx1 expression secondary to epigenetic modification occurs in growth-restricted rodents and remains reduced into adulthood, suggesting the window for epigenetic modification of  $\beta$ -cell gene expression extends beyond the embryonic period [152,155].

### Abnormal fetal growth

Factors influencing fetal growth include maternal–fetal nutrient transfer, maternal weight and nutritional status [156], placental size, uterine blood flow, and fetal and parental genes [157]. In a healthy non-diabetic pregnancy, parental and fetal genes will be the major contributor to birth weight, while the fetal metabolic intrauterine environment is also a major influence in diabetic pregnancies. The infant of a mother with diabetes is often “growth promoted” [158], a finding confirmed in the CEMACH audit, in which 51% of infants were above the 90th percentile for gestational age [2]. An analysis of 643 singleton babies born after 28 weeks’ gestation to mothers with T1DM in Scotland, 1960–1999, found birth weight to be 1.41 SD above the population norm, an increase that remained unchanged over the 40 years of the study [159]. The potential consequences of accelerated growth *in utero* include an increased risk of emergency cesarean section, birth trauma and birth asphyxia [160,161] as well as future childhood and adult obesity.

Glucose is the major fetal and placental fuel substrate and fetal insulin and IGF-I are both fetal anabolic hormones [162], while

IGF-II is a placental growth factor. Fetal insulin secretion in humans occurs in response to glucose and the amino acids arginine and leucine by 13 weeks’ gestation [147,163]. Maternal hyperglycemia increases placental fetal transfer of glucose and results in fetal hyperinsulinemia [164–166]. The availability of amino acids and lactate is also increased in diabetic pregnancies [167]. The diabetic intrauterine metabolic environment promotes abdominal fat disposition and visceral growth; notably liver, spleen and heart. This type of accelerated growth pattern is visible on routine clinical ultrasound as an increased abdominal circumference from 28 weeks’ gestation (Figure 53.1) [168]. Such growth patterns are less common in hypertensive diabetic pregnancies complicated by hypertension or vascular disease which can result in decreased uterine and placental blood flow that compromises nutrient transfer [169].

Maternal glycemic control influences fetal growth as early as the first trimester as shown in a longitudinal study on 136 pregnancies involving 120 women with diabetes in which an elevated first-trimester HbA<sub>1c</sub> level was the strongest predictor of macrosomia [170].

Accelerated growth patterns occur through maternal hyperglycemia causing fetal hyperinsulinemia, as illustrated by human and animal studies [171]. In human diabetic pregnancies there is a strong association between birth weight and fetal insulin, as assessed by amniotic and umbilical cord insulin, C-peptide and proinsulin [149,172–178].

Inducing hyperinsulinemia in the fetuses of healthy non-diabetic pregnant Rhesus monkeys produces similar accelerated fetal growth to human diabetic pregnancies [163,179]. Conversely, fetal lambs rendered hypoinsulemic *in utero* by streptozocin have decreased somatic and skeletal growth [180].

IGF-I is an important fetal growth factor in humans and a homozygous IGF-I gene deletion results in severe prenatal and postnatal growth restriction and mental retardation [181]. The placental growth factor IGF-II is paternally imprinted, and functions to facilitate maternal–fetal nutrient transfer in late pregnancy, an effect that may depend on fetal insulin [182]. In healthy non-diabetic pregnancies, cord IGF-I and IGF-II are correlated with birth weight [162]. The bioavailability of the IGFs is regulated by the IGF binding proteins (IGFBPs) [183] and proteases that inhibit these binding proteins are increased in human pregnancies [184]. Cord blood IGFBP-1 is lower in T2DM and GDM compared with controls without diabetes, suggesting IGF-I bioavailability is increased in diabetic pregnancies [185].

### Stillbirth

Stillbirth in the UK is currently defined as fetal loss occurring after 24 completed weeks’ gestation. In both women with and without diabetes, there are identifiable causes for stillbirth that include congenital malformations, chromosomal abnormalities, infection and intrauterine growth restriction. Approximately one-quarter of all cases are unexplained [186]. The risk of stillbirth in diabetic pregnancies is approximately fivefold higher than for non-diabetic pregnancies [101,106,140]. In the CEMACH

**Figure 53.1** Accelerated fetal growth, manifested as a progressive increase in abdominal circumference (lower panel), while head circumference remains on the 50th centile (upper panel). The red line represents the 50th centile and the shaded area represents the 3rd to 97th centile.

audit, there were 63 stillbirths in 2536 births in one calendar year, representing a 4.7 (3.7–6.0) higher risk than for the general UK antenatal population that has a stillbirth rate of 5.7/1000 births. There was no difference in the stillbirth rate between T1DM (25.8/1000) and T2DM (29.2/1000). A similar stillbirth rate of 25/1000 births was seen in an earlier audit of T1DM pregnancies in the north-east of England, 1990–1994, in which there were nine stillbirths among 462 pregnancies in 355 women [102]. In a Danish cohort of 1361 consecutive singleton births to women with T1DM, 1990–1999, 1.8% resulted in stillbirth [187]. Detailed

information of these pregnancies including autopsy data was available on all 25 stillbirths (22 women). No anatomical or other identifiable cause was found in 12 cases. Compared with a reference group of 236 consecutive births to women with T1DM, suboptimal glycemic control early and late in pregnancy occurred more frequently; the HbA<sub>1c</sub> level was above 58 mmol/mol (7.5%) in 64% of the stillbirth group in the first trimester and 67% in the third trimester compared with 33% and 4%, respectively, in the reference group. The CEMACH audit and other earlier studies also identified poor glycemic control throughout pregnancy as a

risk factor for stillbirth [2,188]. Other identifiable risk factors in the Danish study were diabetic nephropathy, smoking and lower social status [187].

Obesity and increasing maternal age are other risk factors for stillbirth in the non-diabetic population [189,190]. Among obstetric units that serve extremely obese T2DM women (e.g. South Pacific Islanders), the stillbirth risk is higher in those with T2DM than T1DM [9,191]. As obesity and T2DM trends continue to rise among women of reproductive years, differences in stillbirth rates between women with T2DM and T1DM may become more apparent in women of Northern European ancestry.

The cause for the excess stillbirths in diabetic pregnancies that cannot be attributable to congenital malformations and other identifiable causes remains uncertain, although chronic fetal hypoxia and acidosis appear to be major contributory factors [192]. Fetal hyperinsulinemia combined with the availability of excessive fuel substrate increases oxygen demand in insulin sensitive tissues and this may exceed placental oxygen supply [193]. Human and large animal studies suggest that the fetuses of diabetic pregnancies are more susceptible to acidosis than those of a non-diabetic pregnancy [194–196].

Amniotic erythropoietin is a marker of chronic fetal hypoxia in late pregnancy and is higher in diabetic than non-diabetic pregnancies [192]. In one study of 156 women with T1DM, amniotic erythropoietin levels correlated inversely with cord blood pH and  $pO_2$  at birth and neonatal hypoglycemia and were positively correlated with maternal  $HbA_{1c}$  levels in late pregnancy [178]. The clinical potential of using fetal amniotic fluid erythropoietin levels to identify high-risk pregnancies needs to be assessed in clinical trials. Another potential factor that could have a minimal affect on fetal hypoxia in late diabetic pregnancies is the greater oxygen affinity of glycated hemoglobin compared with non-glycated hemoglobin which could theoretically impair oxygen delivery to the fetus.

## The neonate

Neonates born to mothers with diabetes have a higher risk of being born preterm (less than 37 weeks' gestation), being large for gestational age, having a congenital malformation or birth injury and developing hypoglycemia requiring treatment. Neonatal admission to a special care baby unit is common although this often reflects hospital policy rather than clinical need [3].

Approximately half of all neonates born to women with diabetes are large for gestational age (above the 90th percentile) [2]. The increase in subcutaneous fat distribution in these infants combined with their high hematocrit gives them a typical “macrosomic” appearance with plethoric features and an obese body (Figure 53.2).

Hypoglycemia is the most common, albeit usually transient, metabolic condition in infants of women with diabetes and

**Figure 53.2** Left: A macrosomic baby born to a mother with diabetes. Right: A normal baby born to a mother without diabetes.

occurs in approximately half of all diabetic pregnancies [197]. Capillary blood glucose readings are often unreliable as many glucose sticks in routine clinical use are not quality assured and validated for neonatal use. It is therefore recommended that ward-based glucose electrode or laboratory analysis is performed to confirm hypoglycemia.

The working definition for neonatal hypoglycemia is a blood glucose value  $<2.6$  mmol/L [198,199]. In the majority of healthy neonates, a low blood glucose concentration is merely a normal physiologic response to the metabolic adaptation to extrauterine life [200].

Macrosomic infants are at higher risk of hypoglycemia because of postpartum hyperinsulinemia secondary to *in utero*  $\beta$ -cell hyperplasia. This risk of hypoglycemia is further increased because hyperinsulinemia inhibits hepatic glucose production. Hypoglycemia may also be aggravated by polycythemia (secondary to increased glucose uptake by red blood cells), and possibly by impaired glucagon release.

Preterm infants have more variable swings in blood glucose and are therefore more at risk of hypoglycemia [201] and this may affect subsequent mental and motor development [202]. Early feeding reduces the risk of hypoglycemia [203] and it is therefore recommended that all mothers with diabetes are encouraged to breastfeed within 30 minutes of birth and then every 3–4 hours, until a regular feeding pattern is established.

The current NICE guidelines only recommend the use of intravenous glucose to treat neonatal hypoglycemia when there are clinical signs of hypoglycemia or a persistent blood sugar <2.0 mmol/L that cannot be raised by oral or tube feeding, or when the blood glucose is very low (1.1–1.4 mmol/L). If intravenous glucose is required, this should be continued until the glucose is >2.5 mmol/L [5].

Other transient neonatal complications include polycythemia resulting from enhanced antepartum hemopoiesis [204] in response to fetal hyperinsulinemia [205] and chronic fetal tissue hypoxia [206].

Respiratory distress syndrome was considered to occur more often in diabetic pregnancies but is likely to result from preterm birth and high rate of cesarean section rather than any underlying metabolic effect [207].

Transient hypertrophic cardiomyopathy, characterized by ventricular septal hypertrophy and subaortic stenosis, occurs in up to 30% of all babies of mothers with diabetes [208,209]. Congestive cardiac failure presents in only 5% of babies and this usually has a benign course resolving within a month and without any clinical sequelae.

Both hypocalcemia and hypomagnesemia occur more frequently in the infant of a mother with diabetes, usually as a consequence of prematurity or birth asphyxia. Jaundice is more common in macrosomic babies. The cause of hyperbilirubinemia is probably multifactorial including birth trauma, polycythemia, hemolysis and immature hepatic uptake and conjugation of bilirubin.

### Increased risk of diabetes in later life

Both T1DM and T2DM are the result of environmental factors operating in a genetically susceptible individual [210,211]. Diabetes in pregnancy can influence the incidence of obesity and diabetes in the offspring [212,213]. Maternal hyperglycemia during pregnancy predisposes to an earlier presentation of T2DM in the child than when diabetes develops in the mother after the pregnancy [212]. Children and young adults of mothers with T1DM are also more insulin resistant and glucose intolerant than children of mothers without diabetes [214–216]. Similar metabolic abnormalities are not seen in the young adults of fathers with T1DM [215]. An influence of the intrauterine environment on the susceptibility to T2DM is also suggested by the observation that a family history of diabetes is more often reported on the maternal than the paternal side of the family [217–219].

Studies in the Pima population on sibling pairs born before and after the mother had developed diabetes has confirmed the importance of the intrauterine exposure to the risk of future T2DM [213]; over 70% of children with a prenatal exposure to maternal diabetes have themselves developed diabetes by 25–34 years. A prenatal exposure to maternal hyperglycemia is believed to be responsible for 40% of all T2DM in the Pima children (5–19 years) [220,221].

Growth restriction and intrauterine nutritional deprivation predispose to diabetes in later life [222]. Small-for-dates babies

are at increased risk of developing T2DM or IGT in middle age [223], suggesting that developing  $\beta$ -cells are programmed by intrauterine events including nutrition and hyperglycemia [224].

## Risks of pregnancy for the mother with diabetes

Pregnancy may affect pre-existing microvascular and macrovascular disease but does not usually have any lasting detrimental effect on either retinopathy or nephropathy. In contrast, pregnancy poses a risk for women with established cardiovascular disease, and this risk should be discussed in older women and those with a long duration of disease.

### Microvascular complications

#### Retinopathy

Diabetic retinopathy is more common in women with T1DM of childbearing age than T2DM [3]. It is not a contraindication to pregnancy but retinopathy may progress during pregnancy, especially in women with moderate or severe retinopathy before pregnancy [225,226]. Nevertheless, it rarely has any long-term detrimental effect on the natural history or progression of diabetic retinopathy [227,228]. An analysis of 59 women with T1DM before pregnancy and yearly follow-up for 5 years post pregnancy, with 10-year follow-up data available for 22 women, showed baseline retinopathy status was the only independent risk factor that predicted later progression of retinopathy [228].

Decreased retinal blood flow and retinal arterial constriction occur in the third trimester of a healthy pregnancy, but are more pronounced in diabetic pregnancies [229]. These changes, combined with pregnancy-related hypervolemia and hypercoagulation, could theoretically lower the threshold for retinal ischemia and hypoxia and hence progression of retinopathy. Pregnancy is associated with many circulating growth factors, angiopoietic factors and pro-inflammatory markers, but to date none have been clearly associated with the progression of retinopathy in pregnancy [230–233].

Retinopathy can develop *de novo* in pregnancy [226], although this is unlikely to progress to proliferative retinopathy [225]. Progression to proliferative retinopathy is also uncommon among women with mild or minimal retinopathy at booking. In a prospective study of 169 pregnancies among 139 women with T1DM followed between 1990 and 1998, progression to proliferative retinopathy requiring laser therapy only occurred in 2.2% of pregnancies. Proliferative changes occurred in only two women, one who had occasional microaneurysms at booking and the other who had fewer than four microaneurysms per eye [225]. Progression to proliferative retinopathy requiring laser treatment is more common in women with more advanced retinopathy at booking and longer duration of diabetes [225,226,234]. Laser treatment before pregnancy protects against proliferative changes in pregnancy [226]. Hypertension influence retinopathy progres-

sion and optimal blood pressure control is therefore important [235].

Poor glycemic control in early pregnancy and rapid improvement of glycemic control are associated with retinopathy progression [227]. In the DCCT, 180 women with T1DM had 270 pregnancies. All women originally assigned to conventional insulin treatment were switched to intensive therapy in early pregnancy. Compared with non-pregnant control subjects in the intensively treated arm, there was a 1.6-fold increased risk of retinopathy deterioration in pregnancy, while the deterioration in the women originally assigned to conventional treatment was 2.5-fold higher than in the non-pregnant control group. The previously conventionally treated group also had a 2.9-fold increased risk of a three-step progression or more from the baseline retinopathy level than the non-pregnant control group, with the greatest risk occurring in the second trimester (4.3-fold increase) and persisting for 12 months postpartum.

Although individual subjects had transient worsening of retinopathy during pregnancy by the end of the DCCT, levels of retinopathy in subjects who had become pregnant were similar to those who had not, for each treatment group. The worsening of retinopathy in pregnancy in the previously conventionally treated group was attributed to the women entering pregnancy with poor glycemic control experiencing a rapid improvement in their glycemic control [227]. A similar conclusion that rapid intensification of glycemic control was a risk factor for progression of retinopathy was observed in the Diabetes in Early Pregnancy Study [234]. These studies highlight the importance of optimizing glycemic control prior to pregnancy.

Annual retinal screening with digital camera is now part of routine diabetic clinical care, and there is evidence that its introduction into clinical practice is improving the natural history of diabetic retinopathy and reducing blindness [236].

### Diabetic nephropathy

Normal pregnancy causes a physiologic increase in glomerular filtration rate (GFR) and creatinine clearance. Estimated GFR formulas based on the Modification of Diet in Renal Disease (MDRD) study equation or the Cockcroft–Gault formulae are consequently unreliable during pregnancy.

Pregnancy is not associated with deteriorating kidney function in most women with diabetes. Among women with established moderate to advanced nephropathy, pregnancy may be associated with a deterioration in kidney function; however, this usually reverts to pre-pregnancy levels in the postpartum period [237].

Women with normal urinary albumin:creatinine ratios (ACR <3.5 mg/mmol) and serum creatinine (<120 μmol/L) seldom experience any adverse effect on renal function during pregnancy. Women with microalbuminuria are not at risk of deteriorating renal function during pregnancy, but are at risk of pregnancy-induced hypertension, pre-eclampsia and preterm birth; early intensive hypertensive management in pregnancy may reduce these risks [238–241], as can good glycemic control [242].

Women with macroalbuminuria or proteinuria (defined as ACR >30 mg/mmol or urinary albumin concentration >200 mg/L) are at increased risk of accelerated deterioration of renal function during pregnancy. The risk of proteinuria on maternal and fetal health increases with increasing proteinuria and declining kidney function. Pre-eclampsia is common within this group. In a prospective study of 203 women with T1DM, pre-eclampsia developed in 6% of women without microalbuminuria, in 42% with microalbuminuria and 64% of women with proteinuria [239].

Women whose protein excretion exceeds 2 g/day or whose serum creatinine concentration exceeds 120 μmol/L before pregnancy require pre-pregnancy advice regarding the risk to themselves and any future unborn child. This should be given by an appropriate specialist who can provide prognostic information on diabetic nephropathy as well as advice on hypertensive management and thromboprophylaxis [5].

Overall survival rates for diabetic nephropathy continue to improve. The Danish National Register on Dialysis and Transplantation reported an increased 5-year overall survival rate of 15% between 1995 and 2005 [243]. These women need to receive realistic and current information on their kidney disease to help them make informed choices to balance a potentially shortened life expectancy and impaired quality of life with the responsibilities of motherhood.

A study of kidney function and end-stage renal replacement requirement in 93 Danish women with T1DM and diabetic nephropathy between 1970 and 1989 followed for 16 years found that the renal outcomes of the 26 women who became pregnant were similar to those who had not become pregnant [244]; however, nine mothers had died during the study period when their children were between 3 and 17 years old (median 9 years), and a further five required renal replacement therapy [244].

Diabetic nephropathy, especially when the serum creatinine is raised, carries a significant risk of preterm birth before 32 weeks' gestation, very low birth weight and neonatal hypoglycemia [245]. Early intensive management of hypertension can lessen this risk [241]. The increased risk of preterm births probably accounts for the mild disturbances in growth and development in early childhood seen in offspring of these pregnancies. A 3-year follow-up study from birth of 10 children of mothers with diabetes and pre-gestational proteinuria and 30 children of mothers without proteinuria found the children of mothers with nephropathy were significantly smaller, had mild linguistic developmental delay and greater susceptibility to infections [246].

The number of women with diabetes undergoing either a renal transplant or a combined renal–pancreatic transplant is increasing. The first report of successful pregnancies following a renal transplant was in 1986 [247]. Successful pregnancies following a transplant are now common [248], with three large registries providing pregnancy outcome data. The National Transplantation Pregnancy Registry in the USA, the European Dialysis and Transplant Association Registry and the UK Transplant Pregnancy Registry all show some increased risk of miscarriages, stillbirths,

ectopic pregnancies, preterm births, low birth weight babies and neonatal deaths [248].

Since 1997, the UK has had a dedicated transplant pregnancy registry and live birth rates among renal transplant recipients now approach 80% [249]. Among 176 renal transplant recipients, pregnancy was not associated with any long-term adverse effect on the transplant. When the pre-pregnancy serum creatinine was  $>150\mu\text{mol/L}$ , however, there was a tendency for the serum creatinine to be higher postpartum. The miscarriage rate, intrauterine fetal loss before 24 weeks' gestation and stillbirth rate were 11%, 2% and 2%, respectively. Approximately half of the births occurred before 37 weeks, with a mean gestation of 35.6 weeks. Hypertension occurred in 60–80%, with pre-eclampsia diagnosed in approximately one-third, although this may be over-reported as the diagnosis of pre-eclampsia is difficult in women with pre-existing hypertension, renal impairment and proteinuria.

The Toronto Renal Transplant Program is one of the few studies to report follow-up data on 32 children born to renal transplant recipients. Postnatal growth was normal although developmental assessment showed one child had moderate to severe sensorineural hearing loss, another a learning disability and a third a pervasive developmental disorder [250].

It is likely in the future that more women with diabetic nephropathy will have a combined pancreas–kidney transplant before a planned pregnancy. The benefit and risk of a combined pancreas–kidney transplant over a single kidney transplant has not yet been evaluated for pregnancy.

### Macrovascular complications

As the general antenatal population becomes more obese and more women give birth in their late reproductive years, ischemic heart disease (IHD) in pregnancy will become more prevalent [251]. Maternal diabetes, obesity and increasing age are all identifiable risk factors for IHD in pregnancy [252,253].

Pregnancy increases the risk of an acute myocardial infarction (MI) three- to fourfold, with the risk being greatest in the peripartum period [252]. The number of pregnant women with IHD and maternal death from IHD has increased in recent years; IHD now represents the most common cause of cardiac death associated with pregnancy in the UK [252–255]. Nevertheless, the mortality rates from acute MI in pregnancy have declined [254,255].

Women with diabetes have a twofold higher risk of dying from IHD than women without diabetes [256,257]. Population studies that capture data on 5–6% of the UK population at any one time have reported that women with T1DM, aged 35–45 years, have a 15-fold higher risk of a major CVD event [258] and women with T2DM, aged 35–54 years, have a fivefold higher risk of an MI than women without diabetes of a similar age [259].

The incidence and maternal mortality rate from acute MI in pregnancy was reported to be 1 in 35700 deliveries and 7.3% respectively in California between 1991 and 2000 [252]; however, the mortality rate from MI among pregnant women with diabetes is likely to be higher than it is in non-pregnant women [260].

## Co-morbidities

### Obesity

Obesity is a common co-morbidity in women with diabetes. The antenatal population is becoming more obese, reflecting the secular trend in obesity. It has a major impact on maternal and fetal health as well as on health services and resources [261]. While one expects the majority of women with T2DM and GDM to be obese, an increasing number of women with T1DM are also overweight or obese [262]. In the CEMACH enquiry, 62% of the 137 women with T2DM and 15% of the 181 women with T1DM were obese [3].

Maternal and infant mortality [253] increases with increasing maternal BMI. The risk of congenital malformations and stillbirth are increased [263]. Obesity increases the risk of pre-eclampsia, GDM [264], the need for induction of labor, emergency cesarean section rates, postpartum hemorrhage and infection [265]. Babies of obese mothers are more likely to have birth weight above the 90th percentile [266] and be at risk of birth trauma and adult obesity and diabetes [267].

The first report linking pre-gestational weight and malformations in South Wales between 1964 and 1966 found that mothers of anencephalic infants were significantly heavier than a matched control group [268]. Subsequent epidemiologic and cohort studies have confirmed this finding. A population-based case-control study of mothers of infants born with and without selected birth defects in metropolitan areas of Atlanta, USA, between 1993 and 1997 showed for every incremental unit increase in BMI, the odds ratio for a major malformation increased by 7% [263]. The most common malformations reported occurring as either single or multiple defects, were NTDs, especially spina bifida, omphalocele and heart defects [263].

Although cardiac malformations and NTD are increased in babies of women with diabetes, obtaining euglycemia in obese women with diabetes may not fully protect them against the added risk of a congenital malformation. A cohort study of 2060 infants born to mothers with GDM showed that both diabetes severity and pre-pregnancy BMI were predictors of the 6% minor and 3.8% major malformations, with the BMI being the main contributor [269]. Data from 22951 pregnant women enrolled in a prospective cohort study reported that major non-chromosomal congenital defects associated with diabetes were more common in obese women [270]. A study of Spanish mothers with GDM also reported that BMI  $\geq 30\text{kg/m}^2$  was associated with a two- to threefold greater risk of cardiovascular defects compared with non-obese women [271]. Maternal obesity and GDM may increase the risk of CNS birth defects through shared metabolic mechanisms.

### Autoimmune diseases

Women with T1DM are at increased risk of other autoimmune disease, especially thyroid disease and celiac disease. Thyroid function should be monitored in pregnant women with hypothyroidism as small increases in thyroxine replacement are frequently

required [272]. This is important as there is some evidence linking mild degrees of hypothyroidism in the first trimester with adverse neurodevelopment [273]. The simultaneous ingestion of iron and thyroxine may inhibit thyroxine absorption, and women should be advised to take any iron supplements at least 2 hours after or before taking thyroxine [274].

Women with a previous history of Graves disease will also need their thyroid function measured before and during pregnancy. Fetal monitoring is also recommended as maternal thyroid-stimulating antibodies can cross the placenta causing transient fetal and neonatal hyperthyroidism [275].

---

## Clinical management

### Pre-pregnancy care

Pregnancy care for women with diabetes should begin prior to conception when glycemic control can be optimized, medication reviewed and folic acid started. All health care providers who look after women with diabetes should emphasize the benefits of pre-pregnancy planning and good glycemic control on pregnancy outcomes and encourage women to plan their pregnancies and to engage in pre-pregnancy care.

Discussions about contraception and pregnancy plans should form part of the ongoing care of all pre-menopausal women with diabetes. Once a woman expresses an interest in becoming pregnant she should have access to a pre-pregnancy clinic where specific pre-conceptual advice can be given.

### Evidence of effectiveness

There have been no randomized clinical trials of pre-pregnancy counseling nor are there ever likely to be. The evidence of effectiveness is therefore based predominately on observational studies of self-selected women. Furthermore, there is no standardized definition of what constitutes pre-pregnancy care [143]. Nevertheless, pregnancy outcomes are better in women with diabetes who plan their pregnancies [138]. One Scottish study analyzed adverse pregnancy outcomes by markers of pregnancy planning and pre-pregnancy care in 423 singleton T1DM pregnancies. The best pregnancy outcomes were in women who achieved an optimal HbA<sub>1c</sub> level before conceiving. These women were five times less likely to have an unfavorable outcome than women with suboptimal HbA<sub>1c</sub> levels prior to conception [276]. Pre-conception care has been shown through economic health care models to be cost effective [5,277].

Clinical studies have shown that planned pregnancies are associated with improved glycemic control in early pregnancy and fewer congenital malformations. A Dutch study of 323 women with T1DM who became pregnant showed a significantly lower incidence of major congenital malformations among the women who had planned their pregnancies (4.2% [11/271] vs 12.2% [6/52]); relative risk 0.34, (95% CI 0.13–0.88) [278].

### Accessing pre-pregnancy care

Some 30–80% of women will attend a clinic for pre-pregnancy advice, but this attendance depends on the woman's perception of its benefits [47,279,280]. A study from Michigan, USA, found half of pregnant women with diabetes who had not received pre-pregnancy care claimed they had not been informed of its importance [279]. Women who seek out and engage in pre-pregnancy care tend to have higher educational and economic status and greater family and social support [281,282].

Unplanned pregnancies are common among women with diabetes. In the CEMACH enquiry, only 60% and 62% of women with T1DM and T2DM, respectively, had planned their pregnancy [3]. Overall, 34.5% of the women had received pre-pregnancy care: 38.2% of the women with T1DM and 24.8% of the women with T2DM.

A survey in New Zealand showed 60% of non-pregnant women with diabetes aged 18–40 years would like more information about diabetes and pregnancy [283], suggesting there is an unmet need for good pre-pregnancy advice. It remains a clinical challenge to increase the awareness and uptake of pre-pregnancy care for all women with diabetes planning pregnancy, especially among more hard to reach groups.

### Information to cover during pre-pregnancy care

All pre-pregnancy advice should be supported by evidence of its benefit in pregnancy. The advice should be constructive and non-judgmental, and communicated in a way that is appropriate for the individual woman [284].

Women should receive information that covers the following topics:

- The benefits of optimal glycemic control and appropriate and safe glycemic targets;
- Folic acid supplementation;
- General lifestyle advice (e.g. smoking and alcohol);
- Advice on diet and exercise;
- Advice on safe prescription medications;
- General information of pregnancy risk to the woman's health;
- General information of pregnancy risk to the fetus, neonate and their long-term health; and
- General information on diabetic pregnancy management guidelines and the need for extra surveillance.

### Benefits of optimal glycemic control prior to conception

The benefits of optimal glycemic control prior to conception on pregnancy outcomes should be explained, stressing the need to continue contraception prior to achieving the agreed glycemic target. While it is important to discuss the strong association between poor pre-conception glycemic control and congenital malformations, this risk should not be exaggerated as malformations only occur in a minority of diabetic pregnancies and may discourage some women in engaging in pre-pregnancy care [280].

There is clinical evidence that pre-pregnancy care is successful in improving glycemic control in the first trimester and reduces

**Table 53.1** Recommended pre-pregnancy HbA<sub>1c</sub> targets in the USA, Australia and the UK.

Country	USA	Australia	UK*
HbA <sub>1c</sub> upper target			
DCCT	<7.0%	<7.0%	<6.1% if safely possible
IFCC	<53 mmol/mol	<53 mmol/mol	<43 mmol/mol
Reference	[4]	[286]	[5] Available from www.nice.org.uk

\* England and Wales.

the risk of malformation, stillbirth and neonatal death; however, it has less effect on the risk of macrosomia in later pregnancy [285]. In a meta-analysis of 14 cohort studies, the major anomaly rate was 2.1% among the 1192 offspring of women who had received preconception care compared with 6.5% in 1459 offspring of non-recipients [143]. In the nine studies that recorded both major and minor congenital anomalies, the relative risk of an anomaly with preconception care was lower (RR 0.32; 95% CI 0.17–0.59). Some of the risk may reflect important demographic differences between women who received preconception care and those who did not.

### Appropriate and safe glycemc targets

Pre-conception glycemc control should be assessed by HbA<sub>1c</sub> and women should be advised to continue using contraception until their HbA<sub>1c</sub> level reaches the agreed target. An HbA<sub>1c</sub> test should be performed at 1–3 monthly intervals during this time.

The recommended pre-pregnancy HbA<sub>1c</sub> targets are lower in the UK NICE guidelines than the national pregnancy guidelines from the USA and Australia (Table 53.1).

A glycemc target of a pre-pregnancy HbA<sub>1c</sub> <53 mmol/mol (<7%) has been recommended in Denmark after a prospective population-based study of 933 T1DM pregnancies found the risk of a serious adverse outcome, defined as congenital malformations and perinatal mortality, was higher when pre-pregnancy HbA<sub>1c</sub> values were >52 mmol/mol (>6.9%). In this study, poor pregnancy outcomes correlated with the incremental rise in HbA<sub>1c</sub>; the risk of a serious adverse outcome was 16% in women whose HbA<sub>1c</sub> exceeded 90 mmol/mol (10.4%) [141].

The NICE UK guidelines recommend women whose HbA<sub>1c</sub> exceeds 86 mmol/mol (10%) should be advised against becoming pregnant [5].

The CEMACH study found only 37.1% of the pregnancies had an HbA<sub>1c</sub> measurement within 6 months of the pregnancy [2]. Evidence of good glycemc control defined as an HbA<sub>1c</sub> <53 mmol/mol (<7.0%) was found in 24% and 41% of the women with T1DM and T2DM, respectively. Further analysis by the CEMACH enquiry showed pre-pregnancy HbA<sub>1c</sub> was suboptimal in 88% (165/187) of those women with poor pregnancy outcome, defined as a major congenital anomalies, stillbirths or early neonatal

deaths death, compared with 69% (115/167) of those women with a good outcome [2].

When setting glycemc target for the pre-pregnancy period, the risk of hypoglycemia and hypoglycemia unawareness should be discussed. Both are increased during pregnancy, especially in women with T1DM [3]. The risk of hypoglycemia increases with lower HbA<sub>1c</sub> which may explain why in some studies women who attend pre-pregnancy counseling are at a greater risk of hypoglycemia in the first trimester than women who do not attend [138,287]. The risks and benefits of achieving an HbA<sub>1c</sub> of <43 mmol/mol (<6.1%) for women with a long history of duration of T1DM [5] need to be discussed and may not be appropriate for all women. Individual HbA<sub>1c</sub> targets should be set and discussed with the woman concerned, emphasizing that any pre-pregnancy HbA<sub>1c</sub> reduction reduces the risk of congenital malformations.

Advice to minimize the risk of hypoglycemia should be given to women receiving insulin and ideally women with T1DM should be taught to adjust their insulin dosage according to their dietary carbohydrate intake [288]. Women with T2DM should receive an equivalent form of structured education.

Many women with T2DM attending pre-pregnancy care need to start insulin for the first time, or have their insulin regimen intensified to achieve the recommended HbA<sub>1c</sub> level. These women need advice on frequency and timing of self-monitoring of blood glucose as well as the need for extra snacks between meals and before bed.

During pre-pregnancy care and insulin intensification, the risk of DKA is low; however, this risk increases during pregnancy and women with T1DM should be taught how to monitor and interpret their blood or urinary ketones.

### Folic acid supplementation

Folic acid supplementation in the form of a folate-rich diet plus 400 µg/day folic acid from before conception until 12 weeks is advised for all women planning a pregnancy as this has been shown to reduce the risk of NTD [289]. A dose of 5 mg folic acid is recommended for women with diabetes as the risk of NTD is higher than the background population.

In the CEMACH enquiry, 49% of women with T1DM and 45% of women with T2DM took folic acid in the pre-conception period; however, few women were taking the recommended 5 mg dose [3,5]. A total of 69% (83/120) of women with a poor pregnancy outcome were not taking folic acid in the preconception period compared with 50% (66/131) with a good outcome [3].

It is likely that awareness of the need to take folic acid prior to pregnancy is rising. An earlier study in the UK in the general antenatal population reported less than 10% of women took folic acid supplements in early pregnancy [290].

### General advice on lifestyle

Smoking in pregnancy is associated with poor pregnancy outcomes and women seeking pregnancy should be given advice and help to stop smoking. In a study of 211 pregnancies in 132 women

with pre-gestational diabetes, women who smoked during the preconception period had an increase risk of a stillbirth, neonatal death or congenital malformation (OR 2.12; 95% CI 1.09–4.10) [291,292].

Advice about alcohol should be similar to the general population, which is to avoid alcohol in the first 3 months of pregnancy [5]. For women with diabetes, this is especially important as alcohol can increase the risk of hypoglycemia and is associated with an increased risk of miscarriage.

#### **Advice on diet and exercise**

Pre-pregnancy is a time to provide dietary information that will optimize glycemic control and minimize hypoglycemia during intensive glycemic management. Obese women should be encouraged to achieve a healthy weight prior to pregnancy through diet and exercise if they have BMI >27 kg/m<sup>2</sup> [293,294].

#### **Advice on safe prescription medications**

Medication should be reviewed prior to conception. The most common drugs that should be stopped are antihypertensive drugs acting on the renin-angiotensin system, lipid-lowering drugs and certain hypoglycemic oral agents. The continuation of long-acting analog insulin needs to be discussed on an individual basis.

Angiotensin-converting enzyme (ACE) inhibitors cross the placenta [295]. Although the use of ACE inhibitors in the first trimester of pregnancy was initially felt to be safe [296–299], there is sufficient evidence to recommend their discontinuation before conception.

First trimester exposure to ACE inhibitors was linked to malformations in a study of 29 507 infants with no drug exposure and 209 infants exposed to ACE inhibitors but no other drugs in the first trimester from 1985–2000. The risk ratio of major congenital malformations, primarily cardiovascular and CNS anomalies in women who took ACE inhibitors was 2.71 (95% CI 1.72–4.27) compared with infants who had no drug exposure [300].

There is little information on the teratogenic effects of the angiotensin receptor blockers (ARBs). Fetal exposure to losartan at 20–31 weeks' gestation has been linked with oligohydramnios and the intrauterine death of a fetus with hypoplastic lungs and skull bones [301]. A series of five cases exposed to ARBs found one term baby with additional digits, two pregnancies complicated with oligohydramnios and prematurity, another infant with transient abnormal renal function and two babies delivered with no abnormalities [302]. Current recommendations are to avoid ARBs in pregnancy [5,303,304].

The HMGCoA reductase inhibitors, statins, are commonly used in diabetic care. A small number of case reports and surveillance registers have reported congenital malformations following first trimester statin exposure [303,305]. Current guidelines recommend that statins are not to be taken during pregnancy or lactation [5].

Methyldopa remains the first-line antihypertensive agent in pregnancy, but other agents considered to be safe include nifed-

ipine, amlodipine, hydralzine and labetalol. Beta-blockers are usually avoided in the first trimester because of the risk of growth restriction. Other antihypertensive agents should be used on an individual basis and the risks and benefits reviewed. Two small cohort studies suggest calcium-channel blockers are not teratogenic [306,307].

The use of oral hypoglycemic agents other than metformin and glibenclamide are not recommended in pregnancy. Women on oral hypoglycemic therapy during pre-pregnancy care should be switched to insulin if their HbA<sub>1c</sub> values are above target, although metformin can be continued.

#### **General information on diabetic pregnancy management guidelines and the need for extra surveillance**

During pre-pregnancy care, women should be informed of the need to access antenatal care as soon as a pregnancy has been confirmed and the need for additional recommended clinic attendances and fetal monitoring above those for routine antenatal care. The increased fetal monitoring includes ultrasound scanning to assess fetal viability and dating in early pregnancy as well as fetal growth in late pregnancy. General information concerning timing and mode of birth can be given at this time.

#### **Screening for diabetic complications**

Women can be reassured that although diabetic retinopathy and nephropathy may progress, it is rare for pregnancy to have long-term detrimental effects. Screening for retinopathy or nephropathy prior to pregnancy is important to assess if any treatment is required before pregnancy and if greater surveillance or treatment will be required during pregnancy. The CEMACH enquiry found that women with T2DM were less likely to have a retinal examination and an assessment of albuminuria in the year prior to pregnancy than women with T1DM [3].

#### **Screening for retinopathy**

All women seeking pregnancy should be informed of the importance of retinal screening and the benefits it offers. Any woman with known proliferative retinopathy should be considered for laser treatment prior to pregnancy. Women actively seeking pregnancy should ideally have a dilated digital retinal photograph if one has not been performed in the preceding 12 months.

Women should be informed of the retinal screening guidelines for pregnancy, which include a first trimester screen and a repeat screen at 28 weeks if no retinopathy is present, with an additional screen at 16–20 weeks if retinopathy is present [5]. Women should be reassured that the use of tropicamide to dilate the eye is safe in pregnancy, as is photocoagulation therapy if required. Women who have or develop retinopathy in pregnancy should be aware that retinal follow-up should continue for at least 6 months postpartum [308].

Worsening of retinopathy in pregnancy may be associated with rapid intensification of glycemic control [227,234], emphasizing the importance of optimizing glycemic control prior to pregnancy.

**Screening for nephropathy**

Women actively seeking pregnancy should be screened for microalbuminuria and have their serum creatinine measured. Women with a normal urinary ACR (<3.5 mg/mmol) and serum creatinine <120 μmol/L can be reassured that their kidney function poses no added risk to the pregnancy. Women with microalbuminuria (ACR 3.5–30 mg/mmol) need to be aware that although pregnancy will not adversely affect their renal function long-term, they are at an increased risk for hypertension and pre-eclampsia in pregnancy [239–241]. For women with macroalbuminuria or proteinuria and established nephropathy, pre-pregnancy advice should cover the evidence that is discussed above.

**Screening for autoimmune disorders**

Thyroid function should be assessed pre-pregnancy as autoimmune hypothyroidism and hyperthyroidism are more common in women with diabetes and both conditions can affect the fetus and neonate [273,275]. Women with T1DM and celiac disease seeking pregnancy need to be aware that compliance with a gluten-free diet helps fertility rates and during pregnancy lessens the risk of anemia [309].

**Ischemic heart disease**

Ischemic heart disease in pregnancy is associated with serious mortality and morbidity for the mother and child. Women with a previous or suspected history of IHD should be referred and assessed by a cardiologist prior to pregnancy. Women with T1DM of long duration and older women with T2DM should be informed of their underlying risk for IHD and the added risk this has during pregnancy. A resting and an exercise electrocardiogram (ECG) may be required prior to pregnancy to assess this risk so an informed decision can be made concerning any future pregnancies. For women known to have IHD the potential mortality associated with pregnancy should be discussed.

**Antenatal management**

Once pregnancy is confirmed women should have easy and immediate access to a combined diabetic and obstetric clinic that can manage and support them throughout the pregnancy. This clinic should comprise a diabetologist with an interest in obstetrics, an obstetrician with an interest in diabetes, a diabetes specialist nurse/educator, a midwife with an interest in diabetes and a dietitian.

The first clinic visit needs to ensure that the woman is taking folic acid and has glycemic management optimized. This will require most women with pre-gestational diabetes not on an insulin pump to be switched to a basal bolus regimen, if not already on one.

**Glycemic management**

Maternal hyperglycemia from the time of conception to birth affects pregnancy outcome. The aim of glycemic management is to achieve glycemic control as near to that of women without diabetes as possible with due consideration to safety.

In clinical practice the limitations in achieving normoglycemia are the high risk of severe hypoglycemia in women intensively treated with insulin and growth restriction in a fetus of a woman too aggressively treated with hypoglycemic management or dietary restriction.

For women with T1DM, glycemic control is dependent on balancing insulin requirements with the physiologic changes of pregnancy and the risk of hypoglycemia. This can only be achieved through frequent glucose monitoring and flexible insulin dosing, using either a basal bolus regimen or insulin pump.

Women with T2DM will also require intensive insulin management alongside diet and exercise to achieve the required level of glycemic control for pregnancy. For women with GDM, approximately half will be able to achieve the desired glycemic target through diet and exercise, with the remainder requiring the addition of an appropriate oral hypoglycemic agent or insulin.

**Risk of hypoglycemia**

Insulin sensitivity increases in the first trimester before declining in the second. Insulin requirements for women who become pregnant with good glycemic control will usually fall in the first trimester before rising in the mid-second trimester [46,310–312]. This initial increase in insulin sensitivity occurs at a time when there is a physiologic fall in fasting blood glucose and makes women with T1DM extremely susceptible to hypoglycemia. This may be further exaggerated by a pregnancy-induced decrease in counter-regulatory hormones to hypoglycemia [313,314].

In a prospective observational study of 108 consecutive Danish pregnant women with T1DM, self-reported episodes of hypoglycemia, validated by structured interview within 24 hours, occurred in 49 women (45%) experiencing 178 severe hypoglycemic events requiring third party assistance. Of these severe episodes, 80% occurred in the first 20 weeks of pregnancy and approximately half occurred at night; 11 women had five or more events. Predictors for severe hypoglycemia were a history of similar events in the preceding year, impaired hypoglycemia awareness and long duration of T1DM. There was no evidence that hypoglycemia unawareness changed during the pregnancy or that pregnancy-related nausea was a significant risk factor [46]. In an earlier Danish study in the first trimester, nocturnal hypoglycemia, defined as blood glucose values <3.0 mmol/L, was detected in 16 of 43 women with T1DM who had hourly blood glucose sampling during the night (22.00–07.00). These episodes of hypoglycemia went unrecognized by all but one of the women despite lasting 1–7 hours (mean 2.4 hours) [315].

In the CEMACH enquiry, 61% of women with T1DM had recurrent hypoglycemia during pregnancy, with 33/133 (25%) episodes requiring external help. While women with T2DM are less likely to experience recurrent or severe hypoglycemia, one-fifth of women with T2DM had recurrent hypoglycemia, with 4/102 (4%) requiring external help [3]. Nocturnal hypoglycemia has also been well documented in insulin-treated pregnant women with T2DM undergoing continuous glucose monitoring [316].

The risk of severe hypoglycemia is less after the first 22 weeks of pregnancy when maternal insulin resistance rises and glucose variability and fluctuations become less marked [46].

Maternal mortality from hypoglycemia is extremely rare but well recognized [317] and has been a recurrent cause of death in women with T1DM in the triennial Confidential Enquiry into Maternal Death in the UK over the last 30 years.

All women intensively managed with insulin need to be informed of the added risk of hypoglycemia in pregnancy and given advice to minimize the risk, including advice about whether it is safe to drive. For women with T1DM, their partner or a family member should be given instruction on when and how to give glucagon.

### **Glucose monitoring**

Accurate self-monitoring of blood glucose is required at least five times a day throughout pregnancy. A study comparing blood glucose values obtained using self-monitoring of blood glucose and data from a continuous glucose monitoring (CGM) system found that unless the women were testing 10 or more times a day many episodes where blood glucose values were outside the target range were missed [146]. Monitoring should be increased for women on insulin pumps, those who are dose adjusting their insulin for each meal, experiencing hypoglycemia and when insulin doses are being changed. Glucose monitoring also needs to be carried out before driving and exercising. Monitoring between 02.00 and 04.00 should be performed if nocturnal hypoglycemia is expected.

For women already on insulin, their evening basal insulin is adjusted against their fasting glucose reading, and their bolus insulin against their 1–2 hour post-prandial glucose value. A pre-bed reading may help to calculate the size of the snack required before bed. The use of a 1-hour post-prandial glucose value is more informative for adjusting insulin requirements than a pre-prandial measurement [318]. In an randomized controlled trial of women with GDM, there were fewer large for gestational age babies, fewer cesarean sections for cephalo-pelvic disproportion and less neonatal hypoglycemia in women self-monitoring 1 hour after a meal than immediately before [319].

The use of CGM is currently too expensive for routine use in pregnancy; however, this is likely to change as CGM provides information on the extent of glucose fluctuations and episodes of hyperglycemia and hypoglycemia undetected by self-monitoring of blood glucose [316,320,321].

CGM performed at intervals of 4–6 weeks during pregnancy was associated with a lower HbA<sub>1c</sub> in the third trimester, lower birth weight and macrosomia compared with standard care in a randomized control trial of 71 pre-gestational pregnant women [322].

The use of CGM in clinical studies in pregnant women with T1DM has also highlighted the extent of glucose fluctuations that are not detected by HbA<sub>1c</sub> [146]. Intensifying insulin regimens to strict and inflexible glycemic targets based on HbA<sub>1c</sub> may not be safe using the clinical tools and insulin currently available in routine care.

### **Glycemic targets in pregnancy**

Glycemic targets for pregnancy have been set by national guidelines, and are the same for all women with diabetes regardless of its type; however, there is a need to adjust and discuss these targets individually according to what is safe and achievable for the woman. This is especially true for women with T1DM who experience recurrent hypoglycemia during the first trimester. The current targets for the UK are fasting blood glucose of 3.5–5.9 mmol/L and 1 hour post-prandial blood glucose <7.8 mmol/L, if safely achievable [5].

In women with GDM, active glycemic management with diet, exercise and insulin, if required, using the targets of a fasting blood glucose <5.5 mmol/L and a 2-hour post-prandial level <7.0 mmol/L was associated with less perinatal morbidity than no active glycemic management (1% vs 4%; RR 0.33; 95% CI 1.03–1.23; *P* = 0.01) in a large randomized trial of 1000 women [323].

Too stringent targets for glycemic control in women with GDM may be potentially detrimental for the infant [324]. In a prospective study of 334 women with GDM who were randomized to maintaining their mean blood glucose levels to <4.8 mmol/L, 4.8–5.8 mmol/L or to >5.8 mmol/L, there was a twofold higher incidence of small for gestational age infants (20%) in the lowest target group compared with a well-matched control group of 334 women without diabetes. In the high glucose group, an approximate twofold increased incidence of large for gestational age infants was seen, while when mean blood glucose values were maintained at 4.8–5.8 mmol/L, the incidence for small and large for gestational age babies was similar to that of the control group.

### **Insulin management**

Women with pre-gestational diabetes who are not using an insulin pump usually require multiple daily injections (MDI) with either short-acting human insulin or quick-acting analog insulin prior to each meal and an intermediate-acting human insulin or long-acting insulin analog before bedtime. In a randomized trial of 60 women with pre-gestational diabetes which compared a MDI regimen with twice daily mixed insulin, the MDI regimen was associated with better glycemic control and less neonatal hypoglycemia [325]. Both US and UK guidelines recommend the use of an MDI regimen for women with pre-gestational diabetes [4,5].

There are theoretical concerns around the use of insulin analogs in pregnancy and no study has yet been sufficiently powered to confirm their complete safety. Quick-acting insulin analogs have been widely used in diabetic pregnancy for over 10 years without any evidence of any harm, and are recommended in both the US and UK guidelines.

Outside pregnancy the use of rapid-acting insulin analogs (Lispro [Eli Lilly], Aspart [Novo Nordisk] and Glulisine Apidra [Sanofi-Aventis]) is beginning to replace short-acting human soluble insulin in MDI regimens, as they potentially offer better post-prandial glycemic control; however, their use puts greater

reliance on the basal insulin for glycemic control between meals, for which the pharmacokinetic profiles of the longer-acting insulin analog (Glargine [Sanofi-Aventis] and Determir [Novo Nordisk]) are better suited than the intermediate human insulin (NPH [Neutral Protamine Hagedorn]). In some clinical studies, especially in T1DM, MDI regimens with insulin analogs are associated with less nocturnal hypoglycemia [326]. Rapid-acting insulin analogs are being increasingly used by patients who carbohydrate count and adjust their insulin dose [288].

For these reasons, MDI regimens with insulin analogs are attractive options for diabetic pregnancies. Increasingly, more women with T1DM are treated with insulin analogs prior to pregnancy and switching them to the older human soluble insulin in early pregnancy puts them at potential risk of worsening glycemic control at this critical time. Patient preference may also be important as the women receiving insulin aspart in a randomized controlled trial in pregnancy expressed greater patient satisfaction than women receiving human insulin [327]. Recruiting women with T1DM to participate in future randomized studies will be increasingly difficult as many will be reluctant to be randomized to the older human insulin.

The clinical studies evaluating the efficacy and safety of insulin lispro, the first widely available rapid-acting insulin analog [328–332], all involve small numbers of women, are mostly retrospective and are inadequately designed or powered to evaluate serious adverse pregnancy outcomes. A multinational multicentered retrospective study of 72 women with T1DM treated with insulin lispro for at least 3 months before and 3 months after conception and a control group of 298 women treated with regular human insulin showed a trend towards fewer hypoglycemic episodes and significantly greater reduction in HbA<sub>1c</sub> during the first trimester in the lispro arm [331]. The early concerns that insulin lispro might be associated with an increased risk of retinopathy progression have not been substantiated by later studies.

An open-labeled randomized control trial compared the safety and efficacy of insulin aspart as part of a MDI regimen with NPH insulin with soluble human insulin in 322 pregnant women with T1DM [327]. Insulin aspart was associated with less nocturnal hypoglycemia and severe hypoglycemia and superior postprandial glycemic control in the third trimester; there were no differences in other pregnancy outcomes between the insulins.

#### *Basal insulin analogs in pregnancy*

At present, neither basal analog insulin is recommended in the USA or UK national guidelines for use in pregnancy; instead human intermediate NPH insulin should be used 1–3 times daily to provide adequate basal cover.

Theoretical concerns persist around the long-acting analog insulin glargine because of its higher binding affinity for the IGF-I receptor and potential mitogenic potency compared with human insulin [333,334]. There have been no adequately controlled studies large enough to ascertain its safety in pregnancy. An audit of the use of insulin glargine in 115 women with T1DM and 109

babies was collected over 2 years in 20 diabetic obstetric units in the UK. Insulin glargine was used prior to pregnancy in 69% of women, and stopped at booking in one patient. The bolus insulin used in this audit was insulin aspart (45%), lispro (42%) and human soluble in 8% of women. This audit identified no unexpected or adverse maternal or fetal outcome [335], similar to earlier smaller clinical pregnancy studies [336,337].

The long-acting analog insulin detemir has no increased affinity binding to the IGF-I receptor [334] and may be a more appropriate basal insulin analog than glargine. The outcome of a large randomized control trial is awaited to show if it offers any clinical advantages in diabetic pregnancy.

#### *Continuous subcutaneous insulin pumps in pregnancy*

The continuous subcutaneous insulin infusion pumps (CSII) potentially offer the most physiologic form of subcutaneous insulin administration. The technology surrounding the CSII is progressing rapidly, with integrated insulin pumps and continuous glucose monitor systems under development. There are no adequately powered multicentred studies evaluating the use of insulin pumps in pregnancy but clinical experience is increasing.

Outside pregnancy the greatest benefit of insulin pumps over MDI on glycemic control is when control is poor beforehand; this benefit is less apparent when HbA<sub>1c</sub> approaches the normal range [338].

A systematic review of six randomized trials published between 1974 and 2006 of CSII involving 213 pregnant women (199 T1DM and 14 T2DM) showed no significant differences in pregnancy outcomes or glycemic control including hypoglycemic events between CSII and MDI [339]. A Cochrane review that examined only two studies involving 60 women with 61 pregnancies also concluded that maternal glycemia and pregnancy outcomes were similar between women on CSII and MDI, and concluded more good quality studies were required [340].

In one study that compared the use of CSII in 30 insulin-treated pregnant women with T2DM and GDM with a matched control group on conventional insulin, pump use was associated with larger daily doses of insulin and greater weight gain, without any benefit on pregnancy outcomes. Large multicentered randomized controlled trials are required to identify which women would benefit from CSII in pregnancy. As HbA<sub>1c</sub> values fall in pregnancy approaching the non-pregnancy range, it is likely that evaluating glycemic control in future trials using CSII will require continuous glucose monitoring systems as these will be more informative than HbA<sub>1c</sub> values.

CSII may improve overall control and glycemic fluctuations in selected women with poorly controlled T1DM. In an Italian study that compared 25 women with T1DM on CSII with 93 women on MDI, there were no differences in glycemic control and pregnancy outcomes between the groups; however, within the CSII group were women with more retinopathy and nephropathy in whom a poorer pregnancy outcome might have been predicted [341].

### **Oral hypoglycemic agents**

The use of oral agents in the management of diabetic pregnancies remains controversial: the ADA do not currently recommend their use, while the UK NICE guidelines endorse the use of metformin in combination with insulin for the management of women with pre-existing T2DM, as well as metformin and glibenclamide in the management of GDM [4,5].

The number of classes of oral hypoglycemic agents is increasing but the only oral hypoglycemic drugs that have been sufficiently evaluated in pregnancy are sulfonylureas and metformin.

Metformin crosses the placenta, with fetal serum levels being comparable with maternal values [342]; however, there is no evidence of any increased risk for major malformations when metformin is taken during the first trimester of pregnancy [343].

The early introduction of metformin and glibenclamide in the 1970s in South Africa for women with T2DM and GDM was accompanied with a fall in neonatal mortality. Switching women from oral agents to insulin in early pregnancy was associated with better pregnancy outcomes than when women were treated with oral agents alone. In these early observational reports, poor glycemic control rather than oral hypoglycemic agents was thought to be the cause of the high malformation rates and perinatal mortality [344,345]. Many of the later studies in the literature are also observational and involve heterogeneous populations of pregnant women without adequate non-exposed controls, limiting the scope for meta-analysis to be undertaken [346].

More robust clinical randomized trials of the use of metformin and glibenclamide in pregnancy have been conducted in women with GDM than in women with T2DM. A systematic review of four randomized controlled trials (1229 women) and five observational studies (831 women) published prior to January 2007 of maternal and neonatal outcomes when GDM was treated with either glibenclamide or metformin found no differences in outcomes when compared with insulin [347].

A randomized control trial of 751 of women with GDM not controlled with diet alone by 20–33 weeks' gestation compared the efficacy and safety of metformin with insulin [348]. Of the 363 women, 92.6% were assigned to metformin and continued on metformin until the birth. Metformin was increased to a maximum of 2500 mg/day after which insulin was added in 46.3% of women to the metformin if glycemic targets were not met. The mean fasting blood glucose was similar in the metformin and insulin-treated groups but the 2-hour postprandial blood glucose was lower in the metformin arm. The weight gain in late pregnancy was less in women treated with metformin and was associated with greater weight loss at 6–8 weeks postpartum compared with women treated with insulin alone. Perinatal complications were broadly similar other than a lower incidence of severe hypoglycemia (blood glucose <1.6 mmol/L) in the infants in the metformin group [348]. A total of 76.6% women in the metformin arm compared with 27.2% of the insulin group stated that they would choose to receive their assigned treatment again in a future pregnancy.

A randomized control trial of 404 women with GDM who had failed dietary management alone and were assigned to either glibenclamide or insulin after 15 weeks' gestation reported only 4% of the glibenclamide-treated women required supplemental insulin. The mean blood glucose values were similar in both treatment arms and the incidence of maternal hypoglycemia was lower in the glibenclamide group (2% vs 20%). Perinatal outcome did not differ between the two groups [349].

Oral hypoglycemic agents offer an attractive treatment option for diabetic obstetric clinics serving large numbers of women and their use will grow if future studies of the children of women with GDM treated with these oral agents show the children to be healthy and at no extra risk.

### **Antenatal care in a diabetic pregnancy**

In addition to routine antenatal care, women with diabetes require extra maternal and fetal surveillance in pregnancy. Details in the obstetric and diabetic management of pregnant women with pre-gestational diabetes will vary according to country in which care is being given. The principles of management will be broadly similar and are outlined briefly below, according to trimester.

#### ***Antenatal care in the first trimester (1–12 weeks)***

All women should be seen at the earliest opportunity once pregnancy is confirmed; this will be earlier than women seen in routine antenatal clinics. At the first clinic visit it is important to review all prescribed and over-the-counter medications for safety and to ensure an appropriate dosage of folic acid has been prescribed.

The importance of optimization of glycemic control during this time requires frequent contact and visits with the members of the multidisciplinary team. This is especially so for women with T2DM who may be starting insulin for the first time. Dietary advice about the avoidance of hypoglycemia should be given, especially to women with T1DM [46].

It is important to confirm viability of the pregnancy at 6–8 weeks; this is before the routine screening for Down syndrome which occurs at 11–13 weeks. The 6–8 week ultrasound provides an accurate gestational age, which is important later in pregnancy when assessing fetal growth and the optimal timing of birth.

The woman's current diet and levels of physical activity should be reviewed and advice given on appropriate food choices taken as snacks for the prevention and management of hypoglycemia. Advice on exercise should be individualized; however, as a general principle, women should be encouraged to take at least 30 min/day of moderate intensity physical activity [4]. This may be modified where there is a risk of exercise-induced hypoglycemia in women with T1DM.

The general advice around diet remains the same as a non-diabetic pregnancy. The ADA guidelines on diet are more prescriptive than those of the UK NICE guidelines, with the former recommending 175 g/day digestible carbohydrate and 28 g/day fiber [4]. Women should be advised to spread their carbohydrate

portions throughout the day as this reduces hypoglycemia while avoiding post-prandial hyperglycemia. Low rather than high glycaemic index carbohydrates may prevent glycaemic excursions. The actual additional calories required to sustain a pregnancy is modest, being approximately 100 kcal in the first trimester rising to 200–300 kcal in the third trimester; this is independent of any reduction in physical activity that might occur [350].

At the start of pregnancy women should be given appropriate weight gain targets. This is especially so for women with T2DM, many of whom will be obese [3]. There is general agreement that for a non-diabetic population a 10–12.5 kg pregnancy weight gain for normal weight women and 12.5–18 kg for underweight women (BMI <19.8 kg/m<sup>2</sup>) is associated with fewer pregnancy-related complications. The appropriate weight gain for overweight (25–30 kg/m<sup>2</sup>) and obese (>30 kg/m<sup>2</sup>) is more controversial and there are no accepted guidelines for morbidly obese women (>40 kg/m<sup>2</sup>).

Historically, guidelines around maternal weight gain were focused on preventing low birth weight infants rather than large for gestational age infants. The original and widely accepted recommendations for maternal weight gain were published in 1990 by the US Institute of Medicine. These guidelines were later updated in 2009 when they lowered the recommended upper weight gain limit for overweight and obese women. These guidelines give no specific weight gain targets for morbidly obese women (>40 kg/m<sup>2</sup>). This is despite good evidence that little or no weight gain during pregnancy improves many pregnancy outcomes with little increase in the risk of small for gestational age infants [293,351–353]. Gestational weight gain is also directly associated with the risk of obesity in the adolescent offspring [354] and the degree of weight retention postpartum in the mother [355].

Maternal surveillance in the first trimester includes diabetic retinopathy and nephropathy screening. Women with pre-existing hypertension need to be identified and methyldopa initiated if required. Other co-morbidities will need to be screened and treated on an individual basis.

Women with previous GDM should be seen so they can start self-monitoring of blood glucose and be given advice on diet and exercise. The glycaemic targets for women with GDM are identical to those with pre-existing diabetes, and pharmacologic treatment should begin if these are not met.

#### **Antenatal care in the second trimester (13–27 weeks)**

Glycaemic profiles and variability are less labile by the mid-second trimester [46], making insulin intensification easier and safer. Insulin requirements increase and multiple basal insulin doses (2–3 times daily) may be needed to avoid nocturnal hypoglycemia, while ensuring adequate 24-hour cover [4].

It is important to limit excessive weight gain in overweight and obese women in this trimester as appetite and food intake increases. The current UK guidelines recommend women with a pre-pregnancy BMI >27 kg/m<sup>2</sup> to restrict their calorie intake to approximately 25 kcal/kg/day in the second trimester [5].

Fetal surveillance for cardiac anomalies using an appropriate ultrasonography should be performed at 18–22 weeks. It is important to examine the four heart chambers as well as the outflow tract of the aorta and pulmonary artery [5,356]. This scan is in addition to the routine detailed anatomical scan for other congenital anomalies which should be undertaken at around the same time.

For women who had an abnormal retinal screen in the first trimester, repeat digital retinal photographs should be performed at 16 weeks' gestation.

The second trimester is associated with worsening hypertension in women with pre-existing hypertension and the development of pregnancy-induced hypertension in women with microalbuminuria [239]. This trimester is also associated with a number of “minor” complications of pregnancy, many of which can be exacerbated by diabetes, including vaginal candidiasis, heartburn, urinary tract infections and carpal tunnel syndrome, and should be treated on an individual basis.

#### **Antenatal care in the third trimester (28–42 weeks)**

Optimizing glycaemic control continues to be important as the third trimester continues, because of the risk of stillbirth [2] and accelerated fetal growth at this time [357].

Serial ultrasound scans to assess fetal growth and liquor volume should start at 28 weeks and should be repeated at 32 and 36 weeks' gestation. Accelerated fetal growth patterns in a diabetic pregnancy typically present as serial fetal abdominal circumference measurements that cross percentile lines (Figure 53.1) [168,358]. The 36-week growth scan is one factor the obstetrician takes into consideration when advising on the optimal timing and mode of delivery.

Maternal surveillance in the third trimester includes further digital retinal photographs and regular checks for hypertension and pre-eclampsia.

### **Gestational diabetes**

#### **Screening for gestational diabetes**

Glucose intolerance developing *de novo* in pregnancy usually manifests itself by 26–28 weeks' gestation. Both the ADA and NICE guidelines currently recommend selecting women to screen for GDM according to maternal risk factors. The NICE guidelines recommend all women attending the routine antenatal clinic with predefined risk factors (Table 53.2) have a diagnostic 75-g OGTT

**Table 53.2** Maternal risk factors for screening women for gestational diabetes.

BMI >30 kg/m <sup>2</sup>
Previous macrosomic baby weighing >4.5 kg
Previous GDM
Family history of diabetes – first-degree relative with diabetes
Family origin with high prevalence of diabetes (e.g. South Asian, Afro-Caribbean, Middle Eastern)

BMI, body mass index; GDM, gestational diabetes mellitus.

at around 28 weeks for GDM, with the WHO criteria for IGT being used to establish the diagnosis [5].

The ADA guidelines advocate an initial 50-g glucose challenge test at 24–28 weeks with a glucose measurement 1 hour later. Women with a positive challenge test, defined as an 1-hour plasma glucose >7.8 mmol/L then proceed to a diagnostic OGTT [12]. The ADA guidelines were based on a consensus document last modified in 2005 and are likely to change following the publication of the HAPO trial [13].

### **Management of gestational diabetes**

The glycemic management for women with GDM was discussed previously. All women diagnosed with GDM need to be taught to self-monitor their blood glucose concentrations, and perform daily tests fasting and 1-hour after meals. The glycemic targets for GDM are identical to those for pre-gestational diabetes. Initial management is with diet and exercise, to which many women will respond. If glycemic targets are not met within 2 weeks, or glycemic levels are considered too high to be controlled adequately with diet and exercise alone, hypoglycemic therapy is required.

Increased physical activity combined with dietary modification and intensive glycemic management reduces perinatal complications in women with GDM [323]. Small clinical studies have reported that exercise programs using upper arm exercises and resistance training reduce fasting and post-prandial blood glucose values in obese women with GDM, as well as reducing insulin requirements when compared with women treated with diet alone [359,360].

The use of metformin and glibenclamide is not recommended by the ADA [12], but has been endorsed in the UK NICE guidelines [5] following the publications of two randomized control trials of their use in the management of GDM [348,349]. Recent case–controlled studies of metformin [361] and glibenclamide [362] in specialized antenatal clinics where insulin therapy is available if glycemic targets are not met suggest these agents have a role in the pharmacologic management of GDM. Both drugs are well tolerated, and in the case of metformin is associated with less maternal weight gain than insulin [348,361]. Patient preference for oral therapies rather than insulin is likely to increase their future use as first-line pharmacologic therapy after diet and exercise for the management of GDM.

### **Birth**

#### **Timing and mode of delivery**

Women with diabetes are at increased risk of a late stillbirth and shoulder dystocia. The observation that the rate of stillbirth rose from 36 weeks' gestation to term prompted Peel and Oakley [363] to advocate delivery at 36 weeks in 1949. By 1980 there was a gradual trend towards later delivery to avoid perinatal morbidity and mortality from prematurity [364]. By 1990, some obstetric units were allowing selected women with T1DM and uncomplicated diabetic pregnancies to go into spontaneous labor irrespective of the gestational age. Experience from Dublin [365], where there was a policy for delivery past 38 weeks in low risk women,

suggests that this was associated with increased perinatal deaths. Current UK obstetric guidelines are to offer induction of labor after 38 completed weeks, or an elective cesarean section if indicated to women with both pre-gestational and GDM [5]. The ADA consensus for the obstetric management of GDM puts greater emphasis on the estimated fetal weight when deciding the timing and mode of delivery [12,366].

The only reported randomized controlled trial of induction of labor versus expectant management involved 200 women with insulin-treated diabetes and 187 with GDM, who were all considered to have uncomplicated pregnancies without macrosomia. Of the mothers in the expectant management group, 49% later required induction of labor for obstetric indications, with 31% having a cesarean delivery compared with 25% among the active induction group. More infants in the expectantly managed group were large for gestational age (23% vs 10%). Shoulder dystocia occurred in 3% of births to the women randomized to expectant management compared with none in the women randomized to induction of labor [367].

A prospective case report study that compared an active policy of induction of labor at 38–39 weeks' gestation in 96 women with insulin-treated diabetes with a previous cohort of 164 women who were allowed to progress to spontaneous labor ( $n = 164$ ), reported an incidence of shoulder dystocia of 1.4% among the women who were induced compared with 10.2% in patients who gave birth beyond 40 weeks' gestation ( $P < 0.05$ ) [368].

In the CEMACH audit, the incidence of shoulder dystocia was two- to threefold higher and for Erb palsy more than 10-fold greater than that reported for the general UK antenatal population. Thirty-nine percent of women had induction of labor compared with 21% in the general maternity population and the cesarean section rate was also higher (67% vs 24%) [2].

The preterm birth rate (birth before 37 completed weeks' gestation) is increased in diabetic pregnancies. In the CEMACH survey, 35.8% of all births were preterm compared with 7.4% in the general maternity population, with 9.4% of all births being spontaneous preterm births [2]. Similarly, 32.2% of births in 323 women with T1DM in the Netherlands between 1999 and 2000 were preterm [278]. Recognized risk factors for spontaneous preterm delivery in women with diabetes are pre-eclampsia [369], nephropathy, poor glycemic control preterm delivery [370] and obesity [352]. It is routine clinical obstetric practice to give steroids (betamethasone or dexamethasone) as two intramuscular injections 24 hours apart to mothers at risk of a preterm birth to accelerate fetal lung maturity. Although not contraindicated in women with diabetes, their use is associated with a worsening of glycemic control, and it is therefore important to increase insulin doses proactively or treat the woman with an insulin infusion to supplement her basal bolus insulin regimen [371,372].

#### **Glycemic management during labor**

There is an association between maternal hyperglycemia during labor and neonatal hypoglycemia [373,374], and so it is

important to maintain normoglycemia (4–8 mmol/L) during labor [375]. To maintain this, most women with T1DM will require treatment with an insulin infusion with variable dosing from the onset of established labor. The use of insulin pumps in labor has not yet been subjected to critical evaluation, but early observational studies would suggest they may have a place [373].

The need for intravenous insulin for all women with GDM during labor and birth is less certain. A retrospective study of 114 singleton pregnancies of women with GDM (62 insulin-treated) in Australia reported that 37 (93%) of the women who were diet-controlled and 55 (89%) of the women treated with insulin were able to maintain their blood glucose <8 mmol/L throughout the peripartum period without insulin [376].

Immediately following birth, insulin requirement falls precipitously to below the pre-pregnancy levels. Clear instructions need to be given in the clinical notes to reduce the insulin at this time and to monitor blood glucose hourly.

## Postnatal management

### Breastfeeding

Breastfeeding provides health advantages for both mother and child. In the offspring of mothers without diabetes, breastfeeding protects against early childhood obesity [377,378]. In the Nurses' Health Study, breastfeeding during the first 6 months was inversely associated with overweight in adolescence. This association was also seen among mothers with diabetes during pregnancy (419 with GDM and 56 with pre-gestational diabetes) as well as offspring of normal-weight women ( $n = 8617$ ) and overweight women ( $n = 6190$ ) without diabetes during pregnancy [379].

In a case-control study of 80 young people with T2DM and 167 matched control subjects aged 10–21 years, fewer people with T2DM had been breastfed for any duration than control subjects (19.5% vs 27.1% for African-Americans, 50.0% vs 83.8% for Latino and 39.1% vs 77.6% for whites of Northern European ancestry). The overall crude odds ratio for the association of breastfeeding (ever compared with never) and T2DM was 0.26 (95% CI 0.15–0.46) [380].

Earlier concerns that the advantages of breastfeeding on childhood weight might be lost if the mother has diabetes because her milk is more calorie dense have not been substantiated by later studies [381].

All women with diabetes should be encouraged and supported to breastfeed if this is their wish. For women with T1DM, there is an increased risk of hypoglycemia in the postnatal period especially when breastfeeding; they should be advised to have a meal or snack available before or during feeds.

For women with GDM there is no risk of hypoglycemia during breastfeeding, not least because all hypoglycemic treatment should be stopped immediately after birth. If maternal blood glucose remains high and oral agents are needed, metformin and glibenclamide are the only ones currently recommended when breastfeeding [5]. Metformin is excreted into breast milk in clinically insignificant amounts [382] while glibenclamide is undetec-

table in breast milk and should be used in preference to other sulfonylureas [5,383].

### Diabetes following gestational diabetes; screening and prevention

Women with GDM are at increased risk of developing diabetes in the future. Indeed, the original O'Sullivan criteria for diagnosing GDM were based on the risk of future diabetes in the mother [65,384]. While the majority of women who go on to develop diabetes have T2DM, a smaller minority will develop T1DM [62,385].

Progression from IGT to diabetes is more common in women with a history of GDM [386]. In the control arm of the Diabetes Prevention Program (DPP), 122 of the parous women had a prior history of GDM while 487 had no history. Both groups had equivalent degrees of IGT at baseline but within 3 years of randomization, despite the women with a history of GDM being younger, 38% had developed diabetes compared with 25.7% among the women without a history of GDM.

The rate of progression to diabetes following a GDM pregnancy depends on the original criteria for its diagnosis and the length of follow-up [387]. The risk factors for the progression to diabetes are as follow [217,388–394]:

- Family origin with high prevalence of diabetes (e.g. South Asian, Afro-Caribbean, Middle Eastern);
- Treatment with insulin in pregnancy;
- Maternal obesity;
- Weight gain postpartum; and
- Family history of diabetes.

In Latin American women, parity has also been identified as a risk factor for T2DM [395]. The rate of progression is quicker in obese women with high pregnancy fasting blood glucose values and who have an insulinopenic response to oral glucose postpartum [387,392,396].

The time interval between a GDM pregnancy and future T2DM has decreased in recent years because of increasing obesity. The prevalence of diabetes at 10 years among two Danish cohorts diagnosed with GDM between 1978–1985 and 1986–1996 rose from 18.3% to 40.9% [16].

Lifestyle intervention, metformin and thiazolidinediones have all been shown in women with a history of GDM to slow the progression to T2DM [64,386,397]. A subanalysis of the DPP found that the 349 women with prior GDM who received intensive lifestyle (117) or metformin treatment (111) had a 55% and 51% less risk of progression to diabetes within 3 years than the women assigned to the placebo arm. The corresponding risk reductions in the 1416 parous women without a history of GDM were 49% and 14% for intensive lifestyle and metformin, respectively. This suggests that a history of GDM identifies a group of women particularly susceptible to the protective effects of metformin. The DPP investigators estimated that only five to six women with a history of GDM and IGT would need to be treated for 3 years with metformin or lifestyle intervention to prevent one case of diabetes [386].

All women with GDM should be part of a surveillance program to assess glucose tolerance because of the risk of diabetes. Both the ADA [12] and the UK NICE guidelines [5] recommend screening at 6 weeks postpartum and then at regular intervals thereafter. Unfortunately, a high proportion of women fail to attend the postpartum check at 6 weeks and many have no regular checks thereafter [398]. Non-attendance is associated with obesity, higher parity and worse glucose tolerance in pregnancy [399,400].

An OGTT will pick up more women with IGT or diabetes than a fasting glucose test, especially in high risk groups [401]. In low risk groups using a fasting glucose and only performing an OGTT for women with a fasting value equal to or above 6 mmol/L has been shown to have a high sensitivity (100%) and specificity (94%) for detecting postpartum diabetes [402].

In light of the success of lifestyle intervention trials to prevent diabetes, all women with GDM should be offered lifestyle advice on diet and exercise [386,403,404]. Following a GDM pregnancy, women need to be informed of their risk of a recurrence of GDM in any future pregnancy [405], and encouraged to plan any future pregnancy; their glucose status should be checked before conceiving.

# 54 Diabetes in Old Age

**Alan J. Sinclair**

The Institute of Diabetes for Older People (IDOP), University of Bedfordshire, Luton, UK

## Keypoints

- Diabetes affects 10–25% of elderly people (>65 years) worldwide, with particularly high rates in populations such as Pima Indians, Mexican-Americans and South Asians.
- Glucose tolerance worsens with age, the main factor being impairment of insulin-stimulated glucose uptake and glycogen synthesis in skeletal muscle.
- Factors precipitating hyperosmolar hyperglycemic syndrome include infections, myocardial infarction, stroke and drugs such as thiazides or glucocorticoids.
- Episodes of hypoglycemia resulting from insulin or sulfonylureas may be severe and prolonged, particularly because counter-regulatory responses are impaired in the elderly.
- High levels of disability are common in older people with diabetes and lead to heavy usage of health care resources and premature mortality.
- About 16% of elderly people with diabetes in the UK are registered blind or partially sighted (eight times more than the non-diabetic population) which justifies regular screening for undetected eye disease.
- Risk factors for foot ulceration affect 25% of elderly people with type 2 diabetes.
- Management strategies for many elderly people with diabetes are as in the younger population, with similar lipid-lowering and antihypertensive treatment schedules and aspirin or clopidogrel for patients with increased cardiovascular risk.
- Effective delivery of diabetes care depends on close cooperation between hospital and community, the involvement of diabetes specialists and practice nurses, and attention to all causes of disability and ill-health.
- Elderly people with diabetes in care homes are particularly vulnerable and require greater diabetes specialist input.

## Introduction

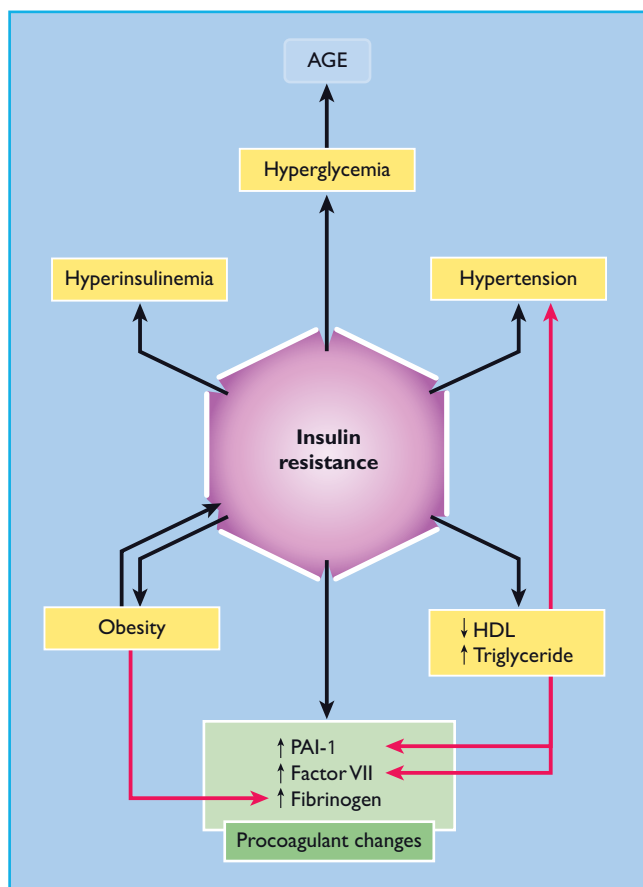

Diabetes, the most common disabling metabolic disorder, imposes considerable economic, social and health burdens [1]. Many of these burdens fall heavily on older patients with diabetes, partly because type 2 diabetes mellitus (T2DM) and its co-morbidities are so much more common in that age group, and partly because of these subjects' special needs. Older people do not accept illness without question, however, and expect equity of access to treatment and services as for younger people. As those who are above pensionable age are, in most Westernized societies, a significant proportion of the voting public, they can be very persuasive in ensuring that there are political commitments to improving the organization and delivery of health care.

Within Europe, T2DM affects 10–30% of subjects above pensionable age and in the USA about 40% of all those with diabetes fall into this category [2]. Older people with diabetes use primary care services two to three times more than their counterparts

without diabetes; in one Danish study [3], insulin-treated patients accounted for over half of the services provided, mainly because of macrovascular disease. The burden of hospital care is also increased two to three times in those with diabetes compared with the general aged population [4], with more frequent clinic visits and a fivefold higher admission rate; acute hospital admissions account for 60% of total expenditure in this group [5]. In the UK, some 5–8% of general hospital beds are occupied by patients with diabetes aged 60 years or more [6,7], accounting for 60% of all inpatients with diabetes [7]. Hospital admissions last twice as long for older patients with diabetes compared with age-matched control groups without diabetes, with the totals averaging 7 and 8 days per year for men and women, respectively [4,6,8]. Introducing insulin treatment increases costs fourfold, both in the community and in hospital, where bed occupancy rises to 24 days per year [4].

The management of T2DM and its common co-morbidity of macrovascular disease is complicated in elderly subjects because of the added effects of aging on metabolism and renal function, the use of potentially diabetogenic drugs and low levels of physical activity (Figure 54.1) [9,10]. Cardiovascular risk is particularly high because many risk factors of the metabolic syndrome can be present for up to a decade before T2DM is diagnosed (Figure 54.1) [11].

**Figure 54.1** Features of the metabolic syndrome. Additional considerations that apply to the elderly population are described in the text. AGE, advanced glycation end-product; HDL, high density lipoprotein; PAI-1, plasminogen activator inhibitor1.

It must be remembered that older people with diabetes, particularly those who are housebound or institutionalized, have special needs (Table 54.1). Overall, the quality of diabetes care for older patients appears to be improving in various countries [12,13], although the UK still seems to be alone in developing geriatric diabetes as a subspecialty.

### Epidemiology of diabetes in aging populations

In 1997, there were approximately 124 million people with diabetes worldwide, of whom 97% had T2DM. By the time of publication of this edition, this number is projected to rise to 285 million. Aging is an important factor in the rapid worldwide rise of T2DM. In the USA, the number of new cases of diabetes in people aged 65–79 years was five times higher than in those aged less than 45 years of age [2]. The prevalence of diabetes begins to rise steadily from early adulthood, reaching a plateau in those aged 60 years or older; the data in Figure 54.2, from the Third National Health and Nutrition Examination Survey (NHANES

**Table 54.1** Special characteristics of older subjects with diabetes.

High level of associated medical co-morbidities
Increased risk of cognitive dysfunction and mood disorder causing more complex decision-making
Varying evidence of impaired activities of daily living and lower limb function
Increased vulnerability to hypoglycemia
Increased risk of inpatient mortality
Unstructured specialist and primary care follow-up
Increased need to involve spouses and informal carers in management

**Figure 54.2** Prevalence of diabetes in men and women in the US population aged  $\geq 20$  years, based on the NHANES III study [14]. Subjects included those with previously diagnosed and undiagnosed diabetes (defined by fasting plasma glucose  $\geq 7.0$  mmol/L). Age-std, age-standardized.

III) in the USA [14], are representative of most developed countries. In some susceptible populations, T2DM may develop earlier; for example, among the Pima Indians prevalence peaks at 40 years of age in men and at 50 years in women, and declines after the ages of 65 and 55 years, respectively.

Overall prevalence rates of diabetes in the elderly are dominated by T2DM, which accounts for 95% of all cases in the UK and European countries, and for virtually all in populations such as the Pima Indians and Mexican-Americans. Some older patients who present clinically with T2DM may have slowly evolving autoimmune  $\beta$ -cell destruction that requires insulin treatment, so-called latent autoimmune diabetes of adults (LADA). This condition appears to be most prevalent in northern Europe and is rare in Asians and Africans.

There are marked ethnic and geographic differences in the prevalence rates of diabetes amongst older people. In the UK and most developed countries, diabetes affects 9–17% of white subjects aged over 65 years and up to 25% of non-white people [15,16]; intriguingly, the prevalence of diabetes in elderly care homes in the UK is also 25% [17]. Among subjects aged over 60 years from NHANES III, Mexican-Americans showed a consist-

**Figure 54.3** Prevalence rates for diabetes among elderly non-Hispanic white, non-Hispanic black and Mexican-American subjects. Data from the NHANES III study [14].

ently higher prevalence of diabetes than non-Latino white and black subjects (Figure 54.3) [14].

### Etiology of diabetes in the elderly

T2DM accounts for virtually all of the age-related increase in the prevalence of diabetes. This is attributed to various combinations of insulin resistance and impaired insulin secretion that result in a progressive age-related decline in glucose tolerance, which begins in the third decade and continues throughout adulthood [18,19]. Plasma glucose levels at 1 and 2 hours after the standard 75-g oral glucose challenge rise by 0.3–0.7 mmol/L per decade, the increase being greater in women. Consistent with this, NHANES III found the prevalence of impaired glucose tolerance (IGT) to be 12% in subjects aged 40–49 years, rising to 21% in those aged 60–74 years [14].

Various factors contribute to age-related glucose intolerance (Table 54.2). Perhaps the most important is impairment of insulin-mediated glucose disposal, especially in skeletal muscle [19,20], which is particularly marked in obese subjects (Figure 54.4) [21]. Insulin receptor number and binding are not consistently affected by age, and so post-receptor defects are presumably responsible. Contributory factors in some cases include increased body fat mass, physical inactivity and diabetogenic drugs such as thiazides. In contrast to younger people with T2DM, fasting hepatic glucose production does not appear to be increased in either lean or obese elderly people with T2DM [21]. The ability of insulin to enhance blood flow is also considerably reduced in obese insulin-resistant subjects with diabetes; this may be etiologically important, as insulin-mediated vasodilatation is thought to account for about 30% of normal glucose disposal.

**Table 54.2** Factors contributing to glucose intolerance in old age.

- Impaired glucose disposal and utilization
  - Insulin-mediated uptake into skeletal muscle
  - Insulin-mediated vasodilatation in muscle
  - NIMGU
- Impaired glucose-induced insulin secretion
- Other factors
  - Obesity
  - Physical inactivity
  - Reduced dietary carbohydrate
  - Diabetogenic drugs (thiazides, glucocorticoids)

NIMGU, non-insulin mediated glucose uptake.

**Figure 54.4** Insulin-mediated glucose disposal is decreased in elderly patients with type 2 diabetes. The euglycemic clamp technique was used to measure the glucose disposal rate in healthy lean and obese elderly controls, and in their counterparts with diabetes. LBM, lean body mass. From Meneilly *et al.* [21], with permission.

As well as insulin resistance, many elderly people with glucose intolerance show impairment of glucose-induced insulin secretion, especially in response to oral rather than intravenous glucose. In addition, recent studies have shown that glucose effectiveness (i.e. the ability of glucose to stimulate its own uptake in the absence of insulin) is decreased in healthy elderly subjects [22]. This non-insulin-mediated glucose uptake (NIMGU) accounts for 70% of glucose uptake under fasting conditions (primarily into the CNS) and for 50% of post-prandial glucose uptake (especially into skeletal muscle). This is therefore a potentially important new target for therapeutic intervention, as exer-

cise, anabolic steroids and decreased non-esterified fatty-acid (NEFA) levels can all enhance NIMGU and improve glucose tolerance, at least in younger patients [23].

## Acute metabolic complications in elderly people with diabetes

### Hyperglycemic states

Older subjects with diabetes can develop diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic state (formerly known as hyperosmolar non-ketotic coma [HONK]), which occurs predominantly in subjects aged over 50 years. In one study from Birmingham, UK, 22% of admissions with DKA were in subjects aged 60 years or more [24], while 13% of cases of hyperglycemic coma in all ages in Melbourne, Australia, were caused by hyperosmolar hyperglycemic state [25]. Many people with T2DM maintain enough residual insulin secretion to suppress lipolysis and ketogenesis, and so develop hyperosmolar hyperglycemic state instead of DKA; hyperosmolarity can worsen insulin resistance and may also inhibit lipolysis. The tendency to hyperosmolarity may be worsened in elderly people, who may not perceive thirst or drink enough to compensate for the osmotic diuresis, and are often taking diuretics [26].

Causes of hyperglycemia include infection (55% of cases in one series of hyperosmolar hyperglycemic state), myocardial infarction (MI), inadequate hypoglycemic treatment or diabetogenic drug treatment. Thiazide diuretics and glucocorticoids can increase blood glucose levels and may precipitate DKA; thiazide diuretics and furosemide (frusemide) appear particularly likely to cause hyperosmolar hyperglycemic state. A specific cause often cannot be identified – for example, in 38% of DKA cases in Birmingham [24]. Residents of care homes are at increased risk of hyperosmolar hyperglycemic state, which is associated with appreciable mortality [27].

Compared with the young, older patients have higher mortality and longer stays in hospital; they are also less likely to have had diabetes diagnosed previously, and more likely to have renal impairment and to require higher insulin regimens [28]. Death may occur from the metabolic disturbance or concomitant illnesses such as pneumonia and MI.

### Investigation and treatment of hyperglycemic comas

The history and examination should pay special attention to previous diabetic symptoms, drug treatment, any precipitating infection (MI), possible MI or medication, evidence of heart failure and the degree of dehydration. Initial investigations are as for younger patients, including arterial blood gases and plasma osmolality (see Chapter 34).

Fluid, insulin and potassium replacement are discussed in general in Chapter 34. In elderly patients, intravenous saline can often be given at a rate of 500 mL/hour for 4 hours, then reducing to 250 mL/hour; faster infusion is needed if the patient is shocked, when a central line is invaluable to monitor filling

pressure, particularly in the presence of cardiac failure or recent MI.

Some older subjects with hyperosmolar hyperglycemic state need very small doses of insulin to reduce plasma glucose levels, although hypercatabolic or severely insulin-resistant states will require higher dosages.

Thrombotic complications may occur, especially in subjects with hyperosmolar hyperglycemic state; prophylactic anticoagulation with low dose subcutaneous heparin is therefore recommended.

### Hypoglycemia

Older patients are particularly susceptible to hypoglycemia, and this problem is often exacerbated because old people may have been given little knowledge about the symptoms and signs of hypoglycemia [29]. Even health professionals may misdiagnose hypoglycemia as a stroke, transient ischemic attack, unexplained confusion or epileptic fit, as illustrated in the case history below.

#### Case history

A 76-year-old man was admitted with a left-sided hemiplegia. He was unconscious and the family was told by the emergency room staff that he had had a stroke and his prognosis was very poor. At this point, no-one had thought to assess his glucose concentration. When requested by the medical registrar, it was found to be 1.4 mmol/L. Following treatment with IV glucose, the man regained consciousness and he was able to leave hospital 1 hour later. He had taken his insulin but delayed his meal.

Personal communication from Richard Holt,  
University of Southampton

Patients with cognitive impairment or loss of the warning symptoms of hypoglycemia are especially vulnerable, as they may not recognize impending hypoglycemia and/or fail to communicate their feelings to their carers. Multiple factors underlie the increased susceptibility to hypoglycemia in the elderly, including recent discharge from hospital with altered sulfonylurea dosages, renal and hepatic impairment, excess alcohol and insulin therapy [30]. In addition, older subjects mount a diminished counter-regulatory response to hypoglycemia [31], and this may delay recovery.

The risk of hypoglycemia is highest with insulin, but prolonged hypoglycemia is an important clinical problem for older subjects taking glibenclamide and chlorpropamide [32]. Glibenclamide-induced hypoglycemia may be more pronounced because the drug accumulates within the  $\beta$ -cell, and its metabolites retain some hypoglycemic activity. The long elimination half-life (approximately 35 hours) of chlorpropamide causes it to accumulate with continued dosing; steady-state is not achieved for 7–10 days. Impaired renal function further prolongs hypoglycemia secondary to sulfonylureas that are cleared through the kidneys. Short-acting sulfonylureas, gliclazide and tolbutamide,

are less likely to cause hypoglycemia [33], although glipizide is considered by some to be unsafe in the elderly [34]. Newer oral agents such as the thiazolidinediones and the meglitinides may decrease the risk of hypoglycemia in the elderly, as may both rapid- and prolonged-acting insulin analogs.

In the elderly, serious hypoglycemia appears to carry a worse prognosis and higher mortality; permanent neurologic damage may occur, presumably because of an already compromised cerebral circulation. Most sulfonylureas have caused fatal hypoglycemia, most commonly chlorpropamide or glibenclamide [35]. Other factors predisposing to fatal hypoglycemia include alcohol consumption, poor food intake, renal impairment and potentiation of hypoglycemia by other drugs.

Treatment and prevention of hypoglycemia are as described in Chapter 33. Many old people cannot treat hypoglycemia themselves [28]. The educational program should focus on detecting and treating hypoglycemia, with advice to others about how to manage cases of unresponsive hypoglycemia. In view of the additional vulnerability of older people to hypoglycemia, extra caution is required when there is a history of recurrent symptoms, drowsiness is present, the patient is on relatively large doses of insulin or when their diabetes care is delegated to an informal carer. This increased risk must be balanced by a lower threshold for admission to hospital when hypoglycemia is suspected. In this setting, a glucose level  $<4$  mmol/L may warrant admission.

---

## Chronic diabetic complications in the elderly

Diabetes in older subjects carries considerable morbidity, mainly through its long-term complications. For example, in a 6-year study of 188 patients aged over 60 years in Oxford [36], the reported incidence rates of ischemic heart disease, stroke and peripheral vascular disease (PVD) were 56, 22 and 146 cases per 1000 person-years, respectively. These were slightly higher than the rates in the Framingham study [37], presumably because of the older age of the Oxford patients. Retinopathy occurred at a rate of 60 cases and cataract at 29 cases per 1000 person-years, while the rate of proteinuria (albumin concentration  $>300$  mg/L) was 19 per 1000 person-years. These incidence rates appeared to be unrelated to sex or duration of diabetes, but stroke and PVD rose significantly with age.

The age-dependence of chronic diabetic complications was also investigated in a cross-sectional study of patients with T2DM aged 53–80 years [38]. Logistic regression demonstrated a significant rise in the prevalence of retinopathy with aging, independent of the effects of metabolic control, duration of disease and other risk variables. Age also increased the prevalence of peripheral neuropathy, hypertension and erectile dysfunction. An independent contribution of age per se to retinopathy, however, was not reported by Ballard *et al.* [39] from Minnesota, USA (who found a positive relationship with persistent proteinuria only), or by Knuiman *et al.* [40], who studied patients with both type 1 diabetes (T1DM) and T2DM and found independent associations

of age with renal impairment, macrovascular complications and sensory neuropathy only.

## Diabetic eye disease and visual loss

Cataract, age-related macular degeneration and diabetic retinopathy remain the major causes of blindness and partial-sight registration in most developed countries (see Chapter 36) [41]. All these conditions are common in elderly patients with diabetes.

Cataract, the most frequent cause of deteriorating vision in the elderly, is more common in subjects with diabetes, even at the time of diagnosis; its presence is associated with premature death [16]. Age-related macular degeneration is also frequent in older patients with diabetes and is an important cause of central visual loss [42]. Risk factors include atherosclerosis, diastolic blood pressure  $>95$  mmHg or antihypertensive medication, and elevated serum cholesterol. Most older patients with diabetes have diabetic retinopathy of some degree, although about 5% show no evidence of retinal damage even after 15 years of the disease [42]. The main sight-threatening consequence of diabetic retinopathy in this population is maculopathy and particularly macular edema (see Chapter 36).

In Nottingham, UK, 16% of elderly people with diabetes are registered blind or partially sighted which is approximately eight times more than among their counterparts without diabetes [43]. The Welsh Community Diabetes Study [44] found that visual acuity was impaired in 40% of elderly subjects with diabetes, compared with only 31% of controls without diabetes ( $P < 0.007$ ). Factors significantly associated with visual loss in people with diabetes included advanced age, duration of diabetes, female sex, a history of foot ulceration and treatment with insulin. Reduced visual acuity was also significantly associated with poorer quality of life, as measured by the SF-36 questionnaire.

## Screening for retinopathy

This is particularly important in the elderly, as deteriorating vision may be accepted by the patient as part of aging. Diabetic retinopathy may be the presenting feature of the disease in older people. Elderly people with diabetes need annual measurements of visual acuity and retinal photography; where the latter may not be available or feasible, patients should undergo dilated-pupil funduscopy by experienced observers. Exudative maculopathy (hard exudates at or within one disc diameter of the macula) is easy to detect, but macular edema is practically impossible to detect by routine ophthalmoscopy; instead, slit-lamp stereoscopic funduscopy is required to measure retinal thickness. Mydriasis is usually a short-term intervention and, in the great majority of cases, is not associated with any major problems, even in older people. It is always important to know whether patients have a history of glaucoma before mydriasis, as this requires a different approach, often under specialist supervision. This highlights the importance of measuring the corrected visual acuity, which is decreased by maculopathy (see Chapter 36). Indications for referral to an ophthalmologist

are generally identical to those in younger patients (see Table 36.3).

### Prevention and management of diabetic retinopathy

The benefits of tight glycaemic control in slowing the progression of diabetic retinopathy have been convincingly proven in both T1DM and T2DM, by the Diabetes Control and Complications Trial (DCCT) and UK Prospective Diabetes Study (UKPDS) trials, respectively [45,46]. In the UKPDS, the risk of retinopathy progressing was reduced by 25% when HbA<sub>1c</sub> was maintained at <53 mmol/mol (7.0%) [46], while improved blood pressure control also reduced risk by 37% [47]. Although there have been no specific intervention studies in elderly patients with T2DM, it seems reasonable to extrapolate the general principles to this population. Problems with hypoglycemia and postural hypotension, however, prevent many elderly subjects from achieving tight glycaemic and blood pressure control.

Laser photocoagulation should be used as indicated in Chapter 36; it halves the risk of severe visual loss with macular edema and exudative maculopathy (if visual acuity is 6/9 or better), which otherwise reaches 50–70% after 5 years [48–50]. It has been calculated that screening and treating diabetic retinopathy would prevent 56% of blind registrations resulting from this condition.

### Diabetic foot disease

Amputation of a limb remains an important and expensive health problem in the diabetic population, with the elderly being particularly affected [51]. A Dutch study [52] identified increasing age and a higher level of amputation as important factors that increased both the duration and costs of hospitalization (estimated at over £10 000 per hospitalization, lasting an average of 42 days). The 3-year survival following lower-extremity amputation is about 50% [53]; in about 70% of cases, amputation is precipitated by foot ulceration [54]. The principal antecedents include peripheral vascular disease, sensorimotor and autonomic neuropathy, limited joint mobility (which especially prevents older people from inspecting their feet) and high foot pressures (Table 54.3) [51]. Most elderly people with diabetes are at increased risk of developing foot ulcers. Peripheral sensorimotor neuropathy, the primary cause or contributory factor in most

cases, becomes more common with increasing age and affects 25% of patients with T2DM aged 80 years or more [55]. As well as the common symptoms of numbness, neurogenic pain, “pins and needles” and hyperesthesia (all typically worse at night), peripheral neuropathy often causes gait disturbances, falls and other foot injuries. Concomitant visual loss worsens the situation [56]. A trivial foot injury in a patient with severe neuropathy can eventually lead to Charcot arthropathy; most of these patients have had diabetes for at least 10 years, and many are elderly (see Chapter 44).

Treatment of painful neuropathy in older patients is often difficult. Recent-onset symptoms may remit with improved metabolic control, but pain associated with loss of sensation and of greater than 6 months’ duration generally requires specific therapy. Localized pain may respond to topical application of capsaicin cream (0.075%), which depletes pain fibers of the neurotransmitter, substance P. Other drugs include tricyclic antidepressants (e.g. amitriptyline) and antiepileptics, such as carbamazepine and gabapentin (now licensed for this indication). Alternative treatments include transcutaneous nerve stimulation or acupuncture, as described in Chapter 38.

Ischemia, secondary to PVD and perhaps microcirculatory disturbances [57], is the other main contributor to diabetic foot ulceration. Macrovascular disease becomes more common with advancing age. As discussed in Chapter 39, atheromatous lesions in diabetes are more diffuse and involve vessels below the knee more often than in individuals without diabetes. Medial arterial calcification is common, especially in association with somatosensory and autonomic neuropathy; this change can affect Doppler ultrasound measurements of blood pressure in the foot and cause a misleadingly high ankle pressure index.

As in younger patients, many older people with diabetes and critical or worsening limb ischemia, or ischemic ulcers that are slow to heal, will benefit from surgical revascularization (angioplasty or arterial reconstruction). Appropriate cases should be referred early for surgery, ideally through joint protocols developed by the diabetes specialist and the vascular surgeon [58]. A reasonable life expectancy is considered important by surgeons, as concomitant cardiac and cerebrovascular disease kill 50% of patients within 5 years [59]. Following proximal arterial reconstruction, the 5-year patency averages 70% and may exceed life expectancy in patients with major co-morbidities; for distal reconstruction surgery, 5-year limb salvage rates approach 85% [59].

Strategies to prevent diabetic foot ulceration are based on a multidisciplinary approach to identifying, educating and treating high-risk patients; as discussed in Chapter 44, these measures can effectively reduce diabetes-related amputation rates. Many elderly patients have great difficulty in performing the most basic routine foot care [60], often because of poor vision and reduced mobility. In such cases, spouses and other carers must be involved to prevent and treat foot lesions. Education needs to be concise and repeated regularly; video presentations may also be helpful.

**Table 54.3** Risk factors for foot ulceration in the elderly.

Visual loss
History of alcohol abuse

### Coronary heart disease and arterial disease

Angina, MI, heart failure, stroke and intermittent claudication are substantially more common in elderly subjects with diabetes than in age-matched control groups without diabetes. Mortality is particularly high following MI, especially because of acute pump failure and later onset of left ventricular failure.

Many elderly patients with diabetes may present with atypical symptoms, including “silent ischemia” (which carries a worse prognosis than in the non-diabetic population); even MI may be painless and present non-specifically as a fall, breathlessness, malaise or hypotension.

Investigation and management of cardiovascular disease is covered in detail in Chapter 41.

### Erectile dysfunction

Erectile dysfunction becomes more common in older adults and occurs earlier and more commonly in men with diabetes after 60 years of age; 55–95% of men with diabetes are affected, compared with 50% of their counterparts without diabetes [61]. It is often neglected, or attributed to a diminished quality of life or depressive illness. Vasculopathy, autonomic neuropathy, hormonal dysregulation, endothelial dysfunction and psychogenic factors have all been implicated, as have certain drugs (notably cimetidine, beta-blockers and spironolactone) and a high alcohol intake.

Investigation should generally proceed as for younger men, beginning with an interview with the patient and his partner, where appropriate. For many older patients, extensive testing is often avoided. Treatments include oral sildenafil (which achieved erections in 67% of elderly men in one study [61]), a vacuum tumescence device, misoprostol urethral pellets and self-administered intracorporeal injection of vasoactive drugs (e.g. prostaglandin E<sub>1</sub>). The latter is relatively successful, but up to 50% of men eventually discontinue because of pain or loss of effect or interest [62].

## Mental illness in elderly people with diabetes

### Cognitive impairment and dementia

Diabetes and cognitive dysfunction are related and have evoked some interest over the last decade (Table 54.4). Impaired cognitive function has been demonstrated in elderly subjects with diabetes, but these studies were mostly not population-based, excluded subjects with dementia and generally used a large battery of tests to show the deficit [63]. Community-based studies in the UK (Melton Mowbray [64], Nottingham [43] and South Wales [65]) have shown worse cognitive function in elderly subjects with diabetes, using simple instruments such as the Folstein Mini-Mental State Examination (MMSE), Hodkinson’s Abbreviated Mental Test (AMT), and the Clock Test. These are easily learned, bedside screening tests of mental status which test several cognitive domains such as memory, orientation, calcula-

**Table 54.4** Background to relationship between diabetes and cognitive disorders. Reproduced from European Diabetes Working Party for Older People [92], with permission.

Professional and public concern about the impact of diabetes on cognition
Long-term influence of hyperglycemia and hypoglycemia on cerebral function unknown
Pathophysiologic mechanisms involved uncertain, but may involve both vascular, inflammatory and neuronal mechanisms
No current agreement on the most optimum method to detect or assess cognitive deficits in diabetes
Clinical relevance of the changes observed uncertain

tion, language and, in the case of the MMSE and Clock Tests, also test planning skills and visuospatial function.

Impaired glucose tolerance has also been shown to be associated with cognitive dysfunction [66]. It has been suggested that certain components of the metabolic syndrome (hyperglycemia, dyslipidemia, hypertension) may each contribute to memory disturbance in T2DM [67], and that hyperinsulinemia is associated with decreased cognitive function and dementia in women [68]. The Rochester study [69] has demonstrated that the overall risk of dementia is significantly increased for both men and women with T2DM; excess risk for Alzheimer disease achieved significance in men only. Poor glucose control may be associated with cognitive impairment, which recovers following improvement in glycemic control [70]. In other cases, vascular or “mixed” dementias are probably responsible.

Cognitive dysfunction in older subjects with diabetes has wide implications including increased hospitalization, less ability for self-care, reduced likelihood of specialist follow-up and increased risk of institutionalization [71]. Impaired cognitive function should be borne in mind when treating elderly subjects with diabetes, as it has implications for their safe treatment; it may cause difficulty with glycemic control because of erratic taking of diet and medication, including hypoglycemia when the patient forgets earlier administration of hypoglycemic medication and takes more.

### Depression

Depression in diabetes is a serious co-morbidity associated with poor outcome and high health care expenditure (see Chapter 55). The presence of a major depressive disorder significantly increases the risk of diabetes [72], this association being apparently independent of age, gender or coexistent chronic disease [73]. Moreover, depression was the single most important indicator of subsequent death in a group of people with diabetes admitted into hospital [74]. Failure to recognize depression can be serious, as this is a long-term life-threatening disabling illness that can significantly damage quality of life. It is also associated with

worsening diabetic control [75] and decreased treatment compliance (see Chapter 55) [76].

The relationship between diabetes and depression is complex and may result from the presence of a chronic medical condition in a susceptible individual. There are also complex neuroendocrine and cytokine changes in both conditions that may provide an explanation to link these two conditions (see Chapter 55).

Diabetes and depression share similar symptomatology (e.g. fatigue, irritability and sexual dysfunction). This may delay or confuse the diagnosis, although the commonly used diagnostic assessment scales are unlikely to be invalidated. Enquiries about well-being, sleep, appetite and weight loss should be part of the routine history, with a more comprehensive psychiatric evaluation if appropriate. A Geriatric Depression Scale (GDS) score of >5 can be regarded as indicative of probable depression [77]. While the GDS-15 may be the scale of choice for older people without cognitive impairment, it does not perform as well in those with dementia. Depression in diabetes can be treated successfully with pharmacotherapy, and/or psychologic therapy, but blood glucose levels should be monitored closely especially with pharmacotherapy. Goals for treating patients with depression and diabetes are twofold:

- 1 Remission or improvement of depressive symptoms; and
- 2 Improvement of poor glycemic control if present [78].

The preferred first-line treatment is a selective serotonin reuptake inhibitor (SSRI) or a serotonin norepinephrin reuptake inhibitor and psychotherapy. Treatment with SSRIs, such as fluoxetine, may improve symptoms and consequently metabolic control although close observation for side effects and changes to glycemic control are needed [79].

There have been reports of an increase in T2DM following treatment with antipsychotic medication which is often prescribed for older people with mental illness. This use of antipsychotics often goes beyond the license of these drugs but nevertheless has been recommended by groups such as the US Expert Consensus Panel for Using Antipsychotic Drugs in Older Patients to treat psychosis and anxiety [80]. It is estimated that as many as half of all repeat prescriptions for antipsychotics occur in people aged over 65 years [81]. Between 38–43% and 60–80% of all elderly patients living in nursing homes or old age psychiatry units, respectively, receive antipsychotics. Around 20% of people aged over 80 years are affected by dementia and 25–50% of these develop psychotic symptoms that require treatment with antipsychotics.

A systematic review of 17 studies examined the relationship between treatment with several antipsychotic agents and the risk of developing diabetes; olanzapine had an increased odds ratio but the risk for risperidone was small [82]. Data are still relatively limited in the elderly but suggest that the relative risk is less than for younger people with schizophrenia. Nevertheless, it seems prudent to undertake regular monitoring of weight, glucose and lipid profile [83].

---

## Disability

### Disability in elderly people with diabetes

Chronic diabetic complications often cause considerable disability in older people. For example, a community-based survey from Nottingham, UK [43], found significant disability in 80% of 98 elderly inner-city patients with diabetes (mean age 73 years); common problems included visual impairment (especially cataract) and previous amputation.

One in four of subjects with diabetes aged over 65 years in the Welsh Community Diabetes Study [65] required assistance with personal care, while older people with diabetes had significantly lower levels of well-being in most of the domains of the SF-36 health status questionnaire. Moreover, one in three subjects with diabetes had been hospitalized in the previous 12 months (twice the rate of those without diabetes), and subjects with diabetes had significantly increased levels of both physical and cognitive disability.

---

### Mortality in elderly subjects with diabetes

People with diabetes die prematurely, mostly from cardiovascular disease. Early reports suggested that excess rates among people with diabetes fell progressively with age, especially in those aged 65 years and over. This has been confirmed largely by the Verona Study, in which the standardized mortality ratio declined from a range of 2–3.5 for middle-aged subjects with diabetes to 1.75 in those aged 65–74 years and 1.3 in patients older than 75 years; at all ages, the impact of diabetes on the standardized mortality ratio was more pronounced in women [84]. A recent systematic review of the relationship between mortality and age has suggested a higher incidence of premature death in older subjects with diabetes [85]. Cardiovascular mortality is primarily responsible, accounting for 42% of the overall mortality in the Verona Study. In the Melton Mowbray, UK, study [86], excess mortality rose substantially in subjects with diabetes aged over 65 years, and impaired glucose tolerance was associated with a relative risk of death of 1.7.

Age remains the strongest predictor of mortality; the contributions of classic cardiovascular risk factors are uncertain in older subjects with diabetes. A Finnish study [87] concluded that smoking, hypertension, low high-density lipoprotein (HDL) cholesterol and high total cholesterol did not affect overall mortality. In the Verona Study, long-term metabolic control was a better predictor of outcome, and subjects with more variable glycemic control (measured by the coefficient of variation of fasting plasma glucose) had lower survival rates, especially in those aged over 75 years [88].

Methodologic variations have prevented a consensus from being reached across different diabetic populations. Unequivocal evidence of increased mortality would argue for a more sustained

commitment to diabetic health care provision; otherwise, future care strategies should focus on reducing morbidity and disability.

### Clinical features of diabetes in the elderly

The presentation of diabetes in older people is varied and often insidious, which may delay diagnosis (Table 54.5) [1]. Many cases are detected by finding hyperglycemia during investigation for co-morbidities or acute illnesses. Some patients do not have classic features of either DKA or hyperosmolar hyperglycemic state, but present with a “mixed” disturbance of moderate hyperglycemia (blood glucose levels 15–25 mmol/L) and modest acidosis (arterial blood pH ≈7.2), but without marked dehydration or altered consciousness.

Recognition of the diverse, atypical and often cryptic symptom profile of hyperglycemia in older subjects can be helpful in making an early diagnosis (Table 54.5). Worryingly, however, even when hyperglycemia is recognized in hospital, about half of elderly subjects receive no further evaluation or treatment of diabetes [89].

### Diagnosis of diabetes in the elderly

Diagnostic criteria are as in younger subjects. Mortality may be higher in those subjects diagnosed with diabetes on the basis of a 2-hour glucose value than with the new fasting criteria alone [90]. Moreover, isolated post-load hyperglycemia with

normal fasting glucose (<7.0 mmol/L) is associated with increased fatal cardiovascular disease and heart disease in elderly women [91].

Some elderly patients have hyperglycemia secondary to acute illness, diabetogenic therapy or other stress-inducing disorders. This can be identified because the HbA<sub>1c</sub> is normal, but the oral glucose tolerance test (OGTT) should be employed where doubt exists. Retesting following an acute illness may sometimes prevent a false diagnosis from being made. Particular difficulties may intrude: a true fasted sample may be difficult to obtain (and may be normal [90]), while an OGTT may be declined because it is time-consuming and inconvenient.

### Management of diabetes in the elderly

#### Prioritizing diabetic care

Ideally, elderly patients with diabetes should be treated as rigorously as younger subjects. Few studies have focused specifically on the elderly but a comprehensive set of evidenced-based clinical guidelines for T2DM in older people has been developed [92], and these provide a logical pathway for clinical decision-making in older people.

In older people, diabetes can cause much physical and mental impairment, and the individual’s problems must be targeted effectively. Approaches such as the five-step evaluation shown in Table 54.6 [58] can help to shape the content of the care package.

Despite their numerous problems [65], about two-thirds of older people with diabetes are suitable for strategies to improve or optimize glycaemic control (Figure 54.5). It is important to identify “frail” patients (i.e. those who are especially vulnerable to a wide range of diverse outcomes secondary to the effects of aging, chronic diabetic complications, physical and cognitive decline, and the presence of other medical co-morbidities). The Frailty Model of Diabetes [58] can assist clinical decision-making by defining factors (e.g. recurrent hypoglycemia, cardiac disease and reduced recovery from metabolic decompensation), which may herald disability and often directly threaten independence, yet may have preventable or reversible components. In clinical practice, the presence of a mobility disorder or severe restriction of activities of daily living, or the presence of several co-morbid-

2 Vascular risk assessment, especially vascular prophylaxis and lifestyle modification
3 Metabolic targeting (“single disease” or “frailty” models)
4 Devise appropriate interventions for diabetes-related disabilities
5 Assess suitability for self-care or carer assistance

**Figure 54.5** Matching treatment aims to functional assessments in elderly people with diabetes.

ities, and/or advanced age (>80 years) will increase the risk of becoming confined to a chair or bed by two- to threefold over 2 years [93].

### Treatment targets for older people with diabetes

Table 54.7 lists metabolic and cardiovascular treatment targets appropriate for “strict” and “optimal” therapy, using evidence derived from large-scale clinical trials (referenced in full in Sinclair [58]); caveats about applying these data to the elderly are acknowledged comprehensively in the European Diabetes Working Party for Older People [92]. The European Guidelines have provided a series of glycaemic targets to guide treatment (see box).

Because of the increased risk of hypoglycemia, a more realistic target HbA<sub>1c</sub> in frailer subjects is often <64 mmol/mol (8.0%), which will still reduce hyperglycemic malaise and may decrease the risk of some vascular complications. There are conflicting data about the relationship between advancing age and HbA<sub>1c</sub>: in a French study of telecom workers aged 18–80 years, HbA<sub>1c</sub> rose with age but then fell in males [94]. In a smaller study of 93 subjects, however, advancing age was not related to glycated

### European guidelines for the management of glycaemic control in older people with diabetes

For older patients with T2DM, with single system involvement (free of other major co-morbidities), a target HbA<sub>1c</sub> (DCCT aligned) range of 7.0–7.5%\* should be aimed for. Evidence level 1+; Grade of recommendation A. *The precise target agreed will depend on existing cardiovascular risk, presence of microvascular complications and ability of the individual to self-manage*

For older patients with T2DM, with single system involvement (free of other major co-morbidities), a fasting glucose range of 6.5–7.5 mmol/L can be regarded as indicating good control. Evidence level 2+; Grade of recommendation B

\*IFCC HbA<sub>1c</sub> 53–58 mmol/mol

hemoglobin or fasting plasma glucose [95]. This is an area requiring further study.

As well as glycaemic and blood pressure control, lipid-lowering therapy should be considered for subjects up to the age of 80 years. Thromboembolic prophylaxis (e.g. with aspirin [75 mg/

day] or clopidogrel [75 mg/day] [96] if aspirin is not tolerated) is appropriate in older subjects with diabetes and macrovascular disease or risk factors such as hypertension, obesity, albuminuria or cigarette smoking. Atrial fibrillation is more common in older subjects with diabetes, but there is no specific evidence to support full warfarin anticoagulation in this advanced age group.

**Evaluation of cardiovascular risk**

Evaluation of cardiovascular risk provides prognostic information and helps to target therapy for the primary and secondary prevention of coronary heart disease (CHD). The available methods estimate risk (e.g. 10–20%) over a 5- or 10-year period, and include the New Zealand tables [97] and data from the Framingham [98] and Seven European Countries studies [99]; all are limited by the lack of data from subjects over 74 years of age.

Reducing triglyceride levels may also help to reduce overall cardiovascular risk in older subjects. In a New Zealand study, subjects with T2DM aged over 70 years had an increased mortality if they were hyperlipidemic [100], while the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) study showed that treatment with gemfibrozil lowered cardiovascular mortality by over 20%; three-quarters of the latter subjects were aged 60–74 years, and 25% had diabetes [101].

A more recent study provides convincing evidence of benefit irrespective of age: the Heart Protection Study [102] included adults with diabetes aged 40–80 years treated with 40 mg simvastatin or placebo over a 5-year period. Treatment led to an average fall in low density lipoprotein (LDL) cholesterol of 1.0 mmol/L and resulted in a highly significant reduction of 27% in the incidence of first non-fatal MI or coronary death, and a 25% reduction in first non-fatal or fatal stroke. Evidence of benefit was observed as early as 12 months of treatment.

A relatively recent clinical trial comparing different antihypertensive regimens in the prevention of CHD and other cardiovascular events was terminated early because of the obvious significant benefits on mortality being achieved with an amlodipine-based regimen. This study involved subjects up to age 79 years, and in those with T2DM benefits were similarly realized [103]. These included the incidence of the composite endpoint (total cardiovascular events and procedures) compared with the atenolol-based regimen (hazard ratio 0.86; 95% CI 0.76–0.98;  $P = 0.026$ ). In addition, fatal and non-fatal strokes were reduced by 25% ( $P = 0.017$ ), PVD by 48% ( $P = 0.004$ ) and non-coronary revascularization procedures by 57% ( $P < 0.001$ ).

Angiotensin-converting enzyme (ACE) inhibitors can also improve cardiovascular outcome. The Micro-HOPE study investigated the effects of ramipril on macrovascular and microvascular disease in people aged over 55 years over a 4.5-year period [104]. All subjects were at high cardiovascular risk because of a previous event (e.g. stroke, MI, PVD) or diabetes together with another cardiovascular risk factor such as hypertension or dyslipidemia. Primary endpoints (stroke, or fatal or non-fatal MI) were significantly reduced from 20% to 15%, while all-cause mortality fell by 24%.

Several other recent studies have looked at the benefits of tighter glucose regulation in a wide range of subjects (including older subjects) with T2DM [105–107]. Excess cardiovascular mortality was demonstrated in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) in the intensive group where the average HbA<sub>1c</sub> was 46 mmol/mol (6.4%) [105], whereas in the Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) study [106] excess mortality was not demonstrated. Neither study indicated any benefit in reducing cardiovascular outcomes despite similar reductions in HbA<sub>1c</sub> in the intensive groups. A further study in American veterans [107] with T2DM (average HbA<sub>1c</sub>: 52 mmol/mol [6.9%] in the intensive group) also failed to show benefit at a level of HbA<sub>1c</sub> in the range usually aimed for by most clinicians. The rates of hypoglycemia were significantly more common in the intensive groups in all studies.

For older people, these results pose several dilemmas in management: first, they do not answer the important clinical question of how to reduce cardiovascular risk, and, secondly, what is the optimal level to aim for which substantially reduces microvascular risk yet avoids severe hypoglycemia. For now we must continue to aim for realistic targets (similar to younger adults) for all those older patients who do not have marked evi-

**Table 54.8** Principal aims in managing older people with diabetes.**Medical**

Freedom from hyperglycemic symptoms  
 Prevent undesirable weight loss  
 Avoid hypoglycemia and other adverse drug reactions  
 Screen for and prevent vascular complications  
 Detect cognitive impairment and depression at an early stage  
 Achieve a normal life expectancy for patients where possible

**Patient-orientated**

Maintain general well-being and good quality of life  
 Acquire skills and knowledge to adapt to lifestyle changes  
 Encourage diabetes self-care

dence of frailty. Intensified treatment in this latter category is not justified at present on the basis of these recent intervention studies.

The principal aims of managing diabetes in older adults are listed in Table 54.8. The priority of each may change with time, the development of complications or the need for external help. An initial diabetes care plan should be drawn up for the individual patient (Table 54.9). The guidelines of the International Diabetes Federation (IDF) for managing T2DM [108] appear equally applicable to older subjects although more detailed specialist guidance is now available [92]. Patients with T1DM are managed as in younger individuals.

**Lifestyle modification**

Dietary and lifestyle advice are given as for middle-aged subjects, including an exercise program if possible. These measures may be sufficient for subjects with minimal symptoms, whose initial random glucose levels lie between 8 and 17 mmol/L. If metabolic targets are not reached by 6–8 weeks, oral therapy is required [109].

Active management of other cardiovascular risk factors, especially hypertension and dyslipidemia, is necessary from the outset (Table 54.7).

**Oral hypoglycemic agents****Sulfonylureas**

Sulfonylureas are often used initially in elderly people with diabetes failing on diet, because they are generally well tolerated. Their main hazard is hypoglycemia. This is a particular problem with glibenclamide, the use of which has been associated with more fatalities than other sulfonylureas, including chlorpropamide; it must be strictly avoided in the elderly. Glipizide can cause prolonged hypoglycemia in older people and has been linked to hypoglycemic deaths in elderly Swedish subjects [34]. Gliclazide has a relatively low risk of hypoglycemia; it may be less likely to cause weight gain, the other common problem with sulfonylureas, and it is undoubtedly safer than glibenclamide [33]. A mod-

**Table 54.9** Care plan for initial management of diabetes in an elderly person.

- 1 Establish realistic glycaemic and blood pressure targets
- 2 Provide an estimate of cardiovascular risk over 5 years
- 3 Ensure consensus with patient, spouse or family, GP, informal carer, community nurse or hospital specialist
- 4 Define the frequency and nature of diabetes follow-up
- 5 Organize glycaemic monitoring by patient or carer
- 6 Refer to social or community services as necessary
- 7 Provide advice on stopping smoking, increasing exercise and alcohol intake

ified-release once-daily preparation of gliclazide is now available. Tolbutamide carries the lowest risk of hypoglycemia and can be used in those with mild renal impairment (serum creatinine  $<150 \mu\text{mol/L}$  (estimated glomerular filtration rate [eGFR]  $<42 \text{ mL/min/1.73 m}^2$  based on a 75-year-old non-black male) [110]. If compliance is uncertain, glimepiride may be useful, because the effective daily dose for all patients is one tablet before breakfast; however, there are no good comparisons between this and gliclazide.

With all sulfonylureas, the maximal glucose-lowering effect is about 4–5 mmol/L. Patients with very high glucose levels will not therefore achieve adequate glycaemic control.

**Metformin**

Metformin is predictable and safe if it is used correctly and its contraindications are respected: these include renal impairment (serum creatinine  $>120 \mu\text{mol/L}$ , eGFR  $<54 \text{ mL/min/1.73 m}^2$  based on a 75-year-old non-black male), hepatic or cardiac failure, critical limb ischemia and severe acute illness. Accordingly, some 40–50% of older subjects are ineligible for the drug.

Particular advantages of metformin are that it does not cause hypoglycemia or weight gain on its own, and is inexpensive. Its glucose-lowering effect is similar to sulfonylureas, including in the elderly. The usual daily dose required is approximately 1.7 g, and it is as effective in the lean as in the overweight. Metformin was the only antidiabetic drug shown to reduce macrovascular events in the UKPDS, and all-cause mortality and combined diabetes-related endpoints were significantly lower with metformin than with insulin or sulfonylurea in obese subjects [111].

**Acarbose**

Acarbose has a weak hypoglycemic effect, including in elderly subjects. Slow introduction of the drug (e.g. 25 mg with the first mouthful of one meal per day initially) can help to diminish gastrointestinal side effects (bloating and flatulence) which often limit its use. Its main contraindications are inflammatory bowel disease and subacute obstruction. Acarbose can be combined with metformin, sulfonylureas or insulin.

### Thiazolidinediones

Thiazolidinediones (TZDs) reduce insulin resistance by activating the peroxisome proliferator activated receptor  $\gamma$  (PPAR $\gamma$ ). They lower glucose by 3–4 mmol/L and, as monotherapy, they reduce HbA<sub>1c</sub> by 5–15 mmol/mol (0.5–1.4%). Although they do not cause hypoglycemia, their main problems are mild edema, dilutional anemia (in <5% of subjects) and weight gain, with a twofold increased risk of heart failure for which they are contraindicated. TZDs can be given in combination with metformin, sulfonylureas and glinides, and pioglitazone can be given with insulin in the UK (see Chapter 29). Several meta-analyses suggest that rosiglitazone treatment may be associated with an increased risk of MI although this has not been demonstrated for pioglitazone. Both TZDs are associated with an increased fracture risk, mainly in women, and this is an additional factor to consider when screening older people with osteoporosis for treatment with a TZD. They are safe in mild to moderate renal impairment; the liver damage associated with troglitazone (now withdrawn) does not appear to extend to rosiglitazone or pioglitazone, but frequent monitoring of liver function is required, especially during the first 12 months of treatment; this is a drawback for many older subjects.

Rosiglitazone and pioglitazone have comparable hypoglycemic effects and the latter shows a modest improvement in lipid profile; up to 6–8 weeks may elapse before the full beneficial actions are seen. These drugs can be given once daily, which is helpful for older patients.

### Non-sulfonylurea insulin secretagogues (glinides)

Repaglinide is a benzoic acid derivative of the meglitinide class which predominantly lowers post-prandial hyperglycemia. It has a rapid onset of action and a lower risk of hypoglycemia than the sulfonylureas, and achieves better post-prandial glucose profiles.

Repaglinide is predominantly metabolized in the liver to inactive metabolites and is safe in mild to moderate renal impairment. Tablets can be missed if meals are omitted, and it may be effectively combined with metformin and with thiazolidinediones (where license permits). Initially, 0.5 mg can be given with each meal (1 mg for subjects transferring from other oral agents), increasing to 4 mg with each meal.

Nateglinide is a recent meglitinide which has a faster and shorter duration of insulin secretory activity than repaglinide but is less effective as monotherapy or in combination than rapaglinide.

### Insulin

Recent improvements in the organization of care between hospital and primary care, and the expanding roles of diabetes specialist nurses and general practice nurses, have made it easier and safer to use insulin in the treatment of older people with diabetes [112]. The main indications in the elderly are T1DM or T2DM where metabolic targets have not been achieved with diet, exercise and oral agents. It should also be used following acute MI (see Chapter 41), acute stroke, hyperglycemic coma and major surgery (see Chapter 32).

The main disadvantage of insulin is hypoglycemia, although the UKPDS found that fewer than 2% of subjects treated with insulin experienced a major hypoglycemic episode. Reported benefits include improvements in well-being and possibly quality of life [113–115] and in cognitive function [70], partly following improved glycemic control; however, others have found lower treatment satisfaction in insulin-treated patients [116].

Some guidelines for insulin treatment in the elderly are suggested in Table 54.10. Rapidly acting insulin analogs such as insulin lispro or insulin aspart may cause less hypoglycemia and weight gain, and can be given after eating where timing may be

**Table 54.10** General guidelines for insulin treatment in older people.

	Indications	Advantages	Disadvantages
Once-daily insulin	Frail subjects Very old (>80 years) Symptomatic control	Single injection Can be given by carer or district nurse	Control usually poor Hypoglycemia common
Twice-daily insulin	Preferred if aiming for reasonable glycemic control Suitable for T1DM	Low risk of hypoglycemia Easily managed by most older people with diabetes	Normoglycemia difficult to achieve Fixed meal times reduce flexibility Expensive
Basal/bolus insulin	Well-motivated individuals For acute illness in hospital	Enables tight control Can reduce microvascular complications Flexible meal times	Frequent monitoring required to avoid hypoglycemia
Insulin plus oral agents	If glycemic control is unsatisfactory with oral agents alone To limit weight gain in obese subjects	Limits weight gain by reducing total daily insulin Increased flexibility	May delay conversion to insulin in thin or type 1 patients

unpredictable (e.g. because of memory disorder). In patients with T1DM, premixed insulins given twice daily may achieve reasonable glycemic control, although nocturnal hypoglycemia may be troublesome because of the longer-acting component of the pre-supper dose (see Chapter 27).

In older patients with T2DM, a twice-daily regimen of human isophane insulin can be used, adding short-acting insulin to cover meals if necessary. The newly introduced long-acting insulin analogs (e.g. insulin glargine and insulin detemir) have more reproducible pharmacokinetics and a “peakless” action profile, and may prove safer in older subjects. Once-daily insulin regimens alone are now little used, except where glycemic control is not a priority or injections are impracticable.

Insulin can usefully be combined with an oral agent in patients failing to be controlled by diet and oral agents. A suitable regimen is a night-time dose of intermediate-acting insulin (e.g. isophane) together with metformin, which causes less weight gain and hypoglycemia and better glycemic control than twice-daily insulin or combinations of glibenclamide with insulin or metformin [117]. The use of insulin in the elderly varies enormously even in developed countries. For frail subjects including those within care-home settings, complex regimens should be avoided so the use of longer-acting insulin analogs during the day often combined with oral agents is a feasible alternative.

Low-vision aids are available to help to inject insulin, and some insulin pens have audible clicks for counting doses.

## Diabetic patients in care homes

In many developed countries the numbers of care-home residents are increasing and the prevalence of diabetes in this setting will inevitably increase. Recent surveys suggest that 7–27% of care-home residents in the UK and USA have diabetes. The wide range is partly because of differences in the diagnostic criteria used [17,118–120]; the prevalence of IGT may be as high as 30% [17]. People with diabetes in care homes should receive care commensurate with their health and social needs [121]. The best possible quality of life and well-being should be maintained, without unnecessary or inappropriate interventions, while helping residents to manage their own diabetes wherever feasible and worthwhile.

Metabolic control should reduce both hyperglycemic lethargy and hypoglycemia, with a well-balanced dietetic plan that prevents weight loss and maintains nutritional well-being. Foot care and vision require screening and preventive measures to maintain mobility and prevent falls and unnecessary hospital admissions.

At present, residents with diabetes in care homes appear to be generally vulnerable and neglected, with high prevalences of macrovascular complications and infections (especially skin and urinary tract), frequent hospitalization and much physical and cognitive disability. Known deficiencies of diabetes care include lack of individual management care plans and dietary supervision, infrequent review by specialist nurses, doctors and ophthal-

**Table 54.11** Some recommendations for improving diabetes management in care homes.

Screen on admission for diabetes and regularly thereafter
Policies must include strategies to minimize hospital admission, metabolic decompensation, pressure-sore development, pain, diabetes-related complications, infections and weight loss
All residents with diabetes must have an annual review and access to specialist services
Care-home diabetes policies must be developed nationally, locally and at the level of the resident with diabetes
Research based on interventional strategies is needed

mologists, and poor knowledge and training for care staff [120,121].

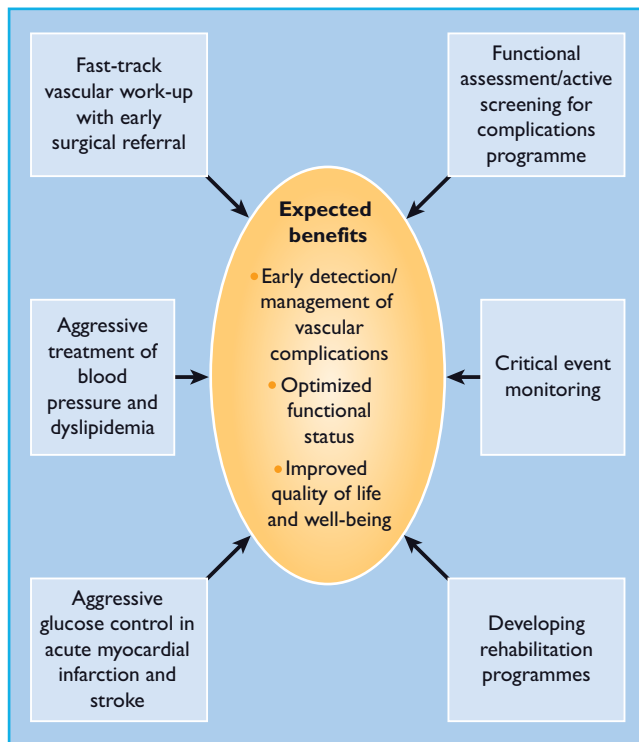

Various strategies can improve diabetes care in this setting (Table 54.11) [117,122,123]. The impact of these initiatives is being followed on outcomes including well-being, metabolic control, access to regular review, rates of hospitalization and diabetic complications such as amputation and visual loss. A UK Task and Finish Group of Diabetes UK is revising previous guidelines and will be publishing new guidance at the beginning of 2010.

## Modern diabetes care for older people

Structured diabetes care is particularly important for older people who are often neglected at present [124]; with the current shift in health care from hospitals to the community, GPs will have an increasingly important role [125,126]. This will require considerable motivation by the GP, effective screening for diabetes program and close liaison with diabetes specialist nurses (see Chapter 56). A shared-care approach, with GPs working in partnership with hospital-based diabetic and surgical specialists and based around agreed clinical protocols, is particularly valuable for older people.

A modern geriatric diabetes service (Figure 54.6) is based on a “multidimensional intervention” model [58]. This emphasizes the importance of early intervention in diabetic complications and of establishing rehabilitation programs for patients disabled by various complications such as amputation, peripheral neuropathy, immobility, falls, stroke and cognitive change. “Critical event monitoring” denotes monitoring periods of ill-health or social care need where patient vulnerability is high and opportunity for intervention is paramount (e.g. admission to hospital, amputation or stroke).

Health care must be cost-effective, which presents a difficult challenge for diabetes, because of its high prevalence, long duration of impact and wide spectrum of complications and emotional and psychologic sequelae; in older subjects, the challenge is even more complex because of the many other confounding factors.

**Figure 54.6** Components of a modern strategy for managing diabetes in the elderly.

Recent studies [127–129] have suggested that aggressive treatment of diabetes in older individuals is not warranted because of their reduced life expectancy; however, implementing the strategies outlined above seems likely to reduce acute hospitalization, outpatient costs and long-term disability. Only well-organized prospective clinical trials will be able to determine how best to manage diabetes in older people.

### Keypoints

- The interactions between diabetes and psychiatric disorders are complex: physical illness raises the risk of psychiatric disorder, but mental illness and its treatment also impact on the risks and outcomes of diabetes.
- Because mental health problems are common among people with diabetes, good levels of awareness and knowledge are vital for the health professionals who work with them.
- A strong case has been made for implementation of screening for mental health problems in a range of care settings.
- Increased availability of mental health expertise in the settings where people with diabetes are treated is required.

### Introduction

The interaction between mind and body is central to the management and outcome of all chronic diseases, but is perhaps particularly complex and fascinating in the case of diabetes. Diabetes is no longer an invariably fatal condition; however, in order to maintain good health, many patients face high behavioral demands. Psychiatric disorders may significantly compromise the ability of the patient to perform self-care to the required standard for optimum health, leading to increased risks of poor outcomes including complications and premature mortality.

Both diabetes and psychiatric disorders are common conditions, and therefore a degree of co-occurrence would be expected purely by chance; however, there is a considerable body of evidence that diabetes is associated more frequently than expected with a range of psychiatric morbidity. In particular, it appears that patients with mood and psychotic disorders are at increased risk of developing diabetes, and people with diabetes go on to develop a range of psychologic problems at increased rates compared to healthy controls. This was first noted over a century ago; as Henry Maudsley said in his celebrated textbook, *Pathology of Mind*, when discussing the increased rates of diabetes observed among psychiatric patients [1]:

*“Diabetes is a disease which often shows itself in families in which insanity prevails. Whether one disease predisposes in any way to the*

*other or not, or whether they are independent outcomes of a common neurosis, they are certainly found to run side by side, or alternately with one another more often than can be accounted for by accidental coincidence or sequence”.*

Knowledge of the special problems that occur when diabetes and a psychiatric disorder coincide is essential if optimum care is to be provided. Unfortunately, in most countries, services are not well organized to deliver good quality care for both the physical and psychologic needs of patients in the same setting. Clinicians need to be aware of the increased risks of co-morbidity, and the need for screening. Diabetes health care professionals should be able to provide “first response” management, and recognize the needs of those more complex patients for whom specialist management is essential. The topic of co-morbidity is also attracting interest from researchers, and there is the potential for considerable progress in understanding the epidemiology and psychobiologic mechanisms involved. The increased availability of objective measures of glycemic control and diabetes outcomes over the past few decades has opened up the possibility of a wide range of psychobiologic research. This chapter provides an overview of the current state of knowledge of these topics, and highlights needs for further research.

### Mood disorders

Until quite recently, any discussion of mood disorders and diabetes would have concentrated solely on the increased rates of depression observed in cohorts of patients with diabetes, and is

likely to have viewed such co-morbidity mainly as an “understandable” reaction to the difficulties resulting from living with a demanding and life-limiting chronic physical illness. We now understand that the interaction between the two conditions is more complex than this:

- Depression may itself be a risk factor for the development of diabetes;
- Biologic aspects of diabetes may contribute to the development of depression;
- Other antecedent factors, such as the early nutritional environment, may have a “common soil effect,” thereby contributing to the risks of both conditions.

Depression can also impact on the clinical course of the diabetes, increasing the risk of poor glycemic control and complications. People with both diabetes and depression have been found to have higher symptom burden, poorer functional status, poorer self-care and higher health care costs [2].

### Case definition

Depressive symptoms exist on a continuum of severity. Standard definitions of “clinical” depression are based on symptom count and duration; the most widely used diagnostic criteria in current practice are those of the American Psychiatric Association’s DSM-IV “major” depression (Table 55.1) [3].

This definition is to some degree arbitrary; however, it approximates to a level of symptomatology that is associated with significant disability and dysfunction, and is very widely accepted as a standard in both clinical practice and research. It is important to note that depressive disorders of lesser severity may still compromise self-care and outcomes in people with diabetes.

The clinical category of mood disorders includes both unipolar depression and bipolar (“manic-depressive”) illness. This section focuses on unipolar depression; bipolar illness is included in the section on psychotic disorders.

**Table 55.1** DSM-IV “major” depressive episode.

Five or more of the listed symptoms should be present nearly every day, for at least 2 weeks, and should represent a change from normal functioning; at least one of the first two symptoms in the list must be present

#### Symptoms

- 1 Depressed mood for most of the day**
- 2 Markedly diminished interest or pleasure in all, or almost all, activities for most of the day**
- 3 Significant weight loss when not dieting, or weight gain (change of 5%), or decrease or increase in appetite**
- 4 Insomnia or hypersomnia**
- 5 Psychomotor agitation or retardation**
- 6 Fatigue or loss of energy**
- 7 Feelings of worthlessness or excessive or inappropriate guilt**
- 8 Diminished ability to think or concentrate**
- 9 Recurrent thoughts of death or suicidal ideation**

### Epidemiology

Unipolar depression is one of the most common mental health problems in the general population, affecting 3–5% of the population at any time, and its prevalence appears to be increasing, such that the World Health Organization have estimated that it will be the second leading cause of disability (after heart disease) in the world by 2020 [4].

There have been many studies of the prevalence of depressive symptoms and disorders in people with diabetes over the past 40 years. Most of the early studies, however, had significant methodologic shortcomings.

First, they lacked standardized definitions of depressive disorders, mainly using rating scales of unknown reliability and validity in a diabetic population. The “gold standard” for ascertainment of case status is a research diagnostic interview; most rating scales can only give a probabilistic estimate of caseness. In addition, there may be an overlap between symptoms of diabetes and those of depression (e.g. fatigue, weight loss).

Second, studies have tended to ignore the heterogeneity of people with diabetes, studying mixed populations of patients with different forms of diabetes (e.g. type 1 [T1DM] and type 2 [T2DM]). It is important to distinguish between these groups for several reasons:

- Although there is increasing overlap, people with T2DM are older and depression prevalence varies with age;
- There may be differences in pathologic mechanisms;
- The rates of diabetic complications and other co-morbid conditions (e.g. obesity, heart disease) differ; and
- The demands of management are different.

Third, studies have often been based on “convenience” samples of patients, usually drawn from diabetic clinics, where the operation of referral and other biases in sample composition was of unknown effect. Ethnicity is also an important confounder for rates of both depression and diabetes.

Finally, studies have had low or unknown response rates, and because the presence of depressive symptoms may reduce the likelihood of responding in such studies, this biases prevalence estimates further. Not surprisingly, as a result the range of prevalence figures that can be found in the literature is very wide.

More recent studies, using better methods, and meta-analyses, have led to lower estimates of prevalence. For example, one recent review of the prevalence of co-morbid depression in people with T1DM [5] concluded that clinical depression was present in 12%, compared with 3.2% in control subjects without diabetes. Caution is still needed in the interpretation of this finding, because it was based on only 14 studies, of which only four included control groups and only seven were based on interview methods. Excluding studies without control groups and interview ascertainment led to a fall in estimated prevalence to 7.8%, a figure that, although still raised, is no longer statistically significantly different from that found in healthy controls (odds ratio [OR] 2.4; 95% confidence interval [CI] –0.7 to 5.4).

Studies of depression in people with T2DM tend to be based on larger samples, given that around 85% of patients have this

disease subtype. A recent study based on clinical diagnoses from a US Health Maintenance Organization [6] concluded that depression was more common in people with T2DM (17.9%) than in matched controls (11.2%), with marked sex differences: depression was nearly twice as common in women, but the effect of the presence of diabetes was greater in men. The effect remained after adjustment for covariates such as cardiovascular disease and obesity.

### Depressive disorders as a risk factor for diabetes

The suggestion that emotional factors, such as grief or sadness, could lead to the onset of diabetes was first raised by Thomas Willis in 1684. It is a common clinical observation that the onset of diabetes may follow a depressive episode, although because T2DM often goes undiagnosed for years, the apparent association may be at least partly the result of ascertainment bias – patients with depression are more likely to have a screening test for diabetes than those without.

A recent systematic review has addressed the question of the direction of the association between these conditions, and summarized the evidence that depression may be a risk factor for diabetes [7]. Unfortunately, the vast majority of existing studies are cross-sectional and therefore uninformative about this issue. The reviewers were able to identify nine longitudinal studies, and the analysis suggested that depressed adults have an increased risk of developing T2DM of around 37%; however, this must be regarded as a preliminary finding, and further large well-designed longitudinal studies are needed.

### Proposed mechanisms linking depression and diabetes

#### Psychosocial factors

Most studies confirm that risk factors for depression in otherwise healthy individuals operate equally in people with diabetes. Thus, socioeconomic hardship, poor education, stressful life events and lack of social support are all important [8]. Gender differences are also important. There is relatively little evidence that people with diabetes differ greatly with respect to these types of risk factors, and it can be concluded that much depression in people with diabetes may be “independent” of the presence of the disease, an issue that may be particularly important when it comes to management planning.

#### Early nutrition

One putative common risk factor that may increase the risks of both of diabetes and depression is that of disrupted nutrition during fetal life. There are now over 38 reports linking poor fetal growth with impaired glucose metabolism in later life [9]. Most of these studies report an inverse relationship or J-shaped relationship between birth weight and plasma glucose and insulin concentrations, the prevalence of T2DM and measures of insulin resistance and secretion. Similarly, the risk of depression has been found to be associated with low birth weight for both young and older adults [10]. Furthermore, data from the Dutch Hunger Winter study showed that exposure to famine during the second

or third trimester of fetal life is associated with increased risk of hospital treatment for major affective disorder [11].

The mechanism underlying this association is not clear but one hypothesis proposes that fetal programming of the hypothalamic-pituitary-adrenal (HPA) axis may play a part.

#### Shared genetic risk

Another suggested mechanism that may link diabetes and psychiatric disorder is that of shared genetic variance. There is some evidence that close relatives of people with some forms of psychiatric disorder have an increased incidence of diabetes [12], and known loci for the disorders occur in overlapping positions within chromosomes [13]. Investigation of this intriguing possibility is in its infancy and further research is needed.

#### Inflammatory mechanisms

It has been hypothesized that inflammation and increased production of proinflammatory cytokines by activated immune cells may mediate the association between depression and diabetes, with associated perturbation of the HPA axis [14]. Parallels have been noted between depression and so-called “sickness behavior” seen in response to the elevation of cytokines, interleukin 1 (IL-1), IL-6 and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ). It is thought that such cytokines may be released in increased amounts from adipose tissue in conditions including diabetes and obesity as people age, and this may interfere with insulin action.

#### Counter-regulatory hormones

Acute psychological stress is known to increase circulating concentrations of counter-regulatory hormones including noradrenaline, glucocorticoids and growth hormone (GH), which antagonize the hypoglycemic action of insulin. Although the effects of chronic stress on the HPA axis are somewhat less well understood, the view of depression as a maladaptive prolonged stress reaction has some empirical support.

Loss of normal diurnal variation in cortisol levels together with non-suppression of cortisol release in response to exogenous steroid administration have long been noted as hallmarks of depressive illness, particularly the “melancholic” subtype. It is suggested that this may lead to increased glycogenolysis, gluconeogenesis, lipolysis and inhibition of peripheral glucose transport and utilization [15]. Non-diabetic patients with depression have been shown to have increased insulin resistance, but further investigation of this mechanism is warranted. Glucose transport in the brains of people with depression has also been shown to be abnormal [15].

#### Depression and glycemic control

Several studies have demonstrated an association between the severity of depressive symptoms and the level of glycemic control as assessed by glycosylated hemoglobin level (HbA<sub>1c</sub>) [16], although the size of this effect has been generally modest, and may be explained by confounders such as the presence of microvascular complications. Most studies have been cross-sectional in

nature, although some treatment studies have suggested that improvements in glycemic control are associated with reduction of depressive symptoms.

### Depression and complications

There seems to be little doubt that the risk of depression increases as microvascular and macrovascular complications accrue over the course of the disease [17]. The evidence is less strong that the presence of depression increases the risk of developing complications, although the fact that self-care and resulting glycemic control are impaired would lead to this expectation. One longitudinal cohort study of 66 people with T1DM found that depression was an independent risk factor for retinopathy at 10 years [18], but other studies have had negative results. The meta-analysis of de Groot *et al.* [17] supports a positive association.

One complication that may have a particular association with depression is that of peripheral neuropathic pain. Recent studies suggest that not only is chronic pain a risk factor for depression, but the presence of depression may itself worsen the experience of pain. Common neurotransmitters appear to be involved in both depression and pain [19].

### Management of people with diabetes and depression

At present, advice for the management of patients with comorbid depression and diabetes is based on evidence derived from populations without diabetes because the number of treatment studies in people with diabetes is as yet too small to lead to robust conclusions. Nevertheless, some inroads into this problem are now being made.

The main aims of treatment are to reduce depressive symptoms and to improve self-care, glycemic control and diabetes outcomes. A major difficulty for most clinics is the lack of readily available specialist mental health input, and this has been a disincentive for services to engage actively in tackling this important clinical problem. By contrast, guidelines are now including the issue of psychologic well-being, increasing the need for attention to be paid to it. It should be possible for most clinics to provide “first response” management for simple depressive disorders, although specialist help will still be required for more complex cases, where there is diagnostic uncertainty or lack of response to initial treatment. Assessment and management of suicide risk is a particularly important issue, although fortunately rare in most clinic settings.

### Screening for depression

Given the high prevalence of depression in people with diabetes, it is recommended [20] that screening and case finding is worthwhile and this is now recommended by the National Institute for Health and Clinical Excellence (NICE) in the UK [21]. NICE recommends that health care professionals who care for or advise adults with diabetes should be alert to the development or presence of clinical or subclinical depression and anxiety. This is particularly the case where someone reports or appears to be having difficulties with self-management. Health care profession-

als should ensure they have appropriate diagnostic and management skills for non-severe psychologic disorders in people from different cultural backgrounds. Knowledge of appropriate counseling techniques and appropriate drug therapy is important, as well as an awareness of the need for prompt referral to specialists of those in whom psychologic difficulties continue to interfere significantly with well-being or diabetes self-management.

In the UK, GPs are now reimbursed specifically for carrying out screening in populations with chronic illness, including diabetes. There are several short screening questionnaires that can be used for this purpose including the Patient Health Questionnaire (PHQ-9) [22], Hospital Anxiety and Depression Scale (HADS) [23] and Beck Depression Inventory (BDI) [24], although none of these have been specifically validated for use in diabetic populations, and scores may be inflated by the presence of diabetes-related symptoms. It may be better to use a very brief clinical interview using three questions [25]. Initially, the patient is asked:

- During the past month, have you been bothered by having little interest or pleasure in doing things?
- During the past month, have you been bothered by feeling down, depressed, or hopeless?

If the answer to either of these is “yes,” the patient should then be asked if they want help with this problem. If the answer to this is also “yes,” then it is reasonable to offer treatment.

### Case history 1: A woman with diabetes and depression

Joan is a 62-year-old married woman who has had type 2 diabetes for 15 years, which is treated by diet and oral hypoglycemic medication. She has a body mass index of 32 kg/m<sup>2</sup>, and at interview was noticeably low in mood. On direct questioning, she gave a history of significant depressive symptoms lasting for several months, and had a history of previous intermittent depressive episodes dating back to the birth of her first child at the age of 24. She had low self-esteem, and admitted to bouts of “comfort eating” (mainly chocolate) to try to treat her low mood. There was no disturbance of body image. In addition, she was socially isolated, and complained of receiving little support from her husband, who was usually busy at work. Management consisted of antidepressant medication, augmented with advice and support focused on increasing socialization and resumption of pleasurable and rewarding activities, such as spending more time with her grandchildren.

### Pharmacotherapy

Many treatment guidelines exist, including those from NICE [26], and similar ones from bodies such as the American Psychiatric Association. Drug treatment is the mainstay of depression management. Effective and well-tolerated antidepressant drugs are widely available and affordable. Choice of agent tends to be based on side effect profile because evidence of differential efficacy is poor. Older families of compounds such as tricyclic antidepressants and monoamine oxidase inhibitors have

decreased in popularity because of their toxicity, particularly in patients who might be at increased risk of heart disease.

Selective serotonin reuptake inhibitors are relatively safe and very widely used as first choice agents; however, caution is needed because there are important drug–drug interactions with some members of this class and oral hypoglycemic agents through inhibition of the cytochrome P450 3A4 and 2C9 isoenzymes (see Chapter 26). For example, the use of fluoxetine may lead to hypoglycemia [15]. Weight gain, which occurs with some antidepressants including mirtazepine, is particularly undesirable in overweight people with T2DM.

It is important to have a clear treatment target, and most guidelines now recommend that this should be complete remission of depressive symptoms. To achieve this, treatment must be sustained at an adequate dosage for a sufficient period of time. Once remission has been attained, treatment should be continued for at least 4–6 months to consolidate recovery. There is an increased risk of relapse and recurrence if the course of treatment is given at too low a dosage or for insufficient duration.

In addition to possible direct pharmacologic effects, it should be remembered that treating depression may lead to a change in the patient's behavior and routine that may require adjustment of the diabetic regimen. For example, if the patient's appetite improves, insulin requirements may increase; if the patient becomes more active, they may decrease. It is likely, however, that improvement in depressive symptoms alone will not translate automatically into improved self-care and diabetes outcomes. Additional attention to diabetes management is required as the depression improves.

### Clinical management

In most health care systems, depression is managed mostly within primary care by family physicians or GPs. Much emphasis has been placed in recent years on the delivery of evidence-based practice, and this has led to a proliferation of guidelines and educational support designed to improve quality of primary care. In the USA, a case management model known as “collaborative care” has been pursued, whereby family physicians are supported in case management by specialist mental health teams. This approach has been shown to be clinically useful and cost-effective [27,28]. Recently, a large study, the Pathways study [29], has attempted to address the question of whether or not this approach can improve outcomes for patients with both diabetes and depression. In this study over 300 patients were randomly allocated to receive the intensified case management approach or usual care. Contrary to expectations, although depression outcomes were improved, no concomitant improvements in glycemic control were observed over a 12-month period. This finding suggests that when treating depression in people with diabetes, attention also needs to be paid to modifications that are needed in the diabetes regimen such as adjustment of diet, activity and medication if the best possible outcomes are to be attained. Such integrated approaches to management are all too rare at the present time.

### Psychologic treatment

The other important aspect of management for depression that has been widely evaluated in diabetic populations is psychologic treatment, which can take a variety of forms. There is some confusion in the literature between approaches that could be broadly described as “educational” – that is, largely based on improving knowledge and understanding of diabetes management – and those with a more psychologic or behavioral basis, such as cognitive–behavior therapy. For most patients with suboptimal self-care, it appears that lack of knowledge of their condition is not the most important cause; rather there are more complex causes, which may have their origins in early life experiences or in current stressful events or circumstances, and it is these that psychologic treatments seek to address.

Educational approaches could be broadly divided into “didactic” and “enhanced”; in the latter form the giving of information and advice is supplemented with behavioral instruction, development of skills such as problem-solving and a range of other techniques such as biofeedback or relaxation. Thus, the boundary between educative approaches and formal psychotherapy has become blurred, and this creates difficulties in evaluating the available literature. The consensus from systematic reviews is that such interventions can improve glycemic control, albeit with a modest effect size of about 0.3 – equivalent to a reduction in HbA<sub>1c</sub> of around 0.6% (7 mmol/mol) – and can also reduce psychologic distress [30].

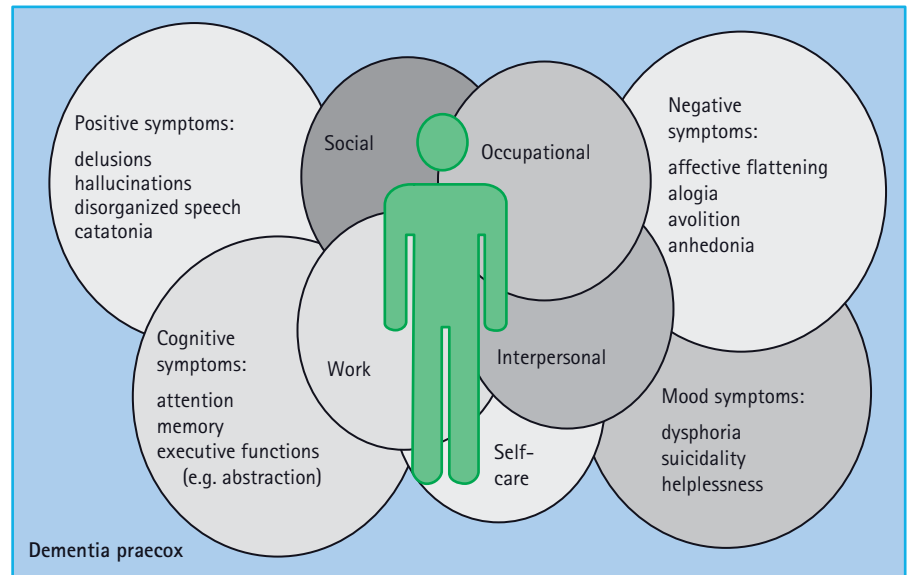

There are few trials that have set out to test directly the efficacy of psychologic treatment in treating depression in people with diabetes. Studies of otherwise healthy subjects with depression show that several forms of treatment including cognitive–behavioral therapy, interpersonal psychotherapy and cognitive–analytic therapy can all be of benefit. A recent systematic review evaluated the efficacy of psychologic interventions aimed primarily at improving glycemic control in people with T2DM [30], and found that benefits were seen in terms of reduced psychologic distress and improved long-term glycemic control.

Given that psychologic treatments are potentially very effective, but expensive and limited in availability, there is an urgent need for more evaluation of their benefits and applicability. In the UK, there is currently a large program evaluating the benefits of widening access to psychologic treatment for depression, and a similar initiative in the case of diabetes is warranted. Unfortunately, it appears as if availability of such treatments to people with diabetes is actually decreasing within the UK [31].

---

### Psychotic disorders

Psychotic disorders are the most serious forms of illness within the mental health field, and are often also known as “severe mental illness” (SMI). (Although this term is imprecise because it is perfectly possible for patients to have equally serious forms of other non-psychotic types of illness.) The two main forms of psychotic disorder in working age adults are schizophrenia and

**Figure 55.1** Impact of schizophrenia on overall functioning.

bipolar mood disorder or “manic depression.” The impact of these disorders on patients’ well-being and functioning is particularly severe because of the presence of psychotic symptoms including delusions and hallucinations which have a profound effect on any or all aspects of daily life (Figure 55.1). When they co-occur with a chronic physical illness, they can create significant management challenges, and such patients are amongst the most complex that health care systems encounter.

It has been noted for over a century that abnormalities of glucose metabolism are more common in those with this type of mental illness [32], although only in recent years have efforts been made to establish the precise nature of this association. The situation is complicated by the fact that some forms of treatment for these disorders may also affect metabolic health. It is known that patients with such disorders have reduced life expectancy, and much of the excess early mortality results from physical disease including diabetes and cardiovascular disease. Intensified efforts to improve the physical health of people with long-term mental illness are now underway in most countries, with detection and management of metabolic and cardiovascular risk factors and diabetes at their core [33].

### Case definitions

Diagnostic criteria for schizophrenia are shown in Table 55.2. It can be seen that the illness is characterized by psychotic symptoms (delusions, hallucinations), disorganization of speech and other behavior, and so-called “negative” symptoms which include loss of drive and blunting of affect. In the longer term, schizophrenia is also associated with cognitive decline. The illness has marked effects on daily functioning, tends to run a chronic clinical course and most patients with the condition will be under the long-term care of specialist mental health services.

Bipolar disorder is characterized by the occurrence of one or more episodes of mania (elevated mood), with or without a previ-

**Table 55.2** DSM-IV schizophrenia.

- 1** Two or more of the following symptoms:
  - (i) Delusions
  - (ii) Hallucinations
  - (iii) Disorganized speech
  - (iv) Grossly disorganized or catatonic behavior
  - (v) Negative symptoms (affective flattening, alogia or avolition)
- 2** Social/occupational dysfunction
- 3** Features continuously present for at least 6 months

ous history of depressive episodes. Criteria for a manic episode are shown in Table 55.3. The strict diagnostic criteria for bipolar disorders are complex, and there is a degree of overlap with schizophrenia, such that some patients may be characterized as having a “schizo-affective” disorder.

### Epidemiology

Schizophrenia is estimated to have a point prevalence of 1–7/1000 in the general population, with an annual incidence of 13–70/100 000 and a lifetime risk of 1–2%. Strikingly, this varies very little across the countries of the world. The clinical course of the illness is variable, ranging from a single brief episode (rarely) to a lifelong illness with marked deterioration over time. There are many theories about the causation of schizophrenia. It has a marked genetic risk profile, but is also associated with early cerebral insults (e.g. birth anoxia) and environmental stress.

Bipolar disorder is much less common than unipolar depression, with an estimated lifetime prevalence of 0.5–1.0%. Again, genetic factors are thought to have an important role in the etiology of bipolar disorders, which are among the most heritable of psychiatric disorders.

**Table 55.3** DSM-IV manic episode.

- 1 A distinct period of abnormally and persistently elevated, expansive or irritable mood, lasting at least 1 week
- 2 During the period of mood disturbance, three or more of the following symptoms have persisted (four if mood only irritable):
  - (i) Inflated self-esteem or grandiosity
  - (ii) Decreased need for sleep
  - (iii) More talkative than usual or pressure to keep talking
  - (iv) Flight of ideas or subjective experience that thoughts are racing
  - (v) Distractibility
  - (vi) Increase in goal-directed activity or psychomotor agitation
  - (vii) Excessive involvement in pleasurable activities that have high potential for painful consequences (e.g. spending, sexual activity)
- 3 Marked impairment in occupational functioning or in usual social activities or relationships with others, or need for hospitalization to prevent harm to self or others, or psychotic symptoms

### Mortality of people with psychotic illnesses

The fact that people with psychotic disorders have premature mortality has long been known. A landmark study in this area was that by Brown *et al.* [34], who showed that the standardized mortality ratio of psychiatric patients was increased threefold, and life expectancy reduced by 10–20 years. Although suicide and accidents were important causes of death, “natural causes” accounted for the majority of the excess mortality in this population.

A difficulty in the interpretation of this finding arises from the fact that patients with long-term mental illness are exposed to a wide range of different risk factors from those of the general population. Older studies suggested that hospitalization itself may have been a risk. Most patients are now cared for in community settings, but there are still marked differences in lifestyle, with psychiatric patients being more likely to smoke, being less active and having different diets from the general population, as well as being exposed to a range of pharmacologic agents. Disentangling risks associated with the disease, its treatment and genetic and lifestyle factors has proved to be particularly challenging [35].

As is the case for schizophrenia, there is growing evidence that patients with bipolar illness also have increased all-cause mortality, and evidence of increased cardiovascular disease, when compared with the general population. Again the findings of longitudinal studies in the face of confounders such as lifestyle differences and the effects of treatments can be difficult to interpret. It is likely that those patients with bipolar illness who are exposed to long-term use of antipsychotic drugs (the majority) will have similar outcomes to those of patients with schizophrenia. Other drugs used in bipolar patients such as lithium and sodium valproate are also associated with weight gain, but there has been much less research on their wider metabolic effects to date.

### Psychotic disorders and their treatment as a risk factor for diabetes

Papers commenting on the association between schizophrenia and diabetes date back to at least the early part of the 20th century, but the volume of literature exploded in the early years of the 21st century, largely driven by marketing claims related to different antipsychotic drugs. Of course, the early papers demonstrating the association date from the period before the availability of these agents, and provide some of the best evidence we have of an association with the disease alone [32]. This has been supplemented more recently by a small number of studies of drug-naïve patients, but such studies are now very difficult to undertake because of the ethical difficulties of leaving people untreated [36]. Another boost to publication rates occurred when the first antipsychotic agents, the phenothiazines, came into widespread clinical use in the 1950s and 1960s, with many reports of “phenothiazine diabetes” appearing. Unfortunately, interpretation of older studies is hampered by the different diagnostic practices in use for both diabetic and psychotic disorders.

#### Case history 2: The interaction of schizophrenia and diabetes

Timothy is a 30-year-old man who was admitted to a hospital with an acute psychotic illness. Following a diagnosis of schizophrenia, he was treated with an atypical antipsychotic and after this remained well both physically and mentally. He had a family history of diabetes. He disliked exercise and he tended to eat snacks and smoke 20 cigarettes per day. After 7 years, he developed diabetes. His psychiatrist was concerned that the antipsychotic may have been involved in the development of his diabetes and switched him to an alternative antipsychotic. Unfortunately, the psychosis relapsed and the patient was readmitted to hospital. His diabetes did not resolve and proved more difficult to control until the original medication was restarted and his mental state improved.

A particular difficulty in establishing whether schizophrenia and its treatment increase the risks of diabetes results from the fact that important known risk factors differ between populations, leading to a high degree of confounding in most epidemiologic studies.

The risk factors with large effect sizes include:

- Overweight and obesity;
- Family history;
- Age; and
- Ethnicity.

It is likely that the disease and its treatment have effects that are of smaller size than these, and so failure to match adequately for these confounders can easily yield results that are uninterpretable (Figure 55.2). Added to this is the fact that most studies are retrospective, and that patients tend to be exposed to a wide range of different antipsychotic drugs over the course of their illness. Prospective studies using single agents are much fewer in number,

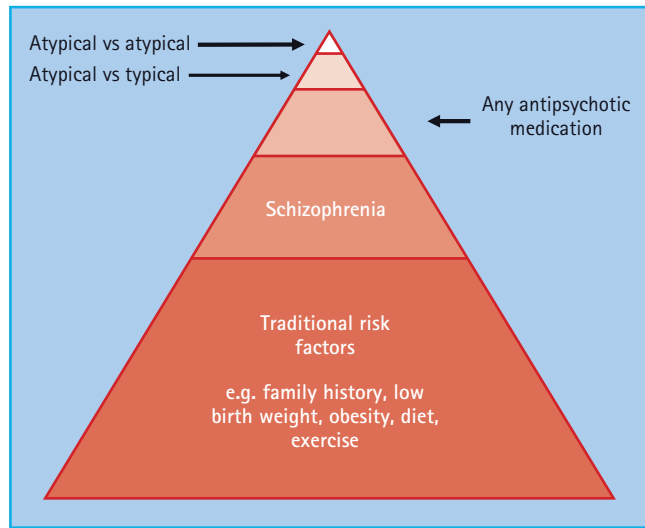

although reviews of such studies are now beginning to appear. Consequently, we are faced with many studies that give inconsistent and often contradictory results.

In order to overcome some of these difficulties, studies in drug naïve, first-episode patients have been instructive in determining the possibility of an underlying abnormality in glucose metabolism associated with schizophrenia. In two small cross-sectional studies of first-episode drug naïve individuals in Ireland, 10–15% of participants had impaired fasting glycemia and were more

insulin resistant than healthy control subjects [36,37]. First-episode patients were also found to have significantly higher waist:hip ratios, and over three times as much visceral fat (a predictor of insulin resistance) when assessed by computed tomography scanning [38]. A study from India found that non-fasting blood glucose concentrations were higher in those with first-episode psychosis than healthy controls [39], while other studies have found differences in body composition between first-episode patients and healthy control subjects but without glucose changes [40]. These findings have not been replicated in all studies [41–43].

The consensus that emerges from the current literature is that having schizophrenia is associated with a two- to fourfold increase in risk of developing diabetes, which leads to an overall prevalence of diabetes of 10–15% in Western populations. Most patients have T2DM and there is some evidence that the rates of T1DM are in fact reduced in people with schizophrenia. Studies conducted in clinical populations suffer from the limitation of screening bias, in that T2DM is often asymptomatic for many years, and ascertainment rates are highly sensitive to such bias. Although subjected to much less systematic study to date, there is a suggestion in the literature that patients with bipolar disorder are also at increased risk of developing diabetes, with a relative risk estimated at two- to threefold. Similar caveats about the effects of treatments and lifestyle differences to those for schizophrenia apply.

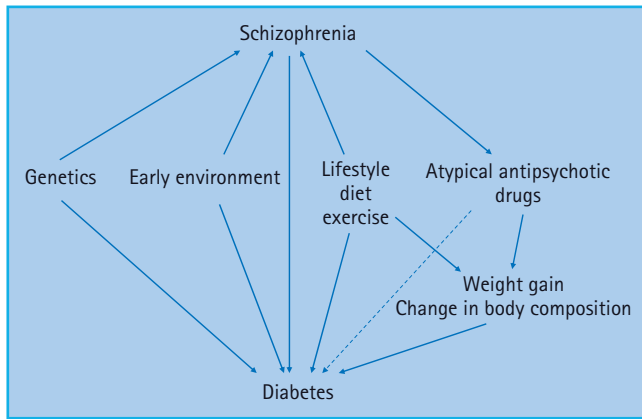

By comparing the rates of diabetes at different age groups (Figure 55.3), it is also possible to see that the onset of diabetes appears to occur around 10–20 years earlier in people with SMI than the general population. There are significant numbers of people with diabetes under the age of 40 years and therefore this issue should not be ignored even in those with a recent diagnosis of mental illness.

**Figure 55.2** The relative contributions of traditional diabetic risk factors, schizophrenia and antipsychotic medication to the development of diabetes in people with serious mental illness. Adapted from Holt RI, Peveler RC. Association between antipsychotic drugs and diabetes. *Diabetes Obes Metab* 2006; **8**:125–135.

**Figure 55.3** Age-specific prevalence rates of diabetes in people with schizophrenia compared with the general US population. Data from Sernyak MJ, Leslie DL, Alarcon RD, Losonczy MF, Rosenheck R. Association of diabetes mellitus with the use of atypical neuroleptics in the treatment of schizophrenia. *Am J Psychiatry* 2002; **159**:561–566 and National Health and Nutritional Examination Survey 2001–2002.

**Figure 55.4** The possible mechanisms linking schizophrenia to diabetes. Reproduced from Holt RI, Peveler RC, Byrne CD. Schizophrenia, the metabolic syndrome and diabetes. *Diabet Med* 2004; **21**:515–523.

**Mechanisms of the association**

There are many difficulties in disentangling the possible mechanisms underlying the apparent associations between psychotic illness and diabetes. Diabetes, schizophrenia and bipolar illness all appear to be strongly heritable, and genetic associations appear to be likely (Figure 55.4). It has been reported that up to 50%, although more commonly 15–30%, of individuals with schizophrenia have a family history of T2DM, compared to 5% of healthy adult controls [12]. Shared susceptibility loci are now being investigated using linkage and candidate gene approaches [13].

Other factors that may underlie the association include a poorer diet, with lower intake of fruit and vegetables and much higher intake of fat, lower levels of physical activity, urbanization and higher rates of smoking among patients [44]. These findings have been documented consistently in several studies; however, it is difficult to assess the size of the effect that they may contribute to the observed association.

Another suggested mechanism involves activation of the HPA axis by stress associated with mental illness, leading to chronic hypercortisolemia and hence an increased risk of diabetes.

The role of antipsychotic medication in contributing to the association remains under debate. There is reasonably strong evidence that most antipsychotic drugs are associated with an increase in risk of developing diabetes, but proof of causation has not been firmly established. Making distinctions between different classes of drug is challenging, and distinguishing between individual agents is extremely difficult. The current consensus is that newer agents (the so-called atypical or second-generation drugs) may have increased propensity to cause diabetes compared to older drugs, although the differences are modest, amounting to perhaps a 10–30% increase in risk (Figure 55.5) [45]. Of the newer agents, clozapine is probably associated with the highest risk but this is not found universally (Figure 55.6). Most antipsychotic drugs induce weight gain, and observational studies suggest that there is a general trend for the drugs with the

**Figure 55.5** Forest plot of relative risks and 95% confidence intervals for diabetes in patients with schizophrenia receiving first-generation antipsychotics compared with second-generation antipsychotics. Adapted from Smith M, Hopkins D, Peveler RC, Holt RI, Woodward M, Ismail K. First- v. second-generation antipsychotics and risk for diabetes in schizophrenia: systematic review and meta-analysis. *Br J Psychiatry* 2008; **192**:406–411.

highest potential for weight gain to also have the highest risk for diabetes, although this is not true in every case. This is in contrast to randomized trials that show no difference in diabetes rates between drugs despite often marked differences in weight gain. Both observational and randomized studies have their pitfalls, which mean that the true risk is difficult to determine [35].

**Metabolic syndrome**

In recent years investigations in this field have broadened their scope to include assessment of intermediate hyperglycemia and the metabolic syndrome. It appears at this early stage that almost all of the wider range of cardiovascular risk factors, with the possible exception of hypertension, that make up this syndrome are elevated in patients with psychotic disorders, increasing yet further the emphasis on the importance of cardiovascular health promotion in these populations [46].

**Management**

From the foregoing review it can be seen that the metabolic health of people with psychotic disorders is a wide-ranging public health issue. Historically, it appears that such patients have experienced considerable disadvantage at a time when health promotion as an approach to cardiovascular risk factors in the general population has been developing rapidly. Consideration needs to be given to lifestyle advice, early detection of risk factors, screening for clinical disease and treatment for established disease.

**Lifestyle advice and health promotion**

National guidelines [33] now stress the importance of physical health promotion for people with long-term mental illness, rec-

**Figure 55.6** Number of cases of diabetes estimated to occur beyond those expected with first-generation antipsychotics per 1000 patients treated with a second-generation antipsychotic, 95% confidence intervals and study sponsorship. Pharmaceutical company sponsorship indicated by figure above or below the upper limit bar in each graph. Independent studies are represented by the scales of justice. Numbers represent additional numbers of cases of diabetes per 1000 treated.

ognizing the health disadvantage that they have experienced in the past. There is still debate about how this is best achieved, with responsibility in many health care systems being split between specialist services and primary care. Primary care is probably the best source of health promotion in most cases, and in many countries this role attracts remuneration, but many patients with long-term mental health problems see their GPs less frequently and depend on the mental health team for most of their health needs. Unfortunately, many such teams have not considered physical health promotion to be part of their remit in the past.

However, there are now signs that this is changing, at least in some countries, and many services are integrating such health promotion into their routine care pathways. Appropriately tailored advice is needed on diet, exercise, weight management, smoking and drug use, supplemented by environmental initiatives such as provision of alternatives to sweetened beverages and “institutional” food in hospital settings, and support for increased activity and body weight monitoring. Contrary to expectation, people with SMI, irrespective of diagnosis or treatment, may well be able to modify their lifestyles with appropriate education and support, and this may result in significant weight loss. Several models to deliver lifestyle education have been proposed but

group sessions appear to be both clinically useful and cost-effective. The most important issue is to engage people with mental illness as engagement with the program was the only predictor of long-term weight loss in the longest running program in the UK [47]. A Cochrane review of lifestyle interventions showed modest weight reduction for those currently treated with antipsychotics and a reduction in antipsychotic-induced weight gain in those about to start treatment [48].

### Prevention of diabetes

The principles of lifestyle modification have been well established as a means of preventing or at least delaying the onset of diabetes. The lifestyle programs described in the preceding section should provide an effective framework to reduce the incidence of diabetes. These programs are not suitable for all and pharmacologic treatments should be considered for those unable to adapt their lifestyles.

The Diabetes Prevention Program (DPP) has established that the use of metformin is associated with a 31% reduction in the incidence of diabetes. Metformin has been shown to lead to modest reductions in weight in several small studies of people receiving antipsychotics. In one study, metformin treatment

**Table 55.4** Drugs that have been tested as potential agents to prevent or reduce weight gain.

Amantadine	Fluoxetine
Nizatidine	Reboxetine
Topiramate	Sibutramine
Metformin	Exenatide
Betahistine	Orlistat

prevented the deterioration in insulin resistance as assessed by homeostasis model assessment in patients treated with antipsychotics [49].

Several other drugs have been tried to prevent or reduce antipsychotic-induced weight gain (Table 55.4). A Cochrane review found that none of the treatments was particularly effective [48] and so none can be recommended without reservation; however, given the long experience with metformin and an understanding of its safety and tolerability, together with its modest cost and proven benefit in reducing incident diabetes, this seems a logical choice for those unable to modify their diet. Further long-term trials are needed, however, to prove that metformin is an effective agent in preventing diabetes in this patient group.

### Screening

We now know enough about the scale of risk involved to suggest that patients with psychotic disorders should undergo routine screening for the presence of diabetes. This should be carried out at least annually and possibly more frequently if other risk factors are present. There is debate about the best method of screening – a fasting blood glucose estimation is clearly the ideal, but not easy to obtain in all cases. A random glucose alone, or in combination with an HbA<sub>1c</sub> test, may be an acceptable substitute, and while its sensitivity and specificity may be lower, it is still preferable to no test at all.

### Patients with established diabetes

There are considerable challenges in managing the patient with both a psychotic disorder and established diabetes. The key to success lies in close liaison between the diabetes and mental health services involved with the patient. Management of the mental illness will follow established guidelines, and deploy drug and psychological treatment, family work, hospital admission and community support as appropriate. It is important to note that most health professionals working in mental health teams are not medically qualified, and will probably have little familiarity with the principles of management of diabetes.

The goals of treating the diabetes should be no different from those in otherwise healthy patients, although achieving these is likely to be much more difficult. Communication with patients with psychotic disorders can be challenging for those with little

experience of such work, and patients may find it difficult to report symptoms or extent of self-care to health professionals as clearly as non-psychotic patients might. Extra time and additional training may be needed for health professionals in diabetes teams who are to work with such patients.

### Pharmacotherapy

Given what we know about the relative risks of metabolic problems associated with antipsychotic drugs, this aspect of safety must be considered when treatments are being chosen. Unfortunately, there is marked individual variation in clinical response to different antipsychotic agents, and for some patients it will be necessary to continue to use an agent for the sake of obtaining the best result in terms of the patient's mental state, even though metabolic risks may be higher than would be ideal. It is never advisable to discontinue an antipsychotic drug on the grounds that it may be contributing to a metabolic problem without careful consideration of the choices available for treating the psychotic disorder and without discussion with the psychiatric team.

## Eating disorders

### Case definitions

Three main forms of eating disorder are currently recognized: anorexia nervosa, bulimia nervosa and a residual category of eating disorder not otherwise specified (EDNOS) [3]. The first two conditions have been the subject of much research for many decades; however, the latter category is much less well studied, but is important from a public health perspective as it tends to be more prevalent, and in many cases equally disabling, as the better known forms. As with depressive symptoms, eating disorders exist on a continuum of severity, and there is a lack of good evidence on which to establish a formal boundary or cut-off for “clinical” significance. When an eating disorder co-occurs with a chronic disease such as diabetes, its significance may be increased by the potential for harm resulting from impaired self-care and glycemic control – thus, eating disorders that may be seen as “mild” in an otherwise healthy individual take on increased clinical importance. Because eating disorders are most common in adolescents and young adults, there has been much more research on the co-occurrence of eating disorders and T1DM; far less is known about such problems in the larger population with T2DM [50].

Diagnostic criteria for the common forms of eating disorder are given in Table 55.5 [3].

### Clinical features

#### Anorexia nervosa

The hallmark of anorexia nervosa is weight loss, usually achieved by a combination of extreme dieting, exercise and, less commonly, self-induced vomiting. Misuse of laxatives and other weight-reducing substances (e.g. diuretics, thyroxine) also occurs.

**Table 55.5** DSM-IV diagnostic criteria for anorexia nervosa, bulimia nervosa and eating disorder not otherwise specified (EDNOS).**Anorexia nervosa**

- A refusal to maintain body weight at or above a minimally normal weight for age and height (e.g. weight loss leading to a maintenance of body weight less than 85% of that expected, or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
- Intense fear of gaining weight or becoming fat, even though underweight
- Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- In postmenarchal females, amenorrhea (i.e. the absence of at least three consecutive cycles)

**Bulimia nervosa**

- Recurrent episodes of binge eating. An episode of binge eating is characterized by:
  - (i) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances; and
  - (ii) a sense of lack of control over eating during the episode
- Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as: self-induced vomiting; misuse of laxatives, diuretics, enemas or other medications; fasting or excessive exercise
- The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months
- Self-evaluation is unduly influenced by body shape and weight
- The disturbance does not occur exclusively during episodes of anorexia nervosa

**Eating disorder not otherwise specified**

- All the criteria for anorexia nervosa are met except that the individual's current weight is in the normal range or, for females, regular menstruation continues
- All of the criteria for bulimia nervosa are met, except that the binge eating and inappropriate compensatory mechanisms occur at a lower frequency than that required for a full diagnosis
- Use of inappropriate compensatory behaviors by an individual of normal body weight after eating small amounts of food
- Repeatedly chewing and spitting out, but not swallowing, large amounts of food
- Binge eating disorder

Patients have a characteristic set of attitudes and values concerning body shape and weight. They complain of intense feelings of fatness, and extreme fear of loss of control over eating and consequent weight gain. They express a level of dissatisfaction with their shape and weight that is far beyond that seen in the normal population, and tend to judge their self-worth almost solely in terms of weight, shape and ability to control food intake. This is described as the “core psychopathology” of the condition. In some cases there is true body shape misperception, when a thin body shape is actually experienced as fat, although this is not a universal feature.

Anorexia nervosa usually begins in adolescence, although prepubertal and adult onset may occur. For some the natural body changes of adolescence appear to be a risk factor; it has also been reported that weight gain and then loss associated with a diagnosis of T1DM and then commencement of insulin treatment may act as a trigger.

The low weight of patients with anorexia gives rise to the physiologic and psychologic features of starvation, including ritualized eating habits, cognitive rumination about eating, irritability, poor concentration, constant feelings of cold and misery, and decreased activity. Social withdrawal and isolation is common, and anxiety, obsessional features and suicidal thoughts sometimes occur. Foods viewed as fattening are typically avoided and the diet contains an average daily intake of calories in the region of 600–900 kcal/day, with very low fat and mineral intake. In spite of this most patients continue to feel hungry, and as such the term “anorexia” is a misnomer.

Common physical symptoms include gastrointestinal complaints (constipation, fullness after eating, bloating and abdominal pain), lack of energy, reduced libido, early waking and postural dizziness. In postmenarchal females not receiving oral contraceptives, amenorrhoea is often present, with infertility and osteopenia a significant risk. Those with prepubertal onset are often small in stature and show failure of breast development. Bradycardia, hypotension and peripheral neuropathy are also reported, and a range of endocrine abnormalities may be found on investigation, including low sex hormone and tri-iodothyronine levels (with normal thyroxine and thyroid-stimulating hormone), and raised growth hormone and cortisol.

**Bulimia nervosa**

Bulimia nervosa is characterized by recurrent episodes of binge eating in which large amounts of food are consumed (typically 2000 kcal or more), and the individual has a feeling of being unable to control the eating. This behavior is accompanied by a range of “compensatory” behaviors designed to prevent weight gain, including dietary restriction, vomiting, exercise and misuse of laxatives or diuretics. People with bulimia seem to have broadly the same set of attitudes and beliefs to those seen in anorexia. Although most patients fall within the normal weight range, some will have a past history of underweight and may have met the diagnostic criteria for anorexia in the past, and some are overweight. The vicious cycle of dieting, bingeing, purging and fear of weight gain invariably has a detrimental impact on other aspects of functioning, such as work and social relationships, and can have financial implications resulting from the cost of the food. For some, binge eating seems to serve an important function as a means of regulating unpleasant emotional states. Some individuals also have other impulse control problems and a history of interpersonal difficulties. Depression and self-harming behaviors such as cutting, overdosing or substance misuse may occur.

Physical complications of bulimia include enlargement of the parotid glands, erosion of dental enamel and hypokalemia resulting from vomiting, laxative or diuretic misuse.

### Eating disorder not otherwise specified

There is still debate about the best set of criteria to use to define this “residual” category of eating disorder. Patients may either have “partial syndromes” (they may have some but not all the features of anorexia or bulimia) or they may be “subthreshold cases” (they have a full set of clinical features, which fall below the severity threshold currently in use).

The best characterized group of patients are those with recurrent binge eating but no compensatory behavior – usually described as “binge eating disorder.” Patients with this syndrome describe:

- Eating rapidly;
- Eating until uncomfortably full;
- Eating when not hungry; and
- Feeling disgusted or guilty after overeating.

Binge eating disorder is associated with obesity, and it appears to affect 5–10% of obese patients in weight loss treatment programs. Physical complications may occur as for anorexia or bulimia, depending on the precise symptom pattern of the presentation and its severity.

### Impact on diabetes outcome

In addition to the clinical picture described above, patients who have both an eating disorder and diabetes manifest additional features. Early case reports in the 1970s and 1980s highlighted the fact that people with T1DM have available to them an additional means of weight control in the form of the under-use or omission of insulin. Such “self-induced glycosuria” is common but not universal in patients with eating disorders, and is now known not to be confined to patients with a frank eating disorder, being more widely observed as an occasional phenomenon in a range of weight conscious patients, mostly females. As a means of weight control, the behavior produces rapid but often not sustained weight loss, the main effect being via acute dehydration. Not surprisingly, this behavior is associated with impaired glycemic control, and probably a higher risk of microvascular and macrovascular complications if it persists. Such patients are particularly likely to be admitted to hospital with ketoacidosis [51].

### Epidemiology

Estimates of prevalence for eating disorders in the general population remain imprecise because of a lack of systematic study. It is thought that about 1 in 250 females and 1 in 1000 males will experience anorexia, usually during adolescence or early adult life. Bulimia is thought to be much more common: in community studies 0.5–1% of young women have been found to be affected. EDNOS appears to be much more common than anorexia or bulimia, and is the most common presentation seen in routine clinical practice.

### Diabetes as a risk factor for the development of an eating disorder

The causes of eating disorders are incompletely understood. Dieting appears to be an important risk factor, although only a

small proportion of all those who diet go on to develop a disorder. Other known risk factors include a history of obesity, and pre-morbid traits including perfectionism and low self-esteem. Family relationships are often disturbed, although this may be either a cause or consequence of the disorder, or both. Genetic risks have also been identified.

### Case history 3: Eating disorders and diabetes

Helen is a 20-year-old student with a 3-year history of disturbed eating habits and attitudes. She developed type 1 diabetes at the age of 11. She displayed extreme concerns about her shape and weight, despite have a body mass index well within the normal range. She had experienced weight gain during puberty, which she had found distressing, and had managed by reducing her insulin dosage, diet and exercise. She had continued to reduce or omit her insulin dosage intermittently since, and in the last 3 years had begun to vomit food occasionally, and to have episodes of binge eating. Details of these clinical features remained hidden from the diabetes team until a specialist nurse noticed that she seemed upset at a clinic visit, and arranged a follow-up home visit for a lengthy discussion about her diabetes management. It was subsequently noticed at the next clinic visit that Helen had developed mild retinopathy and proteinuria. Referral to the eating disorder services was made, and a course of cognitive-behavior therapy was offered in an outpatient setting.

There has been a strong clinical impression for many years that eating disorders are over-represented in people with diabetes, and several studies have been conducted to address this. Although both diabetes and eating disorders are common conditions, and so a degree of co-occurrence by chance is expected, there are some theoretical grounds to expect eating disorders to occur more commonly in people with diabetes. The following have been suggested as risk factors:

- The stress of living with a chronic disease;
- The availability of a means of rapid weight control via insulin misuse;
- Prescription of a rigid dietary regimen; and
- The experience of marked weight fluctuation around the time of diagnosis of diabetes.

Insulin treatment itself can lead to weight gain and adjustment of insulin dose through the pubertal period in females is notoriously difficult. In contrast, there may also be protective factors that operate; most notable of these is close medical and family surveillance during the period of highest risk of behaviors such as vomiting and bingeing.

Early studies appeared to support the contention that prevalence was raised in people with diabetes, but these studies had many methodologic shortcomings including use of non-validated assessment measures, recruitment of highly selected populations from specialist diabetes clinics (mainly in the USA) and the absence of well-matched control groups. More recent studies and

analyses using better methods of assessing the full range of diagnoses, including EDNOS, have indicated that there may be a slightly raised prevalence in diabetic populations, although the increase in risk appears to be modest if assessed by cross-sectional prevalence comparisons (around a threefold increase for bulimia and a doubling for EDNOS) [50].

Longitudinal studies have now shown that for most patients eating disorder diagnoses are unstable over time, and cross-sectional studies underestimate the proportion of the population that may be affected in the long run. Incidence rates in adolescent and young adult patients are higher than previously estimated, and it is clear that such disorders, especially if persistent, are a major cause of poor outcome in people with diabetes [51]. Rates of serious microvascular and macrovascular complications and mortality are significantly increased in these cohorts, even in those patients whose eating disorder features are relatively short-lived. It appears that adolescence and young adulthood is a particularly vulnerable time for people with T1DM, and even short periods of poor control can have serious consequences in middle and later adult life.

## Management

### Detection

Although some people with diabetes may volunteer information about eating problems, many will be secretive as a result of factors including denial, guilt or shame. Thus, an essential first step in management is successful detection of the problem. It is important to note that, although eating disorders are generally associated with poor self-care and erratic glycemic control, alternating periods of hypoglycemia and hyperglycemia may be undetected by a screening test such as HbA<sub>1c</sub>. Warning symptoms include the following:

- Marked weight fluctuation or loss;
- Symptoms of hyperglycemia (thirst or tiredness);
- Frequent episodes of ketoacidosis (often requiring hospital admission) or hypoglycemia leading to loss of consciousness;
- Growth retardation and pubertal delay may be seen in younger patients with T1DM.

Unfortunately, most of these features are not specific for eating disorders and are only indicative of poor self-care. The only way to establish a diagnosis of an eating disorder is by means of a clinical interview, although brief self-report scales do exist and may be a useful means of screening. Unfortunately, none have been validated specifically for use with people with diabetes, and many contain items (e.g. “I always avoid foods with sugar in them”) that may be contaminated by the presence of diabetes. Sensitive but direct questions related to eating habits and attitudes, concerns about body weight and methods of weight control should be asked.

### Principles of treatment

There is a lack of primary research to guide the treatment of patients with an eating disorder and diabetes, and advice is therefore based on existing guidelines for patients without diabetes

### Questions to ask to establish possible eating disorder features

- What is your current weight?
- What would be your ideal weight?
- Are you happy with the shape of your body?
- If not, why not?
- Would you prefer to be a different weight or shape?
- If so, what would you wish to change?
- Do you do anything to control your weight or body shape?
- If so, what do you do?

If appropriate:

- Do you diet?
- Are there any foods that you particularly avoid?
- Do you ever feel that your eating is out of control?
- Have you ever vomited food to avoid weight gain?

such as the one by NICE [52]. Dietary counseling by a dietitian or specialist nurse may be a helpful first step, especially for those with milder disorders, but most cases will require specialist help. Guided self-help appears to be a viable option as a first step for patients with bulimia. In all cases, close liaison between the therapist managing the eating disorder and the team managing the diabetes will be required. Eating disorder treatment needs to be enhanced with attention to the following:

- Insulin or medication use;
- Glycemic control;
- Diabetes-related dietary restrictions;
- Relationships with family and medical staff; and
- Feelings about having diabetes.

Although most patients can be managed on an outpatient basis, the risk of impaired physical health necessitating inpatient admission is increased in people with diabetes. Regular physical monitoring is needed to manage the high risk of complications and mortality [53].

### *Anorexia nervosa*

The evidence base for the treatment of anorexia remains surprisingly weak. A necessary first step for all patients is restoration of weight towards normal levels. During this process it is usually necessary to accept that glycemic control may not be perfect, but severe hypoglycemia or hyperglycemia must be avoided. The patient will need to monitor insulin dose and blood glucose levels as eating habits and weight change. It is essential that the eating disorder therapist has a good knowledge of the principles of treatment for diabetes.

### *Bulimia nervosa*

Treatment for bulimia, particularly by means of cognitive-behavioral therapy (CBT) has been widely researched, although

the suitability of CBT for people with diabetes has been subjected to much less study. The coexistence of diabetes with bulimia inevitably complicates management. Successfully engaging patients in treatment may itself be more difficult, and approaches such as motivational interviewing may have a role in future [54]. Modification to the standard treatment approach includes the monitoring of self-care behaviors, and it is desirable that the eating disorder therapist has knowledge and experience of the standard management of diabetes. Conflict may arise between the modifications to eating behavior usually advocated for the treatment of bulimia (promoting a more flexible approach to eating) and the dietary advice often given for management of diabetes (regular controlled eating and avoidance of certain food groups). The development of the approach known as DAFNE (diabetes adjusted for normal eating) may offer a solution to this dilemma [55].

Other forms of treatment for bulimia include interpersonal psychotherapy, and the use of antidepressant drugs. Although clinical trials are lacking, there is a clinical impression that medication may be a useful adjunct to psychologic treatment for some patients. A group educational program for patients with bulimia and T1DM was shown to be better than “standard care” in improving eating behavior, but did not lead to improvements in glycemic control [56]. Inpatient treatment has also been evaluated for this group, and appeared to be successful, although the applicability of this approach in most health care systems remains to be tested.

#### ***Eating disorder not otherwise specified***

Little is known about the optimum management of patients with these more prevalent but less severe forms of eating disturbance. Similar approaches to those used for anorexia and bulimia are usually tried.

#### ***Treatment of children and adolescents***

Cross-sectional studies investigating the association between family environment, eating problems and diabetes outcomes suggest that family factors have a particularly important role in younger patients. Family-based interventions addressing issues such as limit setting, communication skills and development of self-esteem may be particularly appropriate and helpful for this group. Family interventions in young people without diabetes are known to be more effective in treating eating disorders than individual therapy.

---

## **Other disorders**

Several other forms of psychiatric or psychological disorder may be important in the management of people with diabetes (see Chapter 49). Needle phobia fortunately appears to be rare among insulin-treated patients, although if it does occur (usually early in treatment) it can create considerable difficulties. It

appears to be usually relatively easy to treat using behavioral principles.

Sexual dysfunction is common, and differential diagnosis between organic and psychologic factors can sometimes be difficult, but psychologic factors are usually important and again relatively easy to address using psychologic treatment.

Substance misuse and dependence, and personality disorder, can prove resistant to treatment and create considerable management challenges. Historically, the term “brittle diabetes” has been used to describe patients with unexplained poor metabolic control. It is now recognized that psychologic and behavioral factors are usually the most important causes of this.

---

## **Conclusions**

This chapter has highlighted the many and various ways in which diabetes and psychiatric disorders can interact. It is clear that such disorders can have a major impact on diabetes outcomes, and health professionals who work with patients with diabetes require good knowledge and awareness of these issues to be able to provide optimal care. There is clearly also a great need for closer working between diabetes services and mental health services. Further research on these topics is clearly required.

# 11 Delivery and Organization of Diabetes Care

# 56

## The Role of Community and Specialist Services

**Jane Overland, Margaret McGill & Dennis K. Yue**

Diabetes Center, Royal Prince Alfred Hospital, Camperdown, NSW, Australia

### Keypoints

- The majority of people with diabetes without complications or co-morbidities can be well managed within the community; however, people with more complicated disease warrant referral to specialists.
- How to design a system to allow most patients to remain in the community, but be referred for specialist treatment at an optimum time, is one of the most important questions in organizing diabetes care. Moreover, to rationalize diabetes care, there are many areas that will need decision-making regarding who is to do what, and at which level. There is no single correct answer as the local situation will influence the decision.
- On a worldwide basis, community care of diabetes by primary care providers is likely to provide the backbone of diabetes treatment. How to improve and support care at this level, and to what extent, is an important strategic question. If it is improved to a specialist level then its cost advantages would be minimized.
- In many areas of the world, specialist care is provided by a hospital, often characterized by a large inpatient unit supported by outpatient clinics. Provision of continuity of care for a chronic disease such as diabetes within hospitals and clinics is a task warranting a great deal of attention.
- Diabetes educators or specialist nurses can complement and enhance what doctors provide. Non-medical staff can be trained to make clinical decisions about the management of diabetes, including the management of glycemic control, hypertension and dyslipidemia, provide self-management education and coordinate team services to meet the patient's health needs, thereby taking the load from the medical staff to allow them to concentrate on more complex cases.
- In some areas of the world, diabetes education centers have been developed to support large diabetes clinics. Staff within these centers have core clinical knowledge of diabetes, as well as understanding teaching and learning principles and behavioral and psychologic strategies to help patients manage their diabetes.
- Some diabetes centers provide integrated specialist diabetes care. Clinical activities undertaken by these centers often include initiation of insulin therapy and stabilization of diabetes without need for hospitalization, screening and management of diabetes complications, management of diabetic foot disease, diabetes in pregnancy, neuropathic pain and insulin pump therapy. This "Rolls Royce" model is expensive and cannot care for every person with diabetes. It must concentrate its role in complementing, not duplicating, what the community doctors can provide. It also has a role in educating community doctors and health care professionals while demonstrating what needs to be done and can be achieved.
- Timely communication is crucial in promoting a seamless interface between community and specialist levels of care. This is most important in improving the skills of primary care health providers, and it involves more than just providing factual information on the level of HbA<sub>1c</sub> and insulin dosage.

### Introduction

The World Health Organization's Declaration of Alma Ata, adopted in 1978, expressed the need to protect and promote the health of all peoples of the world. The Declaration highlighted the inequity between developed and low and middle income countries. Despite the number of decades that has passed since this Declaration, providing appropriate care for all people with

diabetes remains problematic. Conclusive evidence now exists that the devastating complications of diabetes can be minimized by timely and effective treatment; however, even in developed countries, with universally funded health services, large proportions of people with diabetes are not routinely monitored either for diabetes or its complications [1]. This is especially so for people living in rural areas [2–5], or for those who are socially disadvantaged [6]. This means that the opportunity to commence early treatment is missed. Today it is estimated that only 5% of people living with diabetes around the world receive optimal care [7]. While clinicians endeavor to provide the best possible treatment, there are often serious limitations stemming from resource availability and/or inadequate models of care.

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

Globally, the spectrum of diabetes services varies from a single health care provider working in an isolated community setting, to small groups of primary care doctors and nurses working in health centers or district hospitals, through to highly sophisticated tertiary units in major urban areas with access to a range of specialists, nurses and other diabetes team members. In this chapter we explore how diabetes care may be best delivered at these various levels, taking into consideration political, cultural and economic environments. Not every case of diabetes can be looked after at the community level. Likewise, not every case of diabetes can be managed at the specialist level. How to support and to balance these two extremes is one of the most important questions in organizing diabetes care.

---

## Primary care for diabetes

Primary care in the community forms an integral part of health care in most countries and is the first level of contact for most people with diabetes. The sheer number of people with diabetes would dictate this to be a necessity. How we improve diabetes care at this level is therefore a matter of great importance. What is considered primary care may vary a great deal between countries, or within regions of the same country. Likewise, improving primary care for diabetes may take on different meanings in different settings.

On a world basis, primary care is usually provided by a doctor, acting alone and almost invariably also treating many other diseases. In many ways, diabetes is just a condition that the patient “happens to have,” and its management can be surreptitiously relegated to a lesser role than the problem of the day. Various attempts have been made to overcome these issues, and it is beyond the scope of this chapter to outline them all, but some examples are mentioned here.

In many countries, primary care is delivered through a system of health centers or clinics which are scattered throughout urban and rural areas. Appropriately supported, these centers can provide routine diabetes management to most people with diabetes within a local area, but require the ability to refer more complicated cases, such as patients with newly diagnosed type 1 diabetes mellitus (T1DM) or those with an active foot problem.

The success of this approach was exemplified by a randomized cluster trial conducted in the Torres Strait, which is located between Australia and Papua New Guinea, and inhabited by indigenous Australians scattered over a wide area in small communities [8]. The study aimed to implement a sustainable system of care by providing basic training in clinical diabetes care to local indigenous health workers employed in randomly selected health centers. The study team also assisted local staff within these centers to establish diabetes registers and recall systems, and to develop diabetes care plans. Diabetes specialist outreach services were established concurrently for all health centers within the Torres Strait, and were designed to facilitate referral and provide care for individuals with more complicated disease. It also pro-

vided a secondary benefit for local staff to learn up-to-date diabetes management principles through working alongside the diabetes specialist during visits to the health centers. It was found that diabetes care processes improved in all health centers and the intervention sites showed greatest progress, with significant improvements in weight, blood pressure and glycemic control measures. Moreover, people with diabetes managed by the intervention clinics were 40% less likely to be admitted to hospital for a diabetes-related condition. Over time, local service providers have assumed increasing responsibility for routine diabetes care, thus ensuring sustainability of the service.

The ability of organizational change to improve diabetes care processes and clinical outcomes at the primary care level has been further emphasized by the recently reported TRANSLATE trial [9]. The multicomponent organization intervention adopted within this trial, which included implementation of an electronic diabetes registry, visit reminders and patient-specific physician alerts, resulted in a significant increase in the proportion of patients achieving recommended clinical outcomes.

Tanzania provides a further example of implementing a well-organized system of care at the community level. Prior to 2004, for a general population of 39 million, specialized diabetes care was available in just five referral hospitals nationally, and was provided by a handful of consultant physicians and diabetes educators. Access to diagnosis and treatment, particularly in rural areas, was extremely limited. With support of the Ministry of Health and the Tanzanian Diabetes Association, teams of health care workers from all regional hospitals, comprising a doctor, two nurses and a laboratory technician, were offered comprehensive diabetes training programs. After training, each team was given a starter kit containing diagnostic and educational tools in order to help establish services. By 2006, 29 diabetes clinics had been established, providing accessible and affordable treatment and education services to more than 100 000 people [5]. This model of care is consistent with the World Health Organization's aim of sustainable interventions by helping countries develop their own infrastructure and professional expertise in health care. It will enable Tanzania to continue to progress independently towards providing sustainable and accessible diabetes care in the long term, and can serve as a model for other low and middle income countries.

Since 1993, general practitioners (GPs) in the UK have been encouraged to develop services for diabetes, with a specific payment for doctors offering structured diabetes care. As a result, the proportion of people with diabetes reviewed annually in primary care has increased. Interestingly, Norway also report improvements in processes of diabetes care over a similar time period, without additional incentives for GPs to follow national guidelines. In the case of Norway, the improvement was attributed to ongoing medical education [10]. In Germany, a diabetes management program was introduced in 2003, the core content of which was defined by a national expert panel. Program initiatives included the use evidence-based guidelines and the development of a basic data set, establishment of quality indicators, as well as recall of patients. Fulfilment of program recommenda-

tions is compulsory for contracts between health insurers and service providers. By mid-2007, approximately 50% of the estimated population with diabetes, and approximately 65% of family practices, had enrolled in the program. A recently reported survey showed that patients being managed under the program perceived improved care [11].

In Australia, the government funds a chronic disease management program in general practice. Under this program it has been made easier financially for GPs to employ a practice nurse to help with various tasks of managing patients, including but not exclusive to diabetes. Many doctors use these practice nurses to complete the annual cycle of diabetes care, which includes periodic examination of the feet, and ensuring other diabetes complications and metabolic variables are regularly assessed. In recognition of the fact that GPs often encounter difficulties in securing the services of allied health professionals for their patients, the Australian government has also begun a subsidy, through the universal health insurance system, for five allied health visits a year, and made such referrals the prerogative of GPs only. These initiatives are obviously in the right direction from the individual doctor's and patient's point of view. Conceptually, they are elevating primary care for a particular disease to a level close to specialist care. Whether this is true primary care or just specialist care in another guise is debatable. The irony for the health care planner is that if primary care for diabetes becomes progressively better, it may become progressively more like specialist care and thus lose its cost-benefit advantage. Whether this move would translate into better clinical endpoints and provide overall cost-benefits for the treatment of diabetes for the entire community needs to be evaluated.

---

## **Traditional specialist care**

### **Hospital clinic**

In many areas around the world most diabetes care is provided by a hospital, often characterized by a large inpatient unit supported by outpatient clinics. While some hospitals have diabetes-specific outpatient services, many people with diabetes are seen within the context of a large general medical clinic. Although specialists are often nominally in charge in this setting, and the clinic is considered a specialized diabetes clinic, much of the time the duty of actually seeing people with diabetes is delegated to junior and rotating medical staff. Typically, nursing staff undertake process tasks such as preparing medical records, measuring the patient's height and weight, and testing blood glucose levels. Many of these clinics are not formatted to cope with caring for people with a chronic disease, and entrenched but unsuitable systems, often as a result of hospital regulations, such as only providing patients with a few weeks' supply of medications, mean that clinics are overwhelmed by people attending to have a prescription written. This ultimately leads to shorter consultation times to cope with increased throughput of clinic attendees. As a consequence, care tends not to be patient-focused nor up-to-date, resulting in poor clinical outcomes.

Simple policy changes can improve diabetes care without imposing too much of a cost penalty. For example, if the rationale for writing monthly (or even shorter) prescriptions is because of cost or supply chain issues, doctors can write a prescription valid for several months that can be dispensed monthly by the hospital pharmacist. This will free up the clinic considerably. Another example that can improve continuity of care is to link the rotating junior doctors' clinics with someone more permanent. At least patients will see someone familiar, and if they have a particularly difficult diabetic problem (be it medical, such as insulin allergy, or psychosocial, such as poor family support), at least the junior rotating doctor could be told beforehand about it by the senior consultant who is next door.

A further step that can improve diabetes care within the traditional system is to allocate nurses to the specialized position of diabetes educator or diabetes specialist nurse, so they can complement and enhance what the doctors provide. For this to be successful, it is important their roles are separate to the clinic nurse, and not just be seen as "an additional pair of hands" to help with routine clinic or ward duties. Rather, they should be employed to provide education regarding self-management principles to either inpatients or outpatients, or a combination of both. In some cases their role may be fully dedicated to educating patients; however, with further training, the specialist nurse can well provide many areas of diabetes management [12–16]. These staff can be trained to make clinical decisions about the management of diabetes, including management of glycemic control, hypertension and dyslipidemia, provide self-management education, and coordinate team services to meet the patient's health needs. Utilizing nursing staff to provide many of the routine clinical services is less expensive than using medical staff, and takes the load from the medical staff so they can concentrate on more complex cases. Indeed, studies comparing clinical outcomes from protocol driven, nurse-led clinics with traditional physician-led clinics have shown care is no worse in a nurse or allied health driven system [13–16]; however, the success of this approach may lie in the careful selection of staff. Recognizing the advanced skills of the diabetes specialist nurse, both through a career structure and improved financial incentives, is important to ensure continuity of staff. There is also a need to convince nursing and hospital administrators of the importance of the specialist nurse role so that trained staff are permanently maintained within their specialist area.

Traditional diabetes clinics have often been considered to be antiquated. However, they can be made to work, and realistically they are likely to remain the backbone of specialist diabetes care worldwide. However, for them to be effective, there are organizational and system issues to which the senior doctor in the clinic must pay attention, rather than limiting his/her role to a medical one only.

### **Private specialist diabetes care**

In many areas around the world, a system of private specialist diabetes care exists to offer choice and to reduce some of the

burden on public funded services. Subsidy or insurance of private health services is often available, but patients may be faced with a co-payment if their diabetes practitioner charges above the subsidized fee. These costs are a major barrier to many patients receiving the level and type of care they require [17], particularly when multiple specialists are involved. In the majority of cases, private services are run by solo practitioners, and access to support services provided by allied health professionals is also costly. In many ways, similar to their primary care counterparts, the private specialists face the same difficulty of providing multi-disciplinary care required by some patients with diabetes.

---

### **Integrated specialist care**

Specialist diabetes care can also be provided in a more integrated and multidisciplinary manner, addressing not only glucose control, but also complications and co-morbidities of diabetes, involving doctors as well as allied health professionals. The health and cost benefits of such integrated specialist care have been reported by the Steno Hospital [18–26], although it is difficult to evaluate the magnitude of benefits by controlled clinical trials. It is also not clear how much of the reported benefit was brought about by multidisciplinary involvement, and how much by multifaceted treatment.

Such integrated care is often conveniently provided at a diabetes center, an entity that is distinct from the diabetes clinic. To appreciate the full potential of a diabetes center, it is worthwhile noting its heterogeneous nature. Although many facilities may function under the same generic name, they can differ quite considerably. Initially, the role of diabetes centers was to provide diabetes education. For many this remains their primary function, and diabetes education center is perhaps a more appropriate name. These education centers have generally been developed to support large diabetes clinics, and are usually located separately from where medical consultations are made. In this model, clinical care is provided by physicians and patient self-management education is conducted by other diabetes team members. These team members need to have core clinical knowledge of diabetes, understand teaching and learning principles, as well as behavioral and psychologic strategies to help patients to manage their diabetes. It is a system of care repeated in many countries around the world, and can be highly successful in meeting the clinical, educational and psychologic needs of the person with diabetes and their family.

Toward the other end of the spectrum, a diabetes center can incorporate clinical activities. In this manner the duties of doctors and other health professionals become more integrated, co-located and co-dependent. This is the model we have relied on extensively at Royal Prince Alfred Hospital in Sydney for the last two to three decades. Initially, a prime motive of such initiatives was initiation of insulin therapy and stabilization of diabetes without the need for hospitalization, duties largely provided by diabetes nurses, but with the backing of doctors. Over the years

more specialized clinical services, such as screening and management of diabetes complications, diabetic foot disease, diabetes in pregnancy, neuropathic pain and use of insulin pump treatment have been progressively added to the services provided by our diabetes center. In many of these activities, nursing and allied health professionals have such a specialized role that the doctor's function can become a supporting as well as a supervisory one. We have found nursing and allied health professionals to be better in these roles than rotating doctors, if for nothing else because patients appreciate more continuity. Conceptually, there is no reason why one good doctor cannot provide all these services to their patients, and we have indeed witnessed some who were able to do so, but in our experience it is logistically difficult. In many ways, in our system there are many specialists that make up the team, but not all of them are doctors. This concept, for example, of a nurse being more "specialized" in a clinical area of diabetes management than a doctor, is sometime difficult for the traditionalist to understand, or with which to feel comfortable.

To provide such specialized services, diabetes center staff members require ongoing training which is at one time more specialized, and yet also broader in scope, philosophically identical to that required by their medical counterparts undergoing specialist training. For example, in addition to understanding general diabetes and dietary principles, dietitians working in a clinical diabetes center need to be expert in insulin adjustment and hypoglycemic unawareness in order to be able to help a patient who is learning carbohydrate counting. Another example is the nurse who is helping the patient to adjust insulin dosage. Such nurses must be familiar with the findings of recent clinical trials such as the ACCORD Study [27] to individualize the level of glycemic control required by that individual.

By its very "Rolls Royce" nature, this type of integrated specialist diabetes care is more resource hungry. By creating such "super centers" there will be constant ambivalence between balancing state of the art services and providing day-to-day diabetes care to a large number of people. Because of resource constraints, this will always be a problem, and it is even worse for a unit that is dependent on throughput for its funding. This dilemma will necessitate a rational debate of who needs specialist care and what this entails.

---

### **Sharing the burden of diabetes between community care and specialist care**

Many aspects of diabetes management can be very capably provided at the community level [28,29]. It therefore makes sense for the majority of patients without complications or co-morbidities of diabetes to be managed within the community; however, patients with more complicated disease warrant referral to specialists, depending on their individual need. For containment of cost, not surprisingly, virtually all governments embrace this position.

While conceptually sound and obvious, a seamless delivery for such a division of labor is not easy to achieve. It is relatively easy

for primary care doctors to notice poor glycemic control. By contrast, patients with complications or risk factors of complications, but who are unaware of their existence, do not readily identify themselves. Various guidelines from learned bodies therefore promote the concept of regular screening for diabetes complications. In Australia, the government rewards primary care doctors with additional remuneration if a patient with diabetes has completed a cycle of care, including assessment for glycemic control and diabetes complications, within a certain timeframe. This push towards primary care, coupled with the natural expectation of a better standard of care, would increase the use of specialized services such as ophthalmology and podiatry, amongst others. Ironically, much of the cost saving of seeing a primary care doctor rather than a specialist may be lost in this manner.

---

### **Improving synergism between primary and specialist care**

A possible solution is the system we have used at the diabetes center of the Royal Prince Alfred Hospital in Sydney. We rely on a shared care system to partition responsibilities between primary care doctors and specialists, and have established a complication assessment service to underpin such a sharing arrangement [29]. In one visit, patients referred by primary care doctors have examination of the fundi, testing of foot sensation and reflexes, quantitation of albuminuria, assessment of lipid profile and other cardiac risk factors, as well as examination of pedal and carotid pulses. This allows the primary care doctors to provide routine diabetes management for the majority of patients, and to make appropriate referrals to specialists when necessary.

A recent study comparing outcomes of patients managed by our model with those of patients attending traditional specialist services found that the adherence to management guidelines in our shared care model was superior to traditional specialist care. Moreover, a significantly higher proportion of patients managed under the shared care model, achieved an HbA<sub>1c</sub> within 1% (11 mmol/mol) of normal range, and/or a blood pressure at target [30]. This would suggest that the majority of people with diabetes do not need to see a specialist service in the traditional 3–4 monthly cycle to receive similar quality of care. Apart from achieving good endpoints of glycemic control and complication detection, this system is more cost effective because specialists services such as ophthalmologists and nephrologists are generally only sought when recommended by a diabetes specialist.

It is worthwhile to note particular issues that can make such a system maximally effective. The specialist team that examines the patients and reports to the primary care doctor must have good clinical skills and judgment in managing the various complications of diabetes. This will allow diabetes specialists to provide more precise recommendations about the timing of referrals to other specialists, or indeed to provide appropriate treatment of some complications themselves. For example, the ability of the

diabetes specialist to recognize not only retinopathy in a particular patient, but also be confident that it is not vision-threatening for the foreseeable future, may appropriately delay the referral to an ophthalmologist until later. It also offers a cost advantage. During 2008, our center screened over 2400 patients, 237 of whom were found to have retinopathy. The cost to the health system for the screen-negative patients to have been seen by an ophthalmologist would have been close to \$AUD150 000. A further example is the ability to identify the occasional patient with non-diabetes-related neuropathic pain; this may save many other patients with typical diabetes neuropathic pain from unnecessary referral to neurologists.

To maximize the effectiveness of this system further, the diabetes center team must also know what a particular primary care doctor is capable of, or willing to do, in the management of diabetes. This will help to decide how much of the care of a patient should be returned to the primary care level. This differential approach to shared care cannot be easily written in a guideline, and can only be established through years of contact with primary care doctors in the community.

There are many other approaches to facilitate complementary primary and specialist diabetes care. For example, telemedicine has been shown to be a useful tool in linking community health services with specialist services. At our center, telemedicine is used in the management of diabetic foot disease, and facilitates routine and urgent consultations between our urban diabetes center and rural sites. Routine consultations are organized by prior arrangement without the patient needing to be present. The process includes the advanced emailing of standardized digital images of the patient's foot for the center's foot team to review before phone linkup. The images are displayed on computer monitors at both sites during the phone linkup and a patient management plan developed, which is then implemented locally. Urgent consultations are booked on demand, and at least one person from the diabetes center foot team is available for immediate advice until further review can be arranged. This system minimizes unnecessary patient travel, facilitates routine clinical care, and allows for urgent consultations, as well as providing ongoing training for community health professionals regarding diabetic foot disease. Such a system has the potential for use in countries where diabetic foot services are limited [31]. Another example is the development of mobile diabetes buses in India [32]. Retinal photographs taken in rural locations are beamed by satellite to specialist diabetes services for their opinion regarding the need for laser therapy. This service is financially supported by local charities and donations from other international organizations, and involves partnerships with government satellite organizations and private medical centers.

---

### **Rethinking diabetes care**

To rationalize diabetes care, decisions will need to be made in many areas regarding who is to do what, and at which level. There

is no single correct answer, since the local situation influences the decision; nevertheless some pertinent examples and relevant points can be raised. For example, emotion would often dictate that the management of gestational diabetes should be at the specialist level; however, the large numbers of women with this diagnosis has the potential to overwhelm diabetes pregnancy clinics. This places increased pressure on staff, and means that women with pre-existing T1DM and type 2 diabetes mellitus (T2DM) may not receive the level of care they need. The morbidity of gestational diabetes is relatively low in comparison with T1DM and T2DM. A better use of resources would be to provide the care for women with gestational diabetes in the community, with appropriate protocols and guidelines to ensure referral to specialist services as required.

Treatment of diabetic foot disease is another example of how care between the community and the specialist services needs to be carefully partitioned, depending on the individual's degree of risk. Guidelines often suggest that all those with diabetes should have their feet assessed and managed by podiatrists. This will place great stress on the availability of podiatrists when their service is better directed to high risk individuals, especially those with active foot lesions. It is better to assign the level of care depending on whether a patient has risk factors for foot ulceration, such as impaired sensation or peripheral circulation, and whether there are active foot lesions. This would allow patients with foot ulceration, severe foot infection and Charcot arthropathy to receive the specialized attention they need.

The care of people with T1DM is challenging. They need more multidisciplinary care, such as dietary counseling of carbohydrate counting or intensive teaching in the use of insulin infusion pumps. These skills are not readily available in the community. The lower prevalence of T1DM also means that most primary care doctors do not have enough exposure to this group of patients to gain experience. Therefore, this group of individuals is probably better managed at the specialist level.

There is also the broader (and economically the most important) question of who should look after the glycemic control for the majority of people with T2DM. There is a great deal of uncertainty about the optimal line of division between primary care and specialist care, both from medical and economic points of view. A reflection of this uncertainty is the ongoing debate on how guidelines on the treatment of T2DM should be framed. There are some who believe that an HbA<sub>1c</sub> target of <7% (<53 mmol/mol) should be adopted because, amongst other reasons, this is what can reasonably be expected at the primary care level. Others believe that this approach is not individualized enough, and could potentially discourage specialists and patients from aiming for even better glycemic control, even when it is appropriate.

---

### Communication between primary and specialist care

Timely communication is crucial in promoting a seamless

interface between primary and specialist care. In our system, we have relied for many years on a report that is a hybrid of a computer report, containing numerical and factual data, supplemented by three free text messages addressing issues related to, respectively:

- 1 Glycemic control;
- 2 Complication status and management; and
- 3 Other important issues.

The messages are intended to provide a management plan and explanation for proposed actions. An example of this report is shown in Figures 56.1 and 56.2. Apart from serving the purpose of documentation and communication, the sending of this report for every patient who attends is, in our opinion, a powerful tool to update our primary care physicians regarding our policy of treatment, and the latest trend in diabetes management. This encourages them to adopt our strategies of diabetes management for other patients; thus, in a de facto way, promoting a more uniform treatment policy for the community. An example of this is our usual practice of maintaining oral antidiabetic agents when we commence someone on insulin treatment. Primary care doctors from out of our area often consider this to be a mistake, and stop the oral agents, while doctors in our area are more than happy to go along with it, having had it explained to them in the past.

In this age of advanced telecommunication, it is possible to communicate through a centralized web-based database, or similar systems to which various health professionals could have access. Technology that enables immediate access to test results means that the clinical consultation is enhanced. For example, a chronic care program conducted in rural Pennsylvania established information systems in the community that allowed for rapid turn around of laboratory results. Local physicians were made responsible for collecting and responding to data, resulting in improved patient outcomes [33]. Patient tracking systems for regular follow-up have also been shown to improve quality of care at the process level and to decrease the number of patients lost to follow-up [13,34–36]; however, while these systems can undoubtedly be helpful in transmitting factual information, they are not as good for individualized advice, which we believe to be the essence of cementing a good community and specialist relationship.

---

### The future challenge

The challenge ahead is to provide accessible and affordable quality care to an increasing number of people with diabetes. If diabetes care is to achieve the health care benefits that the diabetes research described in this textbook has made possible, it must be tackled at both the community and specialist levels. In this regard, the complementarity of primary and specialist care has a pivotal role and is a relationship that must be carefully considered by health care planners.

CANTERBURY 2193

Date of birth:15/05/1940

-----  
COMPLICATIONS THAT WE DRAW YOUR ATTENTION TO ARE:

Diabetic retinopathy  
Diabetic nephropathy  
Dyslipidaemia  
Ischaemic heart disease  
-----

Mrs Smith who is 69 years old has had Type 2 diabetes since 1987. Her current weight is 105.1 Kgs and her BMI is 39.6. She is a non smoker.

CURRENT DIABETIC TREATMENT::

Lantus BB:40 units BL: BD: BBed:49 units  
Novorapid BB:6 units BL:8 units BD:12-12 unitsBBed:

OTHER RELEVANT MEDICATIONS INCLUDE:

Atacand Plus 16/12.5 mg  
Lipitor 40 mg  
Actonel 30 mg  
Aspirin 100 mg

EYE ASSESSMENT:

\*\*Corrected visual acuity:

Right eye =6/12

Left eye =6/12

\*\*Retina:

\*\*Retinopathy

Right eye: minimal NPDR

Left eye: minimal NPDR

\*\*Macular Oedema:

Right eye: Not clinically present

Left eye: Not clinically present

COMMENT: Please see final comments

\*\*No cataracts present

\*\*No evidence of previous laser therapy

**Figure 56.1** Example of the computer-generated section of the report to referring primary care physicians. BB, before breakfast; Bbed, before bed; BD, before dinner; BL, before lunch; BMI, body mass index; CAG, coronary artery grafting; CHOL, cholesterol; eGFR, estimated glomerular filtration rate; HDL, high density lipoprotein; LDL, low density lipoprotein; NPDR, non-proliferative diabetic retinopathy; TRIGS, triglycerides.

RENAL FUNCTION:

Microalbuminuria: 2.5 mg/L (Normal: 0-20 mg/L)  
Albumin Creatinine Ratio: 0.32 mg/mmol (Normal adjusted for age:<4.0 mg/mmol)

COMMENT: Normal

Haemoglobin: 117 g/L (Reference Range:115 - 165 g/L)

eGFR: 34.458 mL/min (Normal:>=60 mL/min)

\*\*Blood pressure:

Mean Sitting BP: 120/61 mm/Hg

COMMENT: Her blood pressure is well controlled on treatment

FOOT AND NEUROPATHY ASSESSMENT

\*\*Ankle jerks:

Right foot: present Left foot: present

\*\*Biothesiometer:

This is a measure of large nerve fibre conduction.

Right foot: 24 Left foot : 24 (Normal for age: < 33 volts)

\*\*Monofilament:

Right foot: Can feel Left foot : Can feel

\*\*Foot pulses:

Right foot:Present Left foot:Present

COMMENT: Her vibration perception as measured by biothesiometer is normal and ankle jerks are present. This makes serious foot problems unlikely.

MACROVASCULAR STATUS

COMMENT: She has a history of ischaemic heart disease and CAG surgery.

AUTONOMIC FUNCTION

Symptoms of autonomic neuropathy: Nil

METABOLIC PARAMETERS

HbA<sub>1C</sub>: 7.2% Normal:4.0 - 6.0

Creatinine: 140 Normal:55 - 120 umol/L

TRIGS: 1.4 mmol/L

CHOL: 4.6 mmol/L

HDL: 0.9 mmol/L

LDL: 2.9 mmol/L

Figure 56.1 Continued

## THE DIABETES COMPLICATION ASSESSMENT SERVICE REPORT

ENQUIRIES: - PH 9515 5888

NAME: Susan Smith

DATE OF VISIT: 8/02/2009

COULD YOU PLEASE CONSIDER IMPLEMENTING THE FOLLOWING RECOMENDATIONS:

1. Her glycaemic control has improved relative to last year associated with an ongoing positive approach to lifestyle management and achieved weight loss of 4kg. We have made some slight adjustment to her Novorapid insulin today. If her fasting levels are consistently above 7mmol/l, you might like to gently increase the evening Lantus by a couple of units every few weeks. Overall, I think the current HbA<sub>1c</sub> of 7.2% is acceptable considering the long history of diabetes and previous ischaemic heart disease. The recently published ACCORD Study suggests that reducing HbA<sub>1c</sub> to less than 6.5% may paradoxically worsen outcomes.

2. She has minimal diabetic retinopathy which is not surprising in view of the long duration of diabetes. It is stable compared with last year, not vision threatening and no intervention is required. Her eGFR is slightly low even adjusted for her age but stable compared with last year and she is appropriately on an ACE-I. Her cholesterol is also slightly on the high side for someone known to have IHD and you may like to push the Lipitor treatment a bit higher.

3. I note also her problems with osteoarthritis. For someone with marginal renal function, it would be nice to avoid the NSAID as much as possible.

Follow-up: From a diabetes complications perspective, we have not made further plans to review Mrs Pike but recommend she return in approximately twelve months time, or earlier if you require.

REPORT PREPARED BY: Prof Dennis K. Yue

cc: Dice,JO

## Note:

To help improve the care we provide your patients, and to shorten the time takes us to forward a detailed report, we would appreciate if you could arrange for the patient to have the following pathology tests when you next refer patients to us. We are happy to accept tests performed within the last 3 months.

- 1- Cholesterol, triglycerides and HDL cholesterol
- 2- Serum biochemistry including LFT and creatinine
- 3- HbA<sub>1c</sub>
- 4- Microalbuminuria (spot urine sample)
- 5- Urine protein
- 6- Urine creatinine
- 7- Haemoglobin

**Figure 56.2** Example of free text message section of the report to referring primary care physicians. ACEi, angiotensin-converting enzyme inhibitor; eGFR, estimated glomerular filtration rate; HDL, high density lipoprotein; IHD, ischemic heart disease; LFT, liver function test; NSAID, non-steroidal anti-inflammatory drug.

**Keypoints**

- There is generally low adherence of both people with type 2 diabetes (T2DM) and care providers to recommended treatment guidelines.
- Current opinion advocates a multidisciplinary approach to the treatment of T2DM. This includes system support to encourage use of evidence-based guidelines, reorganization of practice systems and team functions, support for patient self-management, improved access to expertise, and enhanced availability of clinical information to facilitate monitoring and feedback on physicians' performance.
- The key elements of quality diabetes care delivered by a multidisciplinary team include periodic risk stratification, protocol-driven care with regular review, patient empowerment, treatment-to-target, and good record keeping to monitor clinical progress and outcomes.

**Introduction**

According to the World Health Organization (WHO), four chronic non-communicable diseases – diabetes, cancer, respiratory and cardiovascular diseases (CVD) – account for 60% of global deaths (i.e. 35 million deaths per year) [1]. In Europe and China, 30–40% of patients with acute myocardial infarction have a known history of diabetes. In the remaining subjects, 70% of patients have either diabetes or intermediate hyperglycemia on formal 75-g oral glucose tolerance testing [2,3]. In addition, diabetes and hypertension frequently coexist. Both are important considerations in the majority of cardiovascular deaths worldwide, which are estimated to be 18 million annually. The number of people with diabetes is projected to increase from 285 million in 2010 to 435 million by 2030 [4]. The resulting increase will lead to considerable losses in productivity as well as greatly increasing the burden on health care systems.

Treatment of diabetes and associated complications is costly. In 2006, the WHO estimated that in both developing and developed areas, 2.5–15% of health care budgets were spent on diabetes-related illnesses. The International Diabetes Federation (IDF) also estimated that 7–13% of annual health care expenditure was spent on treatment of diabetic complications [5]. The total direct annual costs of diabetes in eight European countries were estimated at €29 billion, with an estimated yearly cost of €2834 per patient [6]. In the USA, diabetes is associated with an annual direct medical expenditure of \$91.8 billion. The per capita cost was estimated to be \$13 243 for individuals with diabetes com-

pared to \$2560 for those without [7]. In China, one of the countries with the most rapid increase in diabetes prevalence, \$558 billion in national income is expected to be lost over the next 10 years as a result of premature deaths caused by non-communicable diseases including heart disease, stroke and diabetes [8].

Early diagnosis and aggressive control of risk factors can prevent complications in both type 1 (T1DM) and type 2 diabetes mellitus (T2DM) [9–11]. International organizations such as the IDF, as well as many national organizations, have published clinical recommendations and set standards to guide clinical practice, in order to optimize metabolic control and prevent complications [12].

**Evidence for optimization of diabetes control**

To date, most evidence supporting the beneficial effects of optimal diabetes care on clinical outcomes [10,13,14] were collected under closely supervised clinical trial conditions. In the Diabetes and Complications Clinical Trial (DCCT), which lasted for 6.5 years, patients with T1DM treated intensively had an HbA<sub>1c</sub> level 2% (22 mmol/mol) lower than those who were conventionally treated (7.2% vs 9.1%, 55 vs 76 mmol/mol). After the study was completed, the authors continued to follow these patients in the Epidemiology of Diabetes Interventions and Complications (EDIC) study. There was progressive deterioration in glycemic control once these intensively treated patients returned to their usual care setting; however, patients previously treated conventionally also improved, and both groups converged to achieve HbA<sub>1c</sub> levels of 8% (64 mmol/mol) [15]. Despite this convergence, patients previously treated intensively maintained over 50% risk reduction in all diabetes-associated complications, including cardiovascular events [16].

Similar findings have also been reported following the post-UK Prospective Diabetes Study (UKPDS). People with T2DM who were previously treated with an intensive regimen continued to have lower rates of complications and all-cause mortality than patients treated conventionally, 10 years after discontinuation of the trial [17]. In the Steno-2 Study, individuals were treated intensively in an attempt to attain control for all major risk factors (HbA<sub>1c</sub>, blood pressure [BP] and low density lipoprotein [LDL] cholesterol), and had 50–60% risk reduction in microvascular and macrovascular complications compared with those conventionally treated [18]. As in the DCCT and UKPDS, in the post-Steno Study period, people who had been treated intensively in the main trial maintained more than 60% risk reduction in all-cause death compared with those conventionally treated for 13.3 years [19]. Findings from these landmark studies clearly demonstrate the beneficial effects of achieving risk factor control during the early course of disease to achieve long-term benefits.

## Diabetes care – the reality

Despite the evidence, national and international surveys have indicated that diabetes management remains suboptimal, regardless of the studied populations and health care settings. It should also be remembered that most of these recommendations, guidelines, surveys and studies emanate from settings, countries and areas that are relatively well-resourced.

According to the National Health and Nutritional Examination Surveys (NHANES), conducted between 1988–1994 and 1999–2002 in the USA, amongst patients with diabetes aged 18–75, although there was a non-significant reduction in the proportion of patients with HbA<sub>1c</sub> >9% (>75 mmol/mol), since the numbers of patients with HbA<sub>1c</sub> 6–8% (64–86 mmol/mol) increased, there was no significant change in mean HbA<sub>1c</sub> between these intervals [20]. In the 1999–2002 survey, there was increased use of multiple antidiabetic agents for control [21], yet nearly half continued to have HbA<sub>1c</sub> levels greater than the American Diabetes Association (ADA) recommendation, of 7% and 20% had HbA<sub>1c</sub> >9% (>75 mmol/mol).

There was also no significant change in the distribution of blood pressure, 33% having BP >140/90 mmHg. In the 1999–2002 survey, 60% achieved LDL cholesterol concentrations of <3.4 mmol/L and received annual screening for eye and foot complications. The levels of care were noted to be suboptimal, especially in females and in those under the age of 45 years [22,23]. Thus, between these surveys, some improvements were documented but many problems remained.

Tables 57.1–57.3 summarize the adequacy of glycaemic, blood pressure and lipid control in various settings during the last two decades. Despite much data, there has been little change in average values attained or percentage of patients reaching treatment goals.

Table 57.1 summarizes adequacy of glycaemic control from the 1988–1994 NHANES, up to the latest International Diabetes Management Practice Study (IDMPS) conducted in 2005 [24].

The latter is a 5-year survey documenting changes in diabetes treatment practice in developing regions including Asia, Eastern Europe and Latin America. It shows that only 37% of people with T2DM achieved HbA<sub>1c</sub> ≤7% (53 mmol/mol). The results were similar in both developed and low and middle income countries [14,21,24–26], different health care settings, primary care [27–32] and specialist centers [33–36].

Table 57.2 summarizes adequacy of blood pressure control in the same period. The blood pressure target in earlier years was 140/90 mmHg, when approximately 40–60% of people with T2DM achieved target [14,29,37]. There was a tendency to improvement in the study conducted by the Department of Veteran Affairs in the USA. In this study, conducted between 1996 and 2000, the proportion of people with T2DM achieving the target blood pressure increased from 40% to 52% [30]. The DiabCare studies in Asia demonstrated that over 70% and 90% of people with T2DM were able to achieve the target of systolic and diastolic blood pressure of ≤140 and ≤90 mmHg, respectively [34]. Emerging evidence of the importance of blood pressure control led to the target blood pressure being revised to <130/80 mmHg. This is not accompanied by further improvement in terms of rate of achievement of targets. Recent studies in different countries and settings showed that only half of people with T2DM were able to achieve the target of 130/80 mmHg [24,26,31,33].

With regard to lipid control (Table 57.3), there was a slow but gradual improvement, probably because of the availability of effective treatment of LDL cholesterol with 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors. In the 1980s and early 1990s, the rate of achievement of target LDL cholesterol <2.6 mmol/L was around 10–15% [14,37]. This had increased to approximately 25–30% subsequently [24,27,29,31,33]. For those on HMG-CoA reductase inhibitors, as illustrated from a study in Sweden, nearly half of patients were able to achieve the target [26].

There are obvious limitations in these studies including heterogeneity of populations in different studies, retrospective reviews, incomplete documentation for medical record review and inaccuracy for claims data. Despite the limitations and lack of comparability of the many studies, the results summarized in Tables 57.1–57.3 indicate the same trend. It should also be noted that, most of these surveys come from well-resourced settings and developed countries, where laboratory assessment for HbA<sub>1c</sub> is readily available.

The Institute of Medicine has defined quality of care as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” [38,39]. There is ongoing controversy as to the degree to which outcomes can be directly related to processes of care, yet both are considered as important measures of quality. Thus, the degree of adherence to recommended guidelines, based on available clinical evidence, provides guidance to the degree of quality of care. Table 57.4 summarizes attempts to address this issue specifically and includes surveys that assess quality of care as measured by frequency of measurement for HbA<sub>1c</sub>. In early years, less than one-third of patients received HbA<sub>1c</sub> monitoring [14,40,41]. Since the early

**Table 57.1** Adequacy of glycemic control in various health care settings in patients with type 1 (T1DM) and type 2 diabetes mellitus (T2DM).

Health care setting	Number of patients	Survey year	Method	Findings	Reference
Population-based (US NHANES III and BRFSS)*	4085	1988–1995	Patient survey, clinical examination	42.9% had HbA <sub>1c</sub> <7% (53 mmol/mol) 18.0% had HbA <sub>1c</sub> >9.5% (80 mmol/mol)	[14]
Primary care (Netherlands) and managed care organization (USA)	2498 (379 patients from the Netherlands and 2119 patients from USA)	1992–1997	Medical record review and administrative data	In 1996, 43.1% vs. 16.8% of patients had HbA <sub>1c</sub> <7% (53 mmol/mol); and 85.6% vs 56.7% had HbA <sub>1c</sub> ≤8.5% (69 mmol/mol) in Netherlands and USA, respectively	[27]
Population survey (USA)	1480	1995	Patient survey, clinical examination	Mean HbA <sub>1c</sub> 7.6% (60 mmol/mol); 44.6% had HbA <sub>1c</sub> <7% (53 mmol/mol), 37.1% >8% (64 mmol/mol)	[25]
Community health center (USA)	2865	1995	Medical record review	Mean HbA <sub>1c</sub> 8.6% (70 mmol/mol) 39% of patients had HbA <sub>1c</sub> ≤8.0% (64 mmol/mol)	[28]
Primary care (USA)	9557–9985	1995–1997	Medical record review	34–42% with HbA <sub>1c</sub> >9.5% (80 mmol/mol)	[29]
Veterans' Affairs (USA)	9578 (in 1995) to 25 764 (in 2000)	1995–2000	Medical record review and administrative data	72%, 82% and 87% had HbA <sub>1c</sub> <10% (86 mmol/mol) from 1995–1998, 59% and 62% had HbA <sub>1c</sub> <8% (64 mmol/mol) in 1999 and 2000	[30]
Diabetes clinic, general medical (resident) clinic and university (faculty) clinic (USA)	6386	1995–2005	Clinical examination	43.7% of type 2 diabetes had HbA <sub>1c</sub> <7% (53 mmol/mol)	[33]
Primary care and hospital outpatient clinics (Sweden)	17 547 T2DM in 1996 and 57 119 in 2003	1996 and 2003	Medical record review and administrative data	Mean HbA <sub>1c</sub> was 7.8% (62 mmol/mol) in 1996 and 7.2% (55 mmol/mol) in 2003. 16% of patients had HbA <sub>1c</sub> <6.5% (48 mmol/mol) in 2003	[31]
Primary care (UK)	18 642	1997	Questionnaire survey and audit data	42.9% with HbA <sub>1c</sub> within normal range of local laboratory	[32]
National Diabetes Registry (Sweden)	9424 T1DM in 1997 and 13 612 T2DM in 2004	1997 and 2004	Medical record review	Mean HbA <sub>1c</sub> was 8.3% (67 mmol/mol) in 1997 and 8% (64 mmol/mol) in 2004 17.4% and 21.1% had HbA <sub>1c</sub> <7% (53 mmol/mol) respectively in 1997 and 2004	[26]
Primary care and hospital outpatient clinics (Asia)	24 317 T2DM in 230 centers	1998	Medical record review and patient interview	Mean HbA <sub>1c</sub> was 8.6% (70 mmol/mol) in 18 211 patients, 21% had HbA <sub>1c</sub> <7% (53 mmol/mol)	[34]
Primary care and hospital outpatient clinic (China)	2246 T2DM in 1998 and 2702 in 2006	1998 and 2006	Medical record review	Mean HbA <sub>1c</sub> was 8.7% (72 mmol/mol) in 1998 and 7.6% (60 mmol/mol) in 2006	[35]
Population-based survey (US NHANES)	15 332 participants, 16.8% diabetes	1999–2004	Patient interview and administration data	52.2% had HbA <sub>1c</sub> <7% (53 mmol/mol)	[21]
Specialist pediatric center in Western Pacific Region	2312 T1DM	2001–2002	Medical record review	Mean HbA <sub>1c</sub> was 8.3% (67 mmol/mol)	[36]
Primary care and specialist center (Asia, Eastern Europe and Latin America)	11 799	2005–2010	Medical record review	Mean HbA <sub>1c</sub> was 8.3% (67 mmol/mol) in 1898 patients with T1DM, 25.3% had HbA <sub>1c</sub> ≤7% (53 mmol/mol); Mean HbA <sub>1c</sub> was 7.8% (62 mmol/mol) in 9901 patients with T2DM, 36.4% had HbA <sub>1c</sub> ≤7% (53 mmol/mol); % of patients achieved HbA <sub>1c</sub> ≤7% (53 mmol/mol) by ethnic group (Asia, Eastern Europe, Latin America) was 21.0 vs 31.3 vs 21.1 in T1DM and 37.3 vs 36.0 vs 36.0 in T2DM	[24]

BRFSS, Behavioral Risk Factor Surveillance System; NHANES III, Third National Health and Nutrition Examination Survey.

Interpretation of the adequacy of glycemic control is affected by the laboratory methods used and the corresponding reference range, which might vary across studies. For simplicity, the table only describes the absolute values cited in the original papers, and direct comparisons between studies may not be valid.

**Table 57.2** Adequacy of blood pressure control in various health care setting in type 1 (T1DM) and type 2 diabetes (T2DM).

Health care setting	Number of patients	Survey period	Method	Findings	Reference
Population-based (US NHANES III and BRFSS)	4085	1988–1995	Patient survey, clinical examination	65.7% had BP <140/90*	[14]
Population-based (US NHANES III)	733	1991–1994	Patient survey, clinical examination	59% of the hypertensive patients had BP >140/90	[37]
Primary care (USA)	9557–9985	1995–1997	Medical record review	64–66% had BP <140/90	[29]
Veterans Affairs (USA)	9578 (in 1995) to 25 764 (in 2000)	1995–2000	Medical record review and administrative data	40%, 44%, 45% and 52% has BP <140/90 (if hypertensive) from 1996–2000	[30]
Diabetes clinic, general medical (resident) clinic and university (faculty) clinic (USA)	6386	1995–2005	Clinical examination	36.7% of T2DM had BP ≤130/80	[33]
Primary care and hospital outpatient clinics (Swedish)	17 547 T2DM in 1996 and 57 119 in 2003	1996 and 2003	Medical record review and administrative data	Mean BP was 150/82 in 1996 and 143/78 in 2003. 13% of patients had BP <130/80 in 2003	[31]
National Diabetes Registry (Swedish)	9424 T1DM in 1997 and 13 612 T1DM in 2004	1997 and 2004	Medical record review	61.3% had BP ≤130/80 in 2004	[26]
Primary care and hospital outpatient clinics (Asia)	24 317 T2DM in 230 centers in Asia	1998	Medical record review and patient interview	Mean BP was 135/81; with 27% had systolic BP >140 and 10% had diastolic BP >90	[34]
Primary care and specialist center (Asia, Eastern Europe and Latin America)	11 799	2005–2010	Medical record review	44.9% T1DM and 19.2% T2DM patients had BP ≤130/80. By ethnic group (Asia, Eastern Europe and Latin America) was 47.4 vs 43.8 vs 44.1 in T1DM and 21.8 vs 20.1 vs 22.1 in T2DM	[24]

BRFSS, Behavioral Risk Factor Surveillance System; BP, blood pressure; NHANES III, Third National Health and Nutrition Examination Survey.

\* BP is expressed in mmHg.

1990s, with the availability of results from the DCCT and UKPDS, the frequency of monitoring has gradually improved [27–29,42–44]. Recently, more than 90% of patients have HbA<sub>1c</sub> regularly monitored in specialist clinics such as the Steno Diabetes Center [45] and in some primary care settings [30,46]. Elsewhere, monitoring is available in 70–80% of patients [24,32,47].

It is important to note that there is often a discrepancy between doctors' claims of frequency of monitoring and that occurring in practice. Although there appears to have been some improvements in the care processes over time, this has not been matched by improvement in rates of achieving treatment targets (Tables 57.1–57.3).

### Discrepancy between evidence-based care and reality

The efficacy of optimization of diabetes control has been confirmed in randomized controlled trials conducted with stringent clinical trial protocols; however, despite improvements in some processes of care such as monitoring of HbA<sub>1c</sub>, this has not been matched by improvement in rates of achieving treatment targets.

In addition, the level of care received by many patients does not meet recommended standards. In a previous survey in USA, only 25% of patients were aware of the term “glycated hemoglobin” or “HbA<sub>1c</sub>” [43]. Only 72% of the subjects visited a health care provider for diabetes care at least once a year, and approximately 60% received complication screening. Furthermore, despite the proven benefits of many therapeutic agents, many people with diabetes were not prescribed insulin, angiotensin-converting enzyme (ACE) inhibitors or lipid-lowering drugs despite the presence of indications [48–53].

The factors that compromise quality of care have been examined in various studies, but have not been well understood. Nevertheless, some components are obvious.

### Patients

Drug compliance by patients receiving chronic medications is consistently reported to be less than 50%, often because of insufficient education and reinforcement [54–56]. Moreover, there is considerable heterogeneity in the patterns and rates of non-adherence to individual components (e.g. diet, exercise, drugs) of a diabetes treatment regimen. Thus, the extent to which people with diabetes adhere to one aspect of the regimen might not cor-

**Table 57.3** Adequacy of lipid control in various health care setting in type 1 (T1DM) and type 2 diabetes (T2DM).

Health care setting	Number of patients	Survey period	Method	Findings	Reference
Population-based (US NHANES III and BRFSS)	4085	1988–1995	Patient survey, clinical examination	11.0% had LDL <2.6, 42.0% had LDL <3.4	[14]
Population-based (US NHANES III)	733	1991–1994	Patient survey, clinical examination	15.4% had LDL <2.6, 49.3% had LDL <3.4, 58.4% had TG <2.3. 41% of those known to have dyslipidemia had LDL <3.4	[37]
Primary care (Netherlands) and managed care organization (USA)	2498 (379 patients from Netherlands and 2119 patients from USA)	1992–1997	Medical record review and administrative data	In 1996, 23.1% vs. 40.4% of patients had total cholesterol <5.2 in Netherlands and USA, respectively	[27]
Primary care (USA)	9557–9985	1995–1997	Medical record review	48–52% had TC <5.2, with median TG 2.2	[29]
Veterans Affairs (USA)	9578 (in 1995) to 25 764 (in 2000)	1995–2000	Medical record review and administrative data	62%, 68%, 72% and 76% has LDL <3.4 from 1996–2000	[30]
Diabetes clinic, general medical (resident) clinic and university (faculty) clinic	6386	1995–2005	Clinical examination	28.6% of T2DM had LDL <2.6	[33]
Primary care and hospital outpatient clinics (Swedish)	17 547 T2DM in 1996 and 57 119 in 2003	1996 and 2003	Medical record review and administrative data	28% of patients in 2003 had TC <4.5 mmol/L	[31]
National Diabetes Registry (Swedish)	9424 T1DM in 1997 and 13 612 T1DM in 2004	1997 and 2004	Medical record review	Among those on LLD, 48% had LDL <2.5 mmol/L	[26]
Primary care and specialist center (Asia, Eastern Europe and Latin America)	11 799	2005–2010	Medical record review	39.5% T1DM and 33.2% T2DM had LDL <100 mg/dL; 73.1% T1DM and 49.0% T2DM had TG <150 mg/dL	[24]

relate with their adherence to other components. Previous studies have shown that only 69% of people with diabetes follow a diet and less than half engage in regular exercise [57]. The reported adherence to self-monitoring of blood glucose ranges from 53% to 70% [58]. Earlier studies have indicated that only 7% of patients with diabetes adhere to all aspects of the treatment regimen [59], while over half made errors with insulin dosage and three-quarters of patients were judged to be in an “unacceptable” category regarding the quality, quantity and timing of meals [60].

In attempts to extrapolate results from clinical trials to daily practice, it is important to individualize interventions taking into account all potential factors. For example, in the elderly, side effects of interventions must be balanced against long-term benefits, limited life expectancy and co-morbidities. Other factors such as education level, access to care, compliance and motivation may also contribute to patient adherence, in addition to treatment-related factors such as adverse effects, polypharmacy and cost [42,43,49]. It is recommended that people with diabetes should be educated about the nature of the disease with particular focus on chronicity and long-term complications, as well as preventability.

## Physicians

The key role of health care providers is to equip people with diabetes with knowledge and skills related to self-management, to individualize medical and behavioral regimens, to assist with informed decisions, and provide social and emotional support via a collaborative relationship [61,62]. An important factor is the inertia of physicians in failing to modify the management of patients in response to an abnormal clinical result [63,64]. In a previous study by Kaiser Permanente, one of the major health management organizations in USA, there was on average 15 months and 21 months lapse before escalation of treatment in patients with HbA<sub>1c</sub> of >8% (64 mmol/mol) on metformin and sulfonylurea monotherapy, respectively [65]. Despite the complexity and rapid advances in diabetes management, generalists often did not perceive the need for further training in the field of diabetes [66–69]. Involvement of other non-medical health care professionals may also not be welcomed in some traditional settings.

## Health care system

Traditional medical practice is organized to respond quickly to acute problems, but does not adequately serve the needs of

**Table 57.4** Frequency of HbA<sub>1c</sub> monitoring in various health care settings in type 1 (T1DM) and type 2 diabetes (T2DM).

Health care setting	Number of patients	Survey period	Method	Performance index (frequency of HbA <sub>1c</sub> measurements in last year or % of patients with at least 1 HbA <sub>1c</sub> measured in last year)	Reference
Primary care (USA)	1429 doctors	1989	Mail and telephone questionnaire survey	16–18% of physicians measured every 2–3 months	[40]
Population-based (US NHANES III and BRFSS)	4085	1988–1995	Patient survey, clinical examination	28.8% with monitoring available	[14]
Primary care (USA)	97 388	1990–1991	"Claims-based" profile	16% with monitoring ever	[41]
Primary care (Netherlands) and managed care organization (USA)	2498 (379 patients from Netherlands and 2119 patients from USA)	1992–1997	Medical record review and administrative data	Frequency of measurement improved from 1992 to 1996, with 1.89 in Netherlands and 1.10 tests/year in USA. 80.7% (Netherlands) and 57.4% (USA) had more than 1 measurement over last 12 months	[27]
Primary care (USA)	1376	1993	Reimbursement profile	26% had HbA <sub>1c</sub> in last 1 year; 19% in African Americans and 27% in Caucasians	[104]
General practitioners or specialist care centers (Hungary)	4824	1993	Administrative database	12% had >1 measurement	[42]
Population-based (USA)	2118	1994	Patient survey	61.8% had HbA <sub>1c</sub> in last 1 year	[43]
Community private practices (USA)	30 589	1994	Administrative database	69.4% had HbA <sub>1c</sub> in last 1 year	[44]
Community health center (USA)	2865	1995	Medical record review	54.6% had HbA <sub>1c</sub> in last 1 year	[28]
Primary care (USA)	9557–9985	1995–1997	Medical record review	70% had HbA <sub>1c</sub> in last 1 year	[29]
Steno Diabetes Center (Denmark)	2011 (T1DM)	1995–1997	Patient survey	55, 65 and 80% had HbA <sub>1c</sub> in last 1 year from 1995–1997	[45]
Veterans Affairs (USA)	9578 (in 1995) to 25 764 (in 2000)	1995–2000	Medical record review and administrative data	>99.5%, had HbA <sub>1c</sub> in last 1 year mean frequency 3 tests/yr	[30]
Health Management Organization (USA)	3612	1997	Patient survey, administrative database	59%, 85%, 91%, 93% and 94% had HbA <sub>1c</sub> in last 1 year from 1995–2000	[46]
Primary care (UK)	18 642	1997	Questionnaire survey and audit data	89.0% had HbA <sub>1c</sub> in last 1 year	[32]
Primary care (Germany)	5057	2001	Medical record review	83.0% had HbA <sub>1c</sub> in last 1 year	[47]
Primary care and specialist center (Asia, Eastern Europe and Latin America)	11 799	2005–2010	Medical record review	69.5% of the insulin-treated patients, 64.3% of patients on single oral antidiabetic agent and 41.1% for those on diet had HbA <sub>1c</sub> in last 1 year	[24]
				77.6% T1DM and 64.2% T2DM had HbA <sub>1c</sub> ever monitored. By countries (Asia, Eastern Europe and Latin America) was 81.1 vs 73.1 vs 81.4 for T1DM and 64.0 vs 55.8 vs 75.5 for T2DM

BRFSS, Behavioral Risk Factor Surveillance System; NHANES III, Third National Health and Nutrition Examination Survey.

individuals with chronic illnesses, when emphases are to alter behavior and to deal with social and emotional impacts of symptoms as well as disabilities [70]. Health care systems need to ensure that the best possible treatment regimens are administered in order to control disease, alleviate symptoms, inform and support.

Thus, suboptimal quality of care is often caused by combinations of factors relating to the affected individual, to the medical care personnel and to the system of health care delivery. In the IDMPs [24], amongst patients in whom HbA<sub>1c</sub>, BP and LDL cholesterol measurements were available, only 3.6% of patients attained target values for all three risk factors (BP <130/80 mmHg,

HbA<sub>1c</sub> <7% (53 mmol/mol) and LDL cholesterol <2.6 mmol/L). In this survey, there was considerable heterogeneity between regions of patient-related factors (e.g. age, disease duration, presence of complications, body weight), health care systems (e.g. health insurance coverage, availability of specialist care, training by diabetes educator) and self-care (e.g. self-adjustment of insulin dosage) all being associated with the likelihood of reaching targets. The problem is particularly marked in low and middle income settings where it is exacerbated by multiple demands upon severely limited resources including those imposed by a continuing burden of infectious diseases and other issues such as accidents and injuries.

## The evolving concept of disease management

It will be clear from the previous sections that although optimal care improves clinical outcomes in clinical trial settings, this is often not achieved in real clinical situations for the reasons discussed. This has led to attempts to develop models of care based on multidisciplinary approaches.

In recent years, there has been increasing emphasis on management via coordination and organization of individual components of care into a structured system. The latter is further supported by reinforcement through multiple contacts, including not only physician appointments, but also telephone reminders and visits to other health care professionals such as nurse practitioners, dietitians and pharmacists. According to Wagner *et al.* [70], there are five key elements to improve the outcomes of patients with chronic diseases:

- 1 A system to support the use of evidence-based guidelines;
- 2 Reorganization of practice systems and team functions;
- 3 Patient self-management support;
- 4 Improved access to expertise; and
- 5 Improved availability of clinical information to facilitate monitoring and feedback on physician's performance.

The Steno-2 study provides excellent evidence in support of the benefits of protocol-driven multifaceted care using a multidisciplinary approach in T2DM [13,18,19]. Patients randomized to the intensive treatment group were managed by a multidisciplinary team according to a protocol that specified a stepwise implementation of behavior modification, smoking cessation, aggressive control of glycemia, BP, lipids and microalbuminuria, and use of an ACE inhibitor and aspirin. The reductions in HbA<sub>1c</sub>, BP, serum cholesterol and triglycerides levels and albuminuria were all significantly greater in the intensive care group than in the usual care group. These benefits in metabolic control were translated to risk reductions of cardiovascular morbidity and mortality by 53% (95% confidence interval [CI] 27–76%), nephropathy by 71% (95% CI 13–83%), retinopathy by 58% (95% CI 14–79%) and autonomic neuropathy by 63% (95% CI 21–82%). By the end of 13.3 years, patients previously treated intensively had lower all-cause mortality (hazard ratio [HR] 0.54; 95% CI 0.32–0.89), cardiovascular mortality (HR 0.43; 95% CI 0.19–0.94)

and cardiovascular events (HR 0.41; 95% CI 0.25–0.67) than the conventional care group.

In another multicenter randomized study comparing structured care delivered by a diabetologist–nurse team with conventional care, 60% of patients with T2DM with renal impairment receiving structured care attained three or more predefined treatment goals (HbA<sub>1c</sub> <7% (53 mmol/mol); BP <130/80 mmHg; LDL cholesterol <2.6 mmol/L; triglycerides <2 mmol/L and use of ACE inhibitor or angiotensin receptor blocker) compared to 20% in the usual care group. After 2 years, patients who attained three or more treatment goals had 60% risk reduction in all-cause mortality and end-stage renal disease (HR 0.43; 95% CI 0.21–0.86) [71].

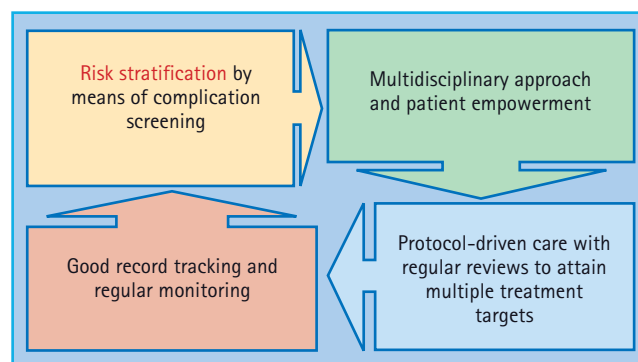

## Implementation of quality structured care

This concept of disease management emphasizes an organized, proactive multidisciplinary approach to health care in complex and chronic diseases, of which diabetes is a prime example [72,73]. People with chronic diseases should be empowered to improve knowledge and self-management [74,75]. Preferences should be taken into account to individualize treatment plans. Evidence suggests that periodic attendance at a diabetes center [76] and frequent reminders by paramedical staff to reinforce self-management could improve metabolic control, clinical outcomes and survival [13,71,77–84]. Clinical information should be made easily available to provide support. Information technology can be used to monitor adherence to guidelines and provide feedback to the care providers (see Chapter 58) [70,72,85–87].

Provision of structured care to people with T2DM is best implemented through a series of interlinked processes based on these principles. These include risk stratification, protocol-driven care, regular review by a multidisciplinary team, patient empowerment and good record keeping to monitor progress (Figure 57.1).

### Risk stratification

Diabetes is characterized by clustering of multiple risk factors that interact in a complex manner to give rise to multiple complica-

**Figure 57.1** Components for quality structured care.

tions [88]. Both the IDF and American Diabetes Association (ADA) recommend that people with diabetes should undergo comprehensive assessment at presentation and annually thereafter to document personal, clinical and laboratory measurements. This enables stratification of risk and placement of patients within different care plans for targeted individualized treatment.

The UKPDS has provided longitudinal data which help to define the natural history of cardiovascular complications in T2DM. Using the UKPDS data, mathematical models have been developed to identify predictors (risk factors) for cardiovascular disease [89]. In addition, the Framingham Heart Study, started in 1948, has prospectively followed a large group of participants in the general population in order to identify factors contributing to development of CVD, and risk engines have also been developed to predict risk of CVD in this population [90]. Both the UKPDS and the Framingham risk equations show moderate effectiveness in risk stratification in UK and USA settings; however, external validation studies show that the performance varies considerably among different countries and ethnic groups [91]. In addition, there were only a few hundred people with diabetes in the original cohort of the Framingham Study, while the UKPDS recruited individuals in the early phase of diabetes. These pose definite limitations in applying the risk engines derived from these two studies to general diabetes populations in Europe, the USA and elsewhere.

Further modification and development of ethnic specific risk equations have now been carried out. For example, equations to predict diabetes complications such as coronary heart disease, stroke, end-stage renal failure, congestive heart failure as well as overall mortality have now been developed for Chinese populations, based on prospective follow-up of approximately 8000 patients, with median follow up of 6 years [89,92–95]. In this particular group of Chinese individuals with diabetes, the Framingham stroke risk engine underestimates, while the UKPDS risk engine overestimates, the risk of stroke. Both of these risk engines for CVD overestimate the risk of CVD in some populations such as Chinese. In addition, it was not possible to develop the UKPDS risk engine to assess risk of end-stage renal disease as an insufficient number of individuals developed this endpoint. Further development in this area is anticipated with expansion of studies into different settings and ethnic-specific areas.

### Protocol driven care using a multidisciplinary approach

Diabetes management involves multiple contacts with different health care personnel, each specialized in a particular process or area of expertise. Non-medical personnel, notably nurse educators, nutritionists, pharmacists, physical trainers and podiatrists, are key members of a successful diabetes team. While the doctor adopts the leading and coordinating role in defining problems and needs, the professional knowledge and clinical skills of these non-medical staff are invaluable in providing counseling and holistic care to patients. These health care professionals can also assist physicians to provide follow-up, empower self-manage-

ment and support carers of patients with cognitive impairment and physical disabilities. This team approach allows physicians to spend more time in discussion of needs, setting of targets and options for management. In high risk individuals, such as those with co-morbidities or those receiving multiple medications, the pharmacist may have a unique role in providing education to patients in collaboration with physicians to improve the safe and effective use of pharmaceutical agents and reduce the risk of drug-related adverse effects and drug–drug interactions.

Given the large number of processes and personnel potentially involved in the delivery of such evidence-based and protocol-driven care, it is important to try to determine which aspects of care can be attributed to which components. In a meta-analysis of 66 publications examining 11 different strategies to improve diabetes care [96], two key strategies were associated with statistically significant incremental reductions in HbA<sub>1c</sub> value. The first was team changes, which involved either the addition of a team member, shared care between primary care and specialist center, or multidisciplinary team care. This resulted in additional HbA<sub>1c</sub> reduction by 0.33% (3.6 mmol/mol). The second was case management, which involved coordination in diagnosis, treatment or management by a person or multidisciplinary team in collaboration with or supplementary to the primary care clinician. This was associated with additional HbA<sub>1c</sub> reduction of 0.22% (2.4 mmol/mol).

This has been replicated in various clinical settings. For example, the Chinese University of Hong Kong Diabetes Group has used different care prototypes since the 1990s to augment delivery of care using nurses and pharmacists. The latter were empowered to run clinics or provide telephone counseling to provide periodic assessments and reinforce treatment compliance. These prototypes consistently showed improved rates of treatment compliance and attainment of multiple treatment targets as well as reduced risk of death and cardiorenal complications by 50–70% in chronic diseases including diabetes with or without complications (Figure 57.2) [82–84]. These two strategies become key components and are applicable globally irrespective of the health care setting. In less resource-rich settings, some of these strategies can be met, at least partially, by appropriate training or relocation of existing staff in response to changing health needs.

### Patient empowerment and self-care

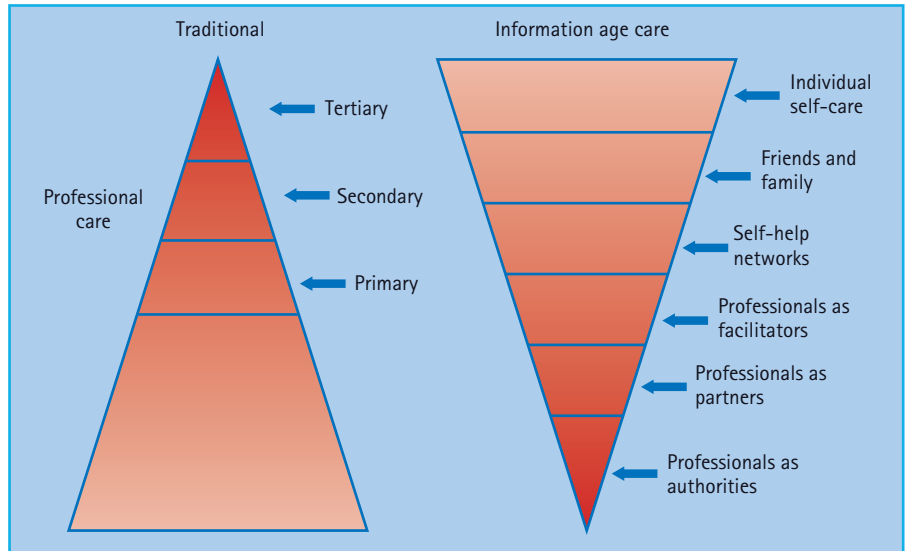

In addition to team changes and case management, other processes that have been shown to improve disease control include patient education (effect sizes 0.24 [0.07–0.40]), reminders (0.27 [0.17–0.36]) and financial incentives (0.40 [0.26–0.54]) [86]. While adherence of physicians and care providers to care processes may improve health outcomes, patient adherence is a critical factor in realizing the benefits of these processes. Patients should be encouraged to participate actively in defining and achieving agreed treatment goals rather than conforming to medically defined regimens or instructions. In diabetes, behavioral changes, including adhering to a meal plan, engaging in regular

**Figure 57.2** Effect of protocol-driven care using a multidisciplinary approach to reduce risk of complications in patients with chronic diseases including type 2 diabetes mellitus (T2DM) [82–84]. (a) Telephone counseling by a pharmacist between clinic visits reduced mortality rate by 50% in patients receiving five or more chronic medications. (b) Patients with T2DM without cardiorenal complications managed in a clinical trial setting was associated with a 70% risk

reduction in death rate compared with matched patients followed up in conventional care setting. (c) Patients with T2DM with chronic kidney disease managed by a pharmacist–doctor team had a 50% risk reduction in death and end-stage renal disease compared with patients managed in conventional care setting.

**Figure 57.3** Change of paradigm using information technology to improve clinical and self-management. Adapted from Jennings *et al.* [109], with permission from Knowledge Exchange LLC.

physical exercise, taking medications regularly, monitoring blood glucose levels and other complications, and attending to foot care demand high levels of self-discipline and are important components of holistic care models [61].

Given the chronic nature of diabetes and large amount of data collected during contact with care providers, there is a need to develop a system to manage this information effectively and enable health care workers to make decisions, track clinical progress, monitor compliance and benchmark quality of care. The use of information technology can also empower people with

diabetes by making information more accessible and understandable. Such technology can also assist individuals with diabetes to keep their own health records, maintain control, and use them to manage their own care in an informed manner (Figure 57.3).

**Importance of periodic monitoring and review**

Depending on complications and control of risk factors, people with diabetes should be reviewed at intervals ranging from weekly to every few months; however, once stabilized, people with dia-

**Table 57.5** Treatment targets, procedures and frequency of monitoring for individual target [12,105–108].

	Frequency	Procedures and targets
<b>Glycemic control</b>		
HbA <sub>1c</sub>	NGSP of IFCC assay 2–6 monthly	6.5–7% (48–53 mmol/mol) Individualized target based on: <ul style="list-style-type: none"> <li>• Duration of diabetes</li> <li>• Age/life expectancy</li> <li>• Co-morbid conditions</li> <li>• Known CVD or advanced microvascular complications</li> <li>• Hypoglycemic unawareness</li> </ul>
Self-monitoring of blood glucose	≥3 daily for patients on intensive insulin regimen ≥1 daily with weekly profile for those on oral agents ± insulin ≥1 weekly profile for selected patients on diet Additional test with unstable or deteriorating condition	Preprandial BG 5–7 mmol/L Post-prandial <8–10 mmol/L
<b>Blood pressure control</b>	At every clinic visit	<130/80 mmHg
<b>Lipid control</b>	Yearly	LDL <2.6 mmol/L; or 30% reduction regardless of baseline LDL Triglycerides <2.3 mmol/L HDL >1.0 mmol/L in men, 1.3 mmol/L in women
<b>Clinic visit</b>	Every 3–6 months	Access progress in achieving treatment goals: <ul style="list-style-type: none"> <li>• Symptoms</li> <li>• Weight goals</li> <li>• Glycemic, blood pressure and lipid goals</li> <li>• Compliance and side effects of medications</li> <li>• Results of self-monitoring</li> <li>• Adherence to lifestyle including cessation of smoking and avoidance of excessive alcohol use</li> </ul> Access complications: <ul style="list-style-type: none"> <li>• Events including admissions or procedures</li> </ul>
<b>Complication screening</b>	Yearly May consider 2–3 yearly for retinopathy in patients with normal examination by experts	Self-care knowledge and beliefs Lifestyle adaptation Psychologic status Self-monitoring skills and equipment Body weight trend Glycemic, blood pressure and lipid control Cardiovascular risk Erectile dysfunction, neuropathy Foot condition Eye condition Kidneys Pre-pregnancy advice Medication review

BG, blood glucose; CVD, cardiovascular disease; HDL, high density lipoprotein; LDL, low density lipoprotein; NGSP, National Glycohemoglobin Standardization Program.

betes should be reviewed by a health care professional at least once a year, no matter how mild the condition may appear. Based on various guidelines, the targets as well as procedures and frequency of monitoring for individual targets are summarized in Table 57.5.

This takes account of the possibility of silent deterioration of metabolic control and development of new risk factors or complications, as proper management cannot be initiated unless indexes of control are measured periodically [97]. In the study shown in Figure 57.2(a), which was conducted in the

early 1990s, the omission of the measurement of metabolic indices was associated with a 15-fold increased risk of death. The comparison group in this study had at least one measurement during a 7-year period of observation [82].

These findings are related to adjustment of regimens facilitated by periodic monitoring [97]. Patients receiving structured care have greater utilization of antihypertensive and lipid-lowering agents. Using ACE inhibitors as an example, despite the compelling evidence supporting their protective effects [98], clinicians in conventional care settings often withhold or discontinue these drugs for fear of side effects such as hyperkalemia and deterioration of renal function, especially in high risk patients who are those most likely to benefit [99,100]. This is further supported by the study shown in Figure 57.2(c), in T2DM with nephropathy, in which 60–70% of patients were treated with an ACE inhibitor or ARB at baseline. At the end of a 2-year study period, over 90% of subjects randomized to structured care delivered by a multidisciplinary team persisted with the treatment compared with less than 20% of subjects randomized to conventional care. Together with better risk factor control, increased usage of drugs, more clinical and laboratory assessments, this difference in usage of ACE inhibitor or ARB collectively contributed to the reduction in death and cardiorenal event rates between the structured and conventional care group [71,84].

### Importance of attaining multiple targets

As shown in Table 57.5, multiple treatment targets, in addition to glycemic control, need to be taken into consideration when managing people with diabetes. In an observational study of 6386 patients with T2DM in Hong Kong, attainment of  $\geq 2$  treatment goals (HbA<sub>1c</sub>, BP or LDL cholesterol) was associated with 30–50% risk reduction in new onset of CHD, demonstrating the importance of attaining multiple targets [33]. In the Steno-2 study in Denmark, which aimed to achieve multiple risk factor control, the overall relative risk reduction of 59% in composite cardiovascular events accords with the expected cumulative effects of control of individual risk factors in an additive manner [19]. This has been further replicated in another study, in individuals with diabetic nephropathy, in which more people receiving structured care attained  $\geq 3$  treatment goals (61%) compared with the conventional care group (28%). This difference translates to a 60–70% reduction in premature death and end-stage renal disease [71].

It has been estimated that use of HMG-CoA reductase inhibitors and blood pressure lowering drugs confers the largest benefit in reducing cardiovascular risk in the initial study period, with optimization of glycemic control and use of aspirin providing additional beneficial effects. The long-term glycemic beneficial effects of glucose lowering on diabetes-related endpoints are expected to occur later. Hence, the attainment of multiple treatment targets might explain the continuing divergence in cardiovascular endpoints, rather than a simple time–effect relationship. The importance of sustained benefits of long-term glycemic control is further supported by the legacy effect associated with

intensive blood glucose control, long after the cessation of the UKPDS [101] and the parallel findings of the DCCT/EDIC study [15,16].

---

### Cost-effectiveness of multidisciplinary care

Cost-effectiveness analysis for intensive glycemic and blood pressure control has been performed based on results from the UKPDS [102]. The cost per quality-adjusted life year (QALY) for intensive blood glucose control with insulin or sulfonylureas was £6028 more than conventional treatment, while that with metformin in overweight patients was £1021 less than conventional treatment. These estimates suggest that intensive blood glucose therapy, particularly the use of metformin in obese patients with diabetes, was effective and cost-saving. The cost per QALY gained for tight blood pressure control was £369 based on the UKPDS. Similarly, according to the Centers for Disease Control (CDC) in the USA, the incremental cost:effectiveness ratio for intensive glycemic control was US\$41 384 per QALY. The respective costs for intensified blood pressure control and reduction of serum cholesterol were savings of US\$1959 and US\$51 889 per QALY [103]. Furthermore, these analyses suggested that these interventions were most cost-effective when instituted early during the course of disease.

Similar analysis has also been performed in the Steno-2 Study [19]. The incremental cost:effectiveness ratio for structured care versus conventional treatment was €3927 and €2538 per life year and per QALY gained, respectively. These incremental costs were mainly attributed to increased pharmacy and consultation costs. The author further pointed out that even assuming that patients in the structured care group continued to receive the most expensive treatment in a specialist setting in Denmark and that the treatment effects between the intensive and conventional groups might decline after completion of the 7.8-year intervention period, the incremental costs still represent good value for money. However, because of the multifaceted nature of the intervention, it was difficult to identify the contribution of individual factors to the improved outcome.

---

### Conclusions

In conclusion, T2DM is a massive public health problem and is associated with reduced life expectancy by 10–12 years. It has major implications on quality of life, health care utilization and societal productivity. Diabetes management is complex and effective management requires creation of care models that take account of this complexity and facilitate care providers to attain multiple treatment targets and empower patients to adhere to self-management. Such models should include continuous quality improvement initiatives with measurement of key performance indices, validated outcome measures and risk–benefit analyses of interventions. Landmark trials such as Steno-2 study

have demonstrated the cost-effectiveness of the use of protocol-driven multidisciplinary care to manage and prevent diabetes complications. With appropriate organization of care, good clinical governance and patient empowerment, quality diabetes care should eventually become accessible, affordable and sustainable, irrespective of circumstances and resource setting.

### Keypoints

- A comprehensive approach to diabetes prevention and care includes policies and activities outside the formal health sector, particularly for primary prevention.
- Integrated care refers to the need to provide care for conditions coexisting with diabetes within the same primary health care service.
- Continuity of care, a cornerstone of effective health care organization, is associated with improved outcomes.
- Prerequisites for improving outcomes include ensuring that essential medications (including insulin) are either free or highly affordable and that tests for the diagnosis of diabetes, monitoring of control, and equipment to screen for complications are available.
- Living health systems should care for, empower and nurture their staff so that they are enabled to do the same for their patients.
- If no one is responsible for chronic care, the tendency is for it to be overlooked.
- A less qualified professional may offer lower quality care, but there is potential for effective substitution, with the right training and organization.
- A respectful, open and curious stance may help different professionals and people to understand each other better.
- Patient-centeredness improves quality of life, increases patient satisfaction, improves adherence to treatment, enhances the integration of preventive and promotive care, and improves the provider's job satisfaction.
- In low resource settings where large numbers of patients overwhelm facilities, it may make sense to extend care into the community.
- Ideally, a systematic process for reviewing the evidence and updating guidance accordingly should be in place in all countries.
- Advances in the usage of information technology and the internet are likely to provide increasingly important contributions to diabetes care both in well-resourced and less-well resourced settings.

### Introduction

Almost no community worldwide remains unaffected by diabetes. Premature mortality and an array of complications, in particular the chronic complications, result in a considerable impact that is experienced by individuals, families and societies. This impact is predicted to increase, primarily in countries such as those in North Africa, sub-Saharan Africa, the Middle East and South Asia. In these countries, lifestyles are transitioning and the populations consume less healthy foods, and have rising levels of physical inactivity and obesity.

Enormous inequalities exist in the provision of health care for people with diabetes, in keeping with the widely disparate socio-

economic status that prevails globally. These inequalities are not only found between countries, they occur within countries, for example in rural-versus-urban settings, private-versus-public sectors and hospital-versus-community-based services. Considerable challenges face health planners and providers, especially in less well resourced countries and areas countries, because of the traditional infectious diseases, such as tuberculosis and malaria, coexisting with HIV/AIDS, and the emerging scourge of chronic diseases, including diabetes, producing a multiple disease burden with competition for limited resources. Furthermore, most health care systems have evolved from the basis of dealing with acute medical problems and have been or, in most instances, remain ill-equipped to provide the kind of care that people with chronic diseases require.

That is not to say well-resourced countries do not face challenges with health care delivery. In these countries, there are also problems in ensuring that quality health care is delivered in a

cost-effective manner. Notwithstanding these challenges, each person with diabetes, wherever they live, should have access to the best care that can be provided in their setting and consequently have the opportunity to achieve the outcomes they seek. Unfortunately, this is not the current situation, even in well-resourced countries and settings. The United Nations Resolution on Diabetes “Encourages member states to develop national policies for the prevention, treatment and care of diabetes in line with the sustainable development of the health-care systems, taking into account the internationally agreed upon development goals, including the Millennium Development Goals” (Resolution 61/225, December 20, 2006). The resolve of the United Nations, together with the policies and influence of the International Diabetes Federation (IDF) and the World Health Organization (WHO), need to be harnessed in order to improve the suboptimal care and outcomes for people with diabetes. After all, it is not that a dearth of evidence exists for the effectiveness of a wide range of interventions to prevent complications associated with diabetes, but rather the reverse. Narayan *et al.* [1] have identified three interventions that are cost-saving and fully feasible in terms of penetration of the target population, technical complexity, amount of capital required and cultural acceptability, even in low and middle income countries and across all regions:

- 1 Improvement in glycemc control;
- 2 Blood pressure control; and
- 3 Foot care.

A fourth intervention, pre-conception care, was found to be cost-saving, but not fully feasible because of concerns of not being able to reach all women with diabetes.

The issue at hand is how to translate the evidence into practice and thus reality, acknowledging that, almost without exception, health services are in need of repair and the specific interventions to be introduced or implemented will undoubtedly vary depending on the health care structure and resources available. There is also the need to recognize that diabetes requires that people not only have access to sufficient resources, such as medication, but also the understanding, motivation and skills to self-manage their condition.

Health care cannot be seen in isolation, occurring as it does within a broad societal framework which places varying degrees of emphasis on ensuring that quality care is prioritized. Thus, in the first instance, for effective health care delivery, a positive policy environment needs to be in place, nationally and locally. The “macro” level of the WHO Innovative Care for Chronic Conditions (ICCC) framework focuses on this very issue (Figure 58.1), highlighting the components that can promote a positive policy environment [2]. Political will, building or strengthening partnerships (e.g. between community-based organizations, patient organizations, health care workers and government), and ensuring consistent funding are key aspects of the process. So too is the need for an inter-sectoral approach or collaboration to building a healthy society, encompassing, for example, urban

**Figure 58.1** Innovative care for chronic conditions framework. Adapted from WHO [2].

planning (with the provision of green areas, easy public transport, access to sport and recreation facilities), the introduction of health promotion activities within schools and the food industry.

The “meso” level in the ICCC framework relates to health care organization and links to the community. It is at this level that the concept “model of care” comes into play. As coined by Davidson *et al.* [3], a health care model can be regarded as an overarching design for the provision of a service that is ideally underpinned by a theoretical framework, evidence base and clearly defined standards. The model has core principles and elements in addition to an agreed upon agenda for implementation and later evaluation. It is unlikely that a single health care model for diabetes exists that can be used effectively and efficiently in all settings – indeed, the model will take different forms or shapes in different settings. Health planners have to decide whether to pursue a diabetes-specific model of care or to incorporate multiple chronic diseases such as diabetes, hypertension and chronic lung diseases in a common chronic care model. There are salient reasons for pursuing the latter, given the commonality of aspects of care for these conditions, but factors such as the available resources are likely to guide this decision. Regardless of the model selected, changing the value system in which health care is delivered, with the aim of ensuring motivated affirmed health care workers, is perhaps key to equipping or enabling people living with diabetes with the information, motivation and skills to self-manage their diabetes. There is a real need to embrace the lessons that can be learned from the successful highly active antiretroviral therapy (HAART) programs for people with HIV/AIDS, which have yielded levels of adherence to therapy that most clinicians and public health specialists can only dream of in relation to diabetes [4].

There are certain core principles for diabetes care that could be applied across all resource settings [2]. These include establishing:

- A comprehensive approach that provides for health promotion to enable prevention and early diagnosis, management of diabetes and complications when they arise and rehabilitation when needed.
- Integrated health care, such that conditions coexisting with diabetes, can be readily managed within the same primary health care service.
- Continuity of care, which has a number of connotations: in terms of the relationship between health care worker and patient; in terms of management strategies and decision-making; and in terms of patient information.
- Access to care, which can be understood in a physical or geographic sense, but extends to access to appropriate equipment for monitoring, diagnosis and management as well as medication.
- Coordination of care from primary to secondary and tertiary levels, with appropriate referral strategies and role delineation. Where multiple professionals and organizations are involved in primary care, horizontal coordination of care is also important.
- Teamwork: diabetes care involves multiple health workers, professional categories and disciplines, even in low resource settings.

Establishment of teams whose focus is on delivering and improving the quality of care permits the development of shared goals, defining and clarifying roles, reflecting on how care can be improved and holding each other accountable for decisions. The identification of a team leader may be a major factor in the success of this element.

- Person-centeredness implies a more collaborative approach and holistic understanding of the patient that elicits, acknowledges and addresses relevant beliefs, concerns and expectations. This is at least partly a paradigm shift in the mind of the health worker from the traditional biomedical, technical and sometimes authoritarian model to a biopsychosocial, holistic and participatory model.
- Family and community orientation are integral to provide support for the individual with diabetes as well as to raise awareness and to extend care from the health centers into the community.
- The use of evidence as far as it is available, accessible and relevant. The evidence base for diabetes is constantly expanding and all resource settings need to look at how they access the latest and ever-changing evidence base.

We now discuss how these principles are being incorporated into care for people with diabetes across different resource settings; low and middle income settings such as encountered in most low and middle income countries as well as in high income countries. Finally, how information technology can be embraced and harnessed appropriately in different settings with the goal of supporting these principles is explored.

---

## A comprehensive approach

Taking a comprehensive approach to diabetes prevention and care implies that policies and activities are put in place to address primary prevention, early diagnosis (including screening if appropriate), management of diabetes and its complications, and rehabilitation for those affected by complications. A comprehensive approach will include policies and activities outside the formal health sector, particularly for the primary prevention of type 2 diabetes mellitus (T2DM). For example, promoting healthier diets and greater physical activity could involve policies on food production, marketing and taxation, and policies on design of local environments and public transport. The WHO’s strategy on diet and physical activity provides a framework for developing national and international policy that is relevant to countries at all levels of development [5]. The best indication of a comprehensive approach is a national government-led strategy that covers primary prevention through to rehabilitation, with the caveat that the presence of a strategy does not guarantee that it has been implemented. A recent survey carried out through IDF member organizations [6] found that of the 98 countries from which responses were received, just over 70% claimed that their country had implemented a national diabetes program. The region with the lowest proportion of countries (30%) with a

national diabetes program was sub-Saharan Africa, but even in richer regions, such as Europe, over 20% of responding countries did not have a national diabetes program. Examples of national diabetes programs in countries at opposite ends of the economic spectrum include the program in Cameroon [7] and the National Service Framework for Diabetes in England [8].

## Integrated health care

Integrated care for people with diabetes refers to the need to provide care for conditions coexisting with diabetes within the same primary health care service. Within most high income countries, primary health care has been developed to provide a range of services covering most of the needs with people with diabetes, and indeed with other chronic conditions. In low and middle income countries, however, integration of care is often a challenge, as donor funding is most often given to specific disease programs such as HIV/AIDS, tuberculosis or malaria, or large-scale government funding is allocated for specific vertical programs, such as HIV/AIDS. For example, in Zambia the donor funding for HIV/AIDS is larger than the total health care budget. While this funding enables higher quality care for a specific disease it can weaken the health care system as a whole. Further, disease-centered programs, through higher salaries and better working conditions, may draw professional staff away from

### Box 58.1 Cambodia: integrated chronic disease clinics

Chronic disease clinics for the combined care of HIV/AIDS, diabetes and hypertension were set up in two provincial referral hospitals in Cambodia based on a number of assumptions: a common approach is needed to respond to the needs of chronic disease patients, with the widespread acceptance that HIV/AIDS has become a chronic disease following increasing availability of antiretroviral therapy; attending a combined clinic would minimize the stigma that a specific HIV/AIDS clinic induces; and that the care model should reflect estimates of disease burden. All patients were managed according to standard treatment protocols. A team of counselors promoted adherence and lifestyle changes to complement medical consultations, and peer support groups extended the efforts of the doctors and counselors.

#### *After 2 years*

- 70.7% of patients with diabetes (90% of those who attended for >3 months) and 87.7% of patients on highly active retroviral therapy (HAART) remained in active follow-up
- Median HbA<sub>1c</sub> was 8.6% (70 mmol/mol), but the degree of improvement could not be assessed in the absence of a baseline measurement
- Median CD4 count doubled in patients on HAART

Thus, integrated chronic care is not only feasible, but can produce good patient outcomes

primary care. Therefore, initiatives aimed at strengthening an approach to diabetes should do this with an integrated model of care and with the goal of strengthening the whole approach to chronic care [9,10]. An example of an integrated chronic care clinic for HIV/AIDS, diabetes and hypertension at provincial hospitals in Cambodia has recently been reported (Box 58.1) [11]. There is no reason why such an approach could not be used in primary health care [12].

## Continuity, access, coordination and teamwork

These four core principles – continuity of care, access to care, coordination between different levels of care and multidisciplinary team work – really belong together, as they concern providing good quality health care for managing diabetes and preventing its complications. A particular challenge in low resource settings is that of moving away from a focus on episodic curative care. High patient numbers, with acute infectious illness and low numbers of trained professionals have nurtured this approach, which will tend to wait for the patient to present with gangrene of the foot rather than invest energy in identifying the patients at risk. Likewise, there is more focus on treating the problem than empowering the person. For example, a patient with elevated blood glucose levels is more likely to receive a change in prescription than a useful exchange of information about diet or exercise and advice about overcoming barriers to adherence.

### Continuity of care

Continuity of care in chronic diseases is a cornerstone of effective health care organization and has been associated with lower mortality, better access to care, less hospitalization and referral, fewer emergencies and better detection of adverse medical events [13,14]. Continuity is easier to achieve when services are offered close to communities where access is easier. Care that requires visits to a distant referral hospital is unlikely to support continuity because of the costs and time taken to travel. In many less well resourced countries and areas, diabetes care has not been part of primary health care offered in the community although there is a clear drive by the WHO to change this.

Central to providing continuity of care is continuity of information, such that the status of individuals is known, in terms of when they attended their last appointment, the next appointment due, and what was found, discussed and prescribed at previous appointments. A diabetes register is therefore essential, providing a list of patients with diabetes being treated at that facility, a record of their appointments, linked to a system to follow-up those who fail to attend for an appointment. In higher income situations, electronic diabetes registers are now the norm, and in some situations registers are maintained across more than one level of care, such as primary and secondary care. In low income situations, an adequate register can be kept using “pencil and paper” at the level of the facility at which most diabetes care is delivered. In addition to keeping a register of patients and their

appointments, there is the need to provide continuity of relevant information between visits. In high-resource settings, electronic records linked between different levels of care provide a state of the art approach. In low-resource settings, a range of approaches have been tried (e.g. color coding of patient records, the use of annual summary sheets and patient-retained records) [15]. A simple but effective approach in some settings can be a combined “paper and pencil” register and record, recording a small number of core items such as blood pressure, a measure of blood glucose control, whether feet were examined, advice given and current medication.

Continuity of management aims to provide continuity with a specific group of health care providers. The challenge here is to maintain the same team of people for a reasonable period of time. Relational continuity with the same health care provider over time is occasionally possible and would be an ideal [16].

### Access to all

Access to care, of any type at all, is still an issue in many low and middle income countries, particularly in more remote areas. A specific example is the lack of availability or access to insulin leading to unnecessary mortality in people with type 1 diabetes (T1DM) [17,18]. Even when available, the cost of purchasing insulin is substantial and can be the equivalent of up to 20 days wages for a 1-month supply of insulin. Thus, addressing the supply chain for medication and ensuring that essential medication is either free or highly affordable is a prerequisite for improving outcomes, but that is not all that is required. Availability of tests for the diagnosis of diabetes, monitoring of control and equipment to screen for complications are also essential.

A shortage of human resources is a serious barrier to providing access to care in many low and middle income countries, the irony being that these countries are often recruiting grounds for high income countries seeking to staff their own health care systems. Given their shortage, health workers in low resource settings often develop a broader scope of practice than their equivalents in high resource settings and as a result need to have a wide range of skills. This is often necessitated by the absence of more highly trained professionals, particularly in rural and remote areas. Although a less qualified professional may offer lower quality care, there is also the potential for effective substitution, with the right training and organization. This has been well demonstrated by Gill *et al.* [19] in rural Africa. Using a wholly primary care level nurse-led program, with key elements of education and drug titration by clinical algorithm and using drugs on the essential drug list, significant improvements in glycaemic control were noted and maintained over an 18-month period (HbA<sub>1c</sub> 11.6 ± 4.5%, 103 ± 49 mmol/mol [SD] at baseline, and 7.7 ± 2.0%, 61 ± 22 mmol/mol at 18 months). The impact of education alone was remarkable, as without any change in drug therapy the HbA<sub>1c</sub> dropped from 10.6 ± 4.2% (92 ± 46 mmol/mol) baseline to 7.6 ± 2.3% (60 ± 25 mmol/mol) at 18 months.

In primary care, well-trained nurses can offer equivalent care to doctors for routine follow-up of chronic conditions, minor

illness and preventative interventions [20]. In diabetes, this may mean the nurse conducting the consultation and reviewing results such as urinalysis, HbA<sub>1c</sub>, glucose and cholesterol levels. The nurse may also screen the feet, take blood pressure and calculate the body mass index. Nurses will then refer to the generalist doctor for complicated or uncontrolled patients. Patient satisfaction may even be higher as consultations are longer and contain more information. Nurses, however, may not necessarily be cheaper as they are less productive [20]. Similarly, in low resource settings the generalist doctor may need a broader range of procedural and surgical skills at the district hospital and the ability to act as a supportive consultant to nurses. A range of mid-level workers such as health promoters and clinical associates/assistants may also provide effective substitution [21].

Management of diabetes and other chronic diseases involves providing access to screening and early intervention to prevent or at least limit the impact of complications [2]. In low resource settings, some complications are easy to screen for (e.g. using a testing strip dipstick to assess for proteinuria or identifying the at-risk foot with a monofilament) provided the necessary tools are available; however, screening for retinopathy is problematic as health providers seldom succeed in overcoming the many obstacles to effective ophthalmoscopy. Nevertheless, even in low resource settings, appropriate technology using a fundal camera may be possible [22,23].

Further decisions need to be made regarding the relative costs and benefits in different resource settings of macro vs micro albuminuria screening; use (and frequency) of glycated hemoglobin vs random/fasting blood glucose as well as total cholesterol vs high density lipoprotein (HDL) cholesterol and low density lipoprotein (LDL) cholesterol measurements. Effective screening requires a structured and systematic approach by the health care team.

### Coordination of care

Coordination of care from primary to secondary and tertiary levels is needed to provide the full range of diabetes care, if resources allow. In well financed and organized systems, this coordination includes well-developed referral pathways within health districts and regions, and well-developed systems of information exchange between the levels, in order to preserve continuity of care. Specialist services likely to be available at a secondary level include the treatment of foot ulcers, retinal laser therapy, and the investigation and medical treatment of renal impairment. Renal dialysis and replacement is an example of services often provided at the tertiary level. In low and middle income settings, and even in some high income countries where universal health insurance does not exist, access to secondary and tertiary care tends to be highly dependent on the ability to pay.

### Teamwork

Teamwork is an essential feature of providing diabetes care. Even at primary health care level, particularly in high income situations, several professionals and disciplines can be involved in the routine care people with diabetes – including, for example,

doctor, nurse, podiatrist and optometrist. In order to develop chronic care, the people involved in managing chronic conditions need to develop a team that meets regularly to focus on improving the quality of care [2], and one of the team should be appointed as the chronic care coordinator. If no one is responsible for chronic care, the tendency is for it to be overlooked. For example, basic equipment, such as glucometers, monofilaments or obese cuffs for blood pressure measurement, is not provided [15]. In addition, new ideas, initiatives and procedures are not sustained in the absence of a leader who is present over a sufficient time period. Continuously rotating staff, such as nurses, erodes the ability to create effective teams and sustain changes. When teams meet they should develop shared goals, clarify their complementary roles, reflect on how to improve care and hold each other accountable for decisions. Health professionals need to be clearly aligned with the purpose of improving chronic care and not with defending professional identities. A respectful, open and curious stance helps professionals and others to understand each other better [24].

When nurses working in a large informal settlement in Cape Town were asked what would help improve diabetes care they replied “caring for the carers,” reminding us that building good teams begins by caring for its members. The nature of the relationship between health workers and managers, and the values embedded in the organizational culture may be reflected in the nature of the relationship between health worker and patient and the culture of caring [25]. Organizations that operate too heavily in a mechanistic and bureaucratic model tend to treat health workers as human resources that can be used and replaced like parts in a machine [26]. Organizations should strive for congruence between individual values and behavior and organizational culture and structures [27]. It is difficult for health workers to empower people for healthy living, motivate change and care for patients when the organization is not congruent with the same values. Wheatley [28] expresses this well when she says, “After years of being bossed around, of being told they’re inferior, of power plays that destroy lives, most people are exhausted, cynical and focused only on self-protection ... when obedience and compliance are the primary values, then creativity, commitment and generosity are destroyed.” Living health systems should care for, empower and nurture their staff so that they are enabled to do the same for their patients.

---

### **Patient-centered care**

In low resource settings the need to be patient-centered is often dismissed as a luxury in the face of high workloads and sometimes broad differences in education, language and culture between health providers and patients. Nevertheless, patient-centeredness has been found to improve quality of life, increase patient satisfaction, improve adherence to treatment, enhance the integration of preventive and promotive care, and improve the provider’s job satisfaction. It does not necessarily imply a longer consultation.

Patient-centeredness implies a more collaborative approach and holistic understanding of the patient that elicits, acknowledges and addresses relevant beliefs, concerns, ideas and fears [14].

Patient-centeredness is in part a paradigm shift in the mind of the health worker from a bio-medical, technical and sometimes authoritarian model to a biopsychosocial, holistic and participatory model [14]. It is fundamentally a way of being with the patient. Nevertheless, a range of specific communication skills can be learnt such as the ability to ask open as well as closed questions, to make reflective listening statements, exchange information or invite mutual decision-making [29]. While training of doctors has begun to include these communication skills, even in low resource settings, the training of nurses and mid-level health workers often has not.

Motivational interviewing builds on a patient-centered approach and can best be described as a guiding style. Diabetes, which involves multiple changes in behavior (diet, exercise, smoking, alcohol, medication), particularly lends itself to adaptations of motivational interviewing. A challenge in low resource settings is to see how a range of health workers can incorporate a guiding style into their consultations.

In a model of care that emphasizes patient empowerment and self-care as key components [2], every consultation needs to be seen as an opportunity for this. Health providers need to have the necessary expertise in the relevant topics, useful communication skills and a range of educational materials appropriate to the literacy level of the community. In some settings, group as well as individual approaches may be effective [30].

---

### **A family and community orientation**

Beyond the individual patient is their family and community context. Clearly, family beliefs and customs and degree of social support will have an impact on the ability of an individual within that family to make lifestyle changes and cope with their diabetes. Involving family members in the consultation or educational program can strengthen the overall response to diabetes [31]. Likewise, an understanding of the patient’s environment will inform discussions about appropriate changes and likely constraints.

In low resource settings, where facilities are overwhelmed with large numbers of patients it may make sense to extend care into the community [2]. For example community-based support groups can be run by health promoters or local non-government organizations to offer some aspects of routine chronic care. Patients can then return to the local clinic for periodic or annual review and help with complications. Support groups can also encourage lifestyle change and adherence to medication. Expert patients, an increasingly developed resource in both low and high income situations, may also be useful to enhance self-care, although further evaluation is required [32]. Community health workers have the potential to promote healthy lifestyle, provide home-based care and link selected patients with the local facilities [33].

Communities should not just be seen as additional platforms for care or targets for interventions but representative structures or key leaders should be engaged with in order to understand how local health priorities are perceived and to elicit feedback and involvement in the planning and delivery of services [14].

Primary care workers usually have a responsibility not just for individual patients but for people living within specific communities or health districts [14]. Concern for the growing number of people with diabetes should lead to interventions that address the underlying determinants of obesity and reduced physical activity: for example, school-based healthy lifestyle programs, provision of green spaces in inner cities, marketing of food to children, sale of junk food on public premises and labeling of food. Many of these require health workers to contribute to interventions in other sectors [34].

---

## Making use of evidence

The evidence base for diabetes is constantly expanding and all the above areas need to be informed by the latest evidence base that is relevant to the resource setting in which it is to be applied. Ideally, a systematic process for reviewing the evidence and updating guidance accordingly should be in place in all countries. An example of such a system from a high income setting is the National Institute for Health and Clinical Excellence (NICE) in the UK. This may be beyond the resources of lower income countries but through regional cooperation, such as coordinated by WHO, the IDF and the World Bank, regular reviews of the evidence appropriate to different resource settings do take place. The availability of evidence does not guarantee that it will be used, and there is a strong and growing literature on how to build local ownership and influence local practice, such as through the development of local treatment guidelines.

---

## Information technology – how to embrace it?

Information technology (IT) is a rapidly growing field that has the capacity to strengthen the model of care for diabetes across different resource settings. The potential targets for IT range from people with diabetes to people at risk for diabetes, health workers and managers. Some of the ways in which IT can strengthen the model for diabetes care are improving continuity of information, assisting in running referral systems between different levels of care, and providing tools for education and empowerment.

Numerous IT modalities or systems exist, although these need to be tailored according to the target population and desired outcome. Thus, real-time imaging and audio contact via equipment such as digital cameras, video phones and computers can permit interaction between health workers and individual patients or groups of patients for education sessions. Dietary management and medication adherence support may be provided by mobile phone messaging; self-care may be enabled by technology-

mediated feedback on blood glucose levels on a daily basis. Quality of care may be enhanced by access to the latest evidence or decision-support tools; auditing may be supported by software that automates the analysis of raw data and integrates it with district health information systems.

Innovative strategies for clinical management, especially those which address monitoring of patients by technology-mediated communication with the diabetes care team, are being introduced in high resource settings. One of the key issues to be addressed is the cost-effectiveness of such IT-based systems [35] and the amount that an individual is willing to pay may well depend on their perception of risk. Furthermore, even in high resource settings, a patient's age and educational background may place limits on their ability to utilize IT [36]. In contrast, at present IT has limited applicability in low resource settings as these are characterized by no or very limited access to the Internet and a lack of familiarity with computers amongst health care workers. Even when a large health center or hospital has computers and Internet access, these are likely to be available to the managers or possibly large clinical areas, certainly not in individual consulting rooms, while such access in primary care settings is simply not to be had for the most part. Furthermore, patients coming from poor backgrounds are very unlikely to have access to the Internet.

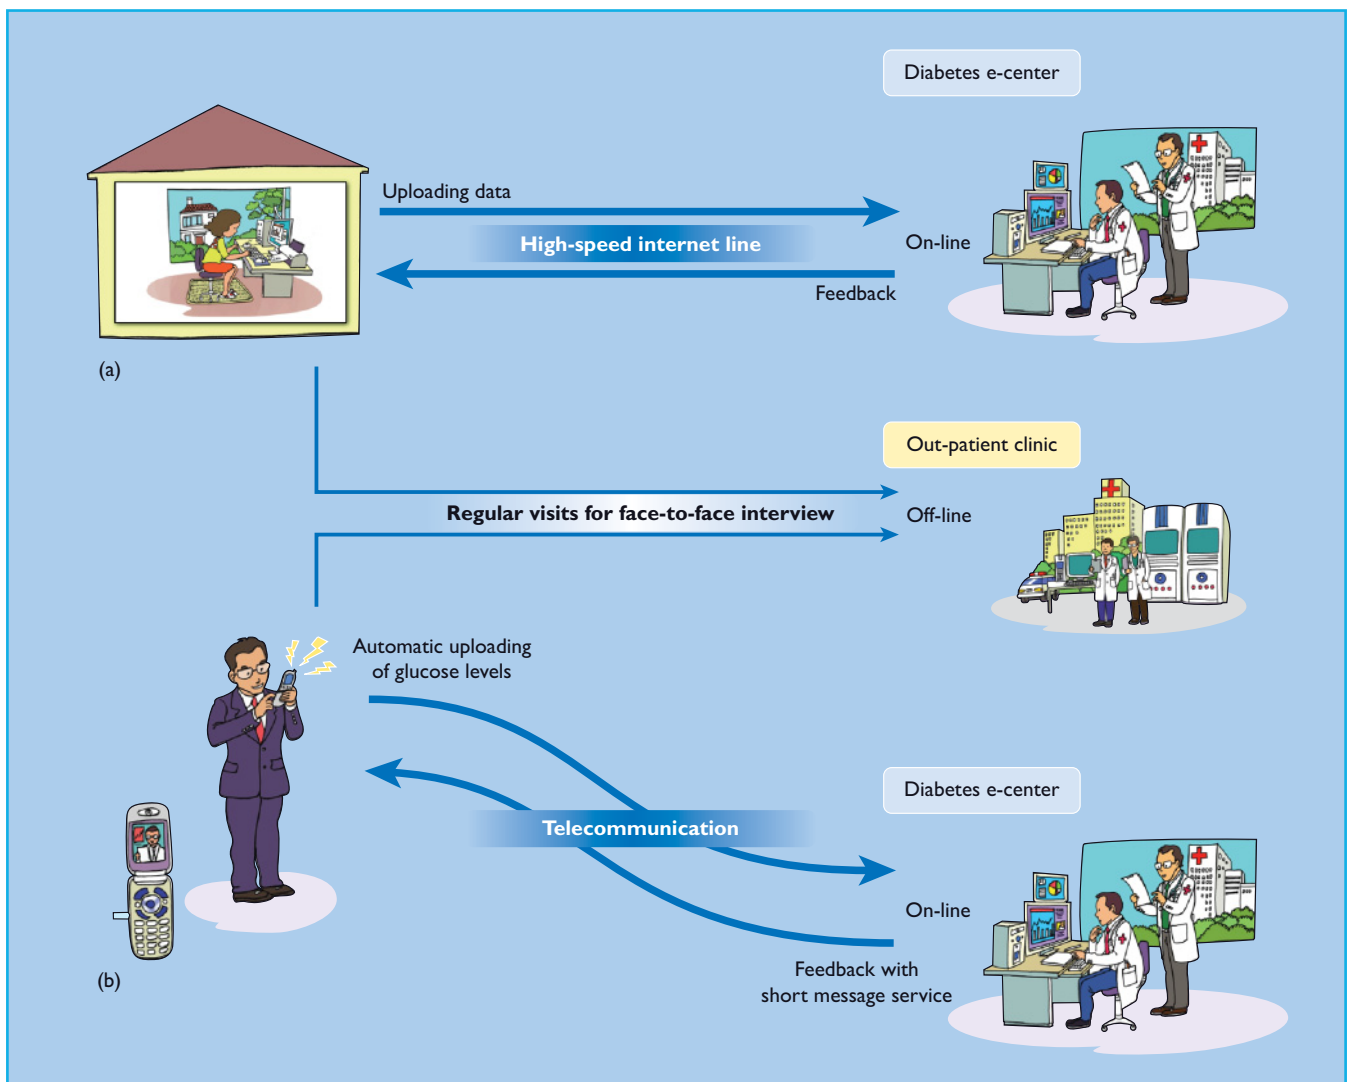

## Mobile phone-based telecommunication system to enhance patient self-care

Mobile phones, of all the currently available technologies directed at the patient, are likely to have the greatest potential use in low resource settings. This is because the digital divide along the socioeconomic gradient appears to be less evident with mobile phones than other forms of IT, such as the Internet [37,38]. Mobile phones are even to be found in remote villages, indicating the extent of their penetration in contrast to the lack of access to land lines in many rural areas; however, unlike the situation in well-resourced countries where the majority of mobile phone owners have a contract for a year or so, the usual practice in low income countries is one using prepaid phone cards and sharing of phones. If the IT involvement is simply related to the patient's receipt of messages to support their care, this may not have a negative impact, since even when phone use exceeds the amount paid, the phone may still receive messages, but may not be able to send outgoing communications.

In countries with better resources, mobile phones have been put to additional uses in diabetes care. A real-time telemedicine transmission system has been developed and tested. One system uses a blood glucose monitor connected to a general packet radio system mobile phone to enable transmission of patients' blood glucose levels [39] with subsequent feedback. Farmer *et al.* [40] demonstrated that real-time telemedicine was feasible and realistic in a randomized controlled trial. Further, the idea of measuring the blood glucose level directly from the mobile phone has also been introduced (Figure 58.2). Cho *et al.* [41] reported that the effect of the mobile communication system using the "diabetes phone" (Figure 58.3b) was not inferior to that of an Internet-

**Figure 58.2** Glucometer with telecommunication. Adapted from Cho *et al.* [41]. (a) The Diabetes Phone (Healthpia, Korea) has a glucometer in a battery pack (phone embedded type). (b) The glucometer can be directly connected to a cellular phone (Dongle type). (Gluco plus, Healthpia, Korea.)

**Figure 58.3** (a) The Internet-based glucose monitoring system (IBGMS). Patients logged on to the website from their homes or offices at a time they found convenient and uploaded their glucose data, together with additional information such as current drug information (type and dosage of oral hypoglycemic medications or insulin), lifestyle modifications and hypoglycemic events. In addition, patients recorded any changes in their blood pressure or weight, and any questions or detailed information that they wished to discuss,

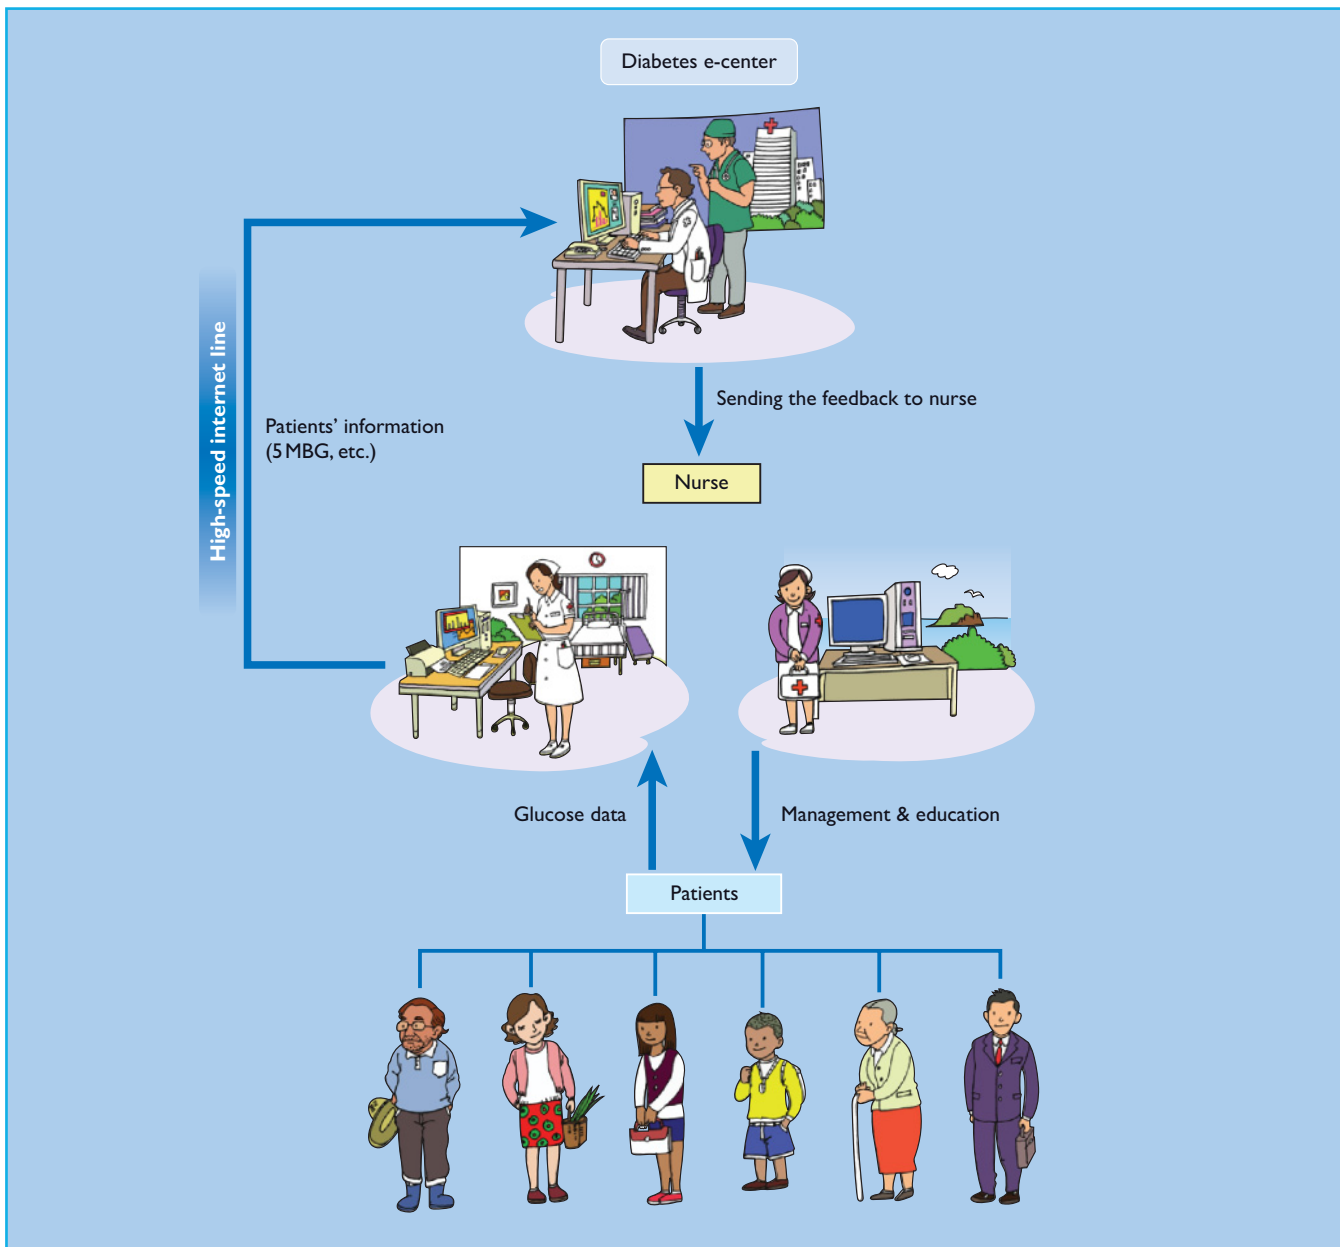

such as changes in diet, exercise, hypoglycemic events, and other factors that might influence their blood glucose level. (b) The telecommunication-based glucose control system in which mobile devices such as a mobile phone with the capacity to measure blood glucose were adopted. Patients could upload their information through telecommunication automatically and the patient–doctor communication could be achieved practically in real-time by the short message service. Adapted from Yoon *et al.* [42].

based glucose monitoring systems in terms of supervision, care and patient's satisfaction. The fact that text messaging on mobile phones is very limited represents a possible disadvantage for utilizing real-time telemedicine in providing information regarding blood glucose status. It is probable that the integration of medical equipment and mobile phones will be developed within the not-too-distant future.

### Technology-based access to the latest evidence and guidelines for health workers

IT can enhance interaction with and use of evidence-based guidelines by health workers even in low resource settings.

This can take the form of palm-held stand-alone personal digital assistant (PDA) devices or stand-alone tablets with periodic updating via Internet or CD ROM. The latter has been used successfully even in remote areas. Devices can contain reference material, evidence-based guidelines or automated decision trees. If Internet access is available, these devices can be used to access electronic databases from the consulting room. Such technologies need to provide information without interrupting the consultation process for health care workers facing serious time constraints. Additionally, the technology must not have a negative effect on the interaction between the patient and health worker.

**Figure 58.4** Technology-based clinical support. First, a nurse checks the self-monitoring of blood glucose (SMBG) data of patients and sends the patients' data, including SMBG data, to the endocrinologist. The endocrinologist reviews the patients' uploaded information and sends messages to the nurse. The nurse educates and manages the patients according to the endocrinologist's recommendations. Adapted from Yoon *et al.* [42].

### Technology-based clinical support

Certain aspects of diabetes care, such as retinal screening, lend themselves to mobile digital photography by fundal camera with transmission of photographs and reports via satellite or Internet between the peripheral and a central reporting site. Examples have been reported from relatively low resource settings in Africa and India [22,23]. Primary care providers can also be supported from referral centers via IT to improve the quality of clinical advice and decision-making. For example, in South Korea a nurse can send information regarding specific patients' glucose readings to an endocrinologist. The specialist can review the data uploaded and send advice on patient management (Figure 58.4) [42]. It is anticipated that the indirect communication system could eventually be applied to health workers living in low resource settings, thereby contributing to the gradual but definite development of universal IT-based diabetes management systems.

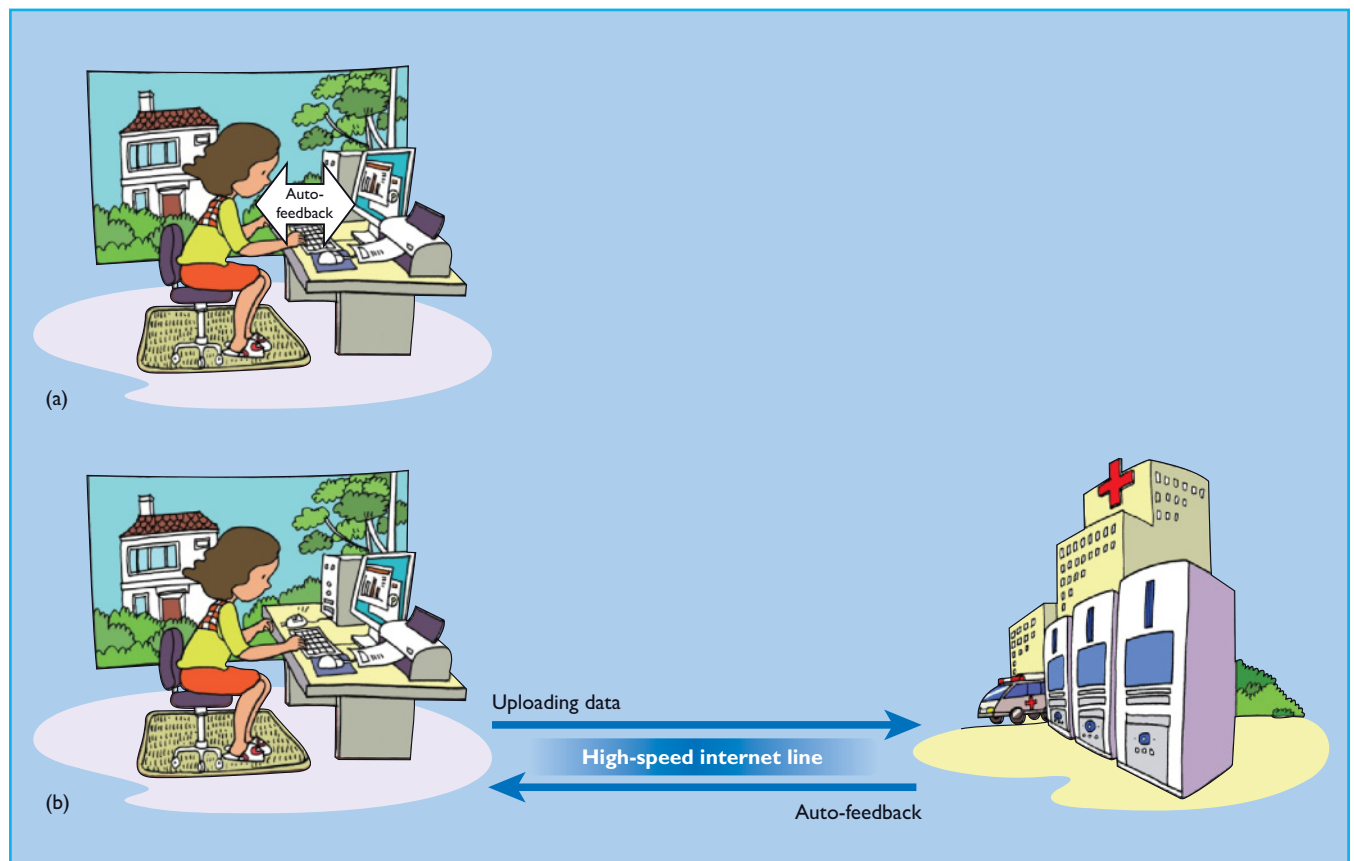

### Automated feedback systems to enhance patient self-care

People with diabetes can use their own personal computer to receive automated feedback on self-management (Figure 58.5a) [43]. Similar automated feedback on glucose levels can be obtained via the Internet (Figure 58.5b). In this situation, it is

imperative to have software or a decision support system that can make an appropriate recommendation on glycemic status. Meigs *et al.* [44] have developed and reported on the clinical applicability of a web-based decision support tool, the diabetes Disease Management Application. Although this system could be highly cost-efficient, long-term compliance and satisfaction could be limited because of lack of flexibility and human contact.

### Interactive feedback systems to enhance patient self-care

Internet-based interactive communication systems enable two-way communication between patients and their physicians via the Internet (Figure 58.3a). Systems are still cost-efficient and yet are more personalized [45]. Options range from utilizing e-mail to developing a private homepage to share clinical information [46]. For instance, Kwon *et al.* [47] reported a short-term reduction in HbA<sub>1c</sub> through the effect of an Internet-based glucose monitoring system (IBGMS), in which patients and doctors shared a web-chart (Figure 58.6). Patients uploaded their glucose data to the remote web server and their doctors provided advice after interpreting the data [47]. The idea of integrating web-based communication with the hospital's own electronic medical record charting system was also introduced [48]. Cho *et al.* [49] reported that the longest prospective study (30 months) of an IBGMS in

**Recommendation**

**Figure 58.6** Screen viewed by patients and physicians on the website for diabetes management (www.biodang.com). Basic profile, past history, family history and laboratory data are shown on the top. Self-monitored blood glucose levels are shown (middle), which are recorded as fasting or post-prandial (breakfast, lunch and dinner). Drug information, notes from the patients and recommendations from the physicians are shown at the bottom. Reproduced from Kwon *et al.* [47] with permission from the American Diabetes Association.

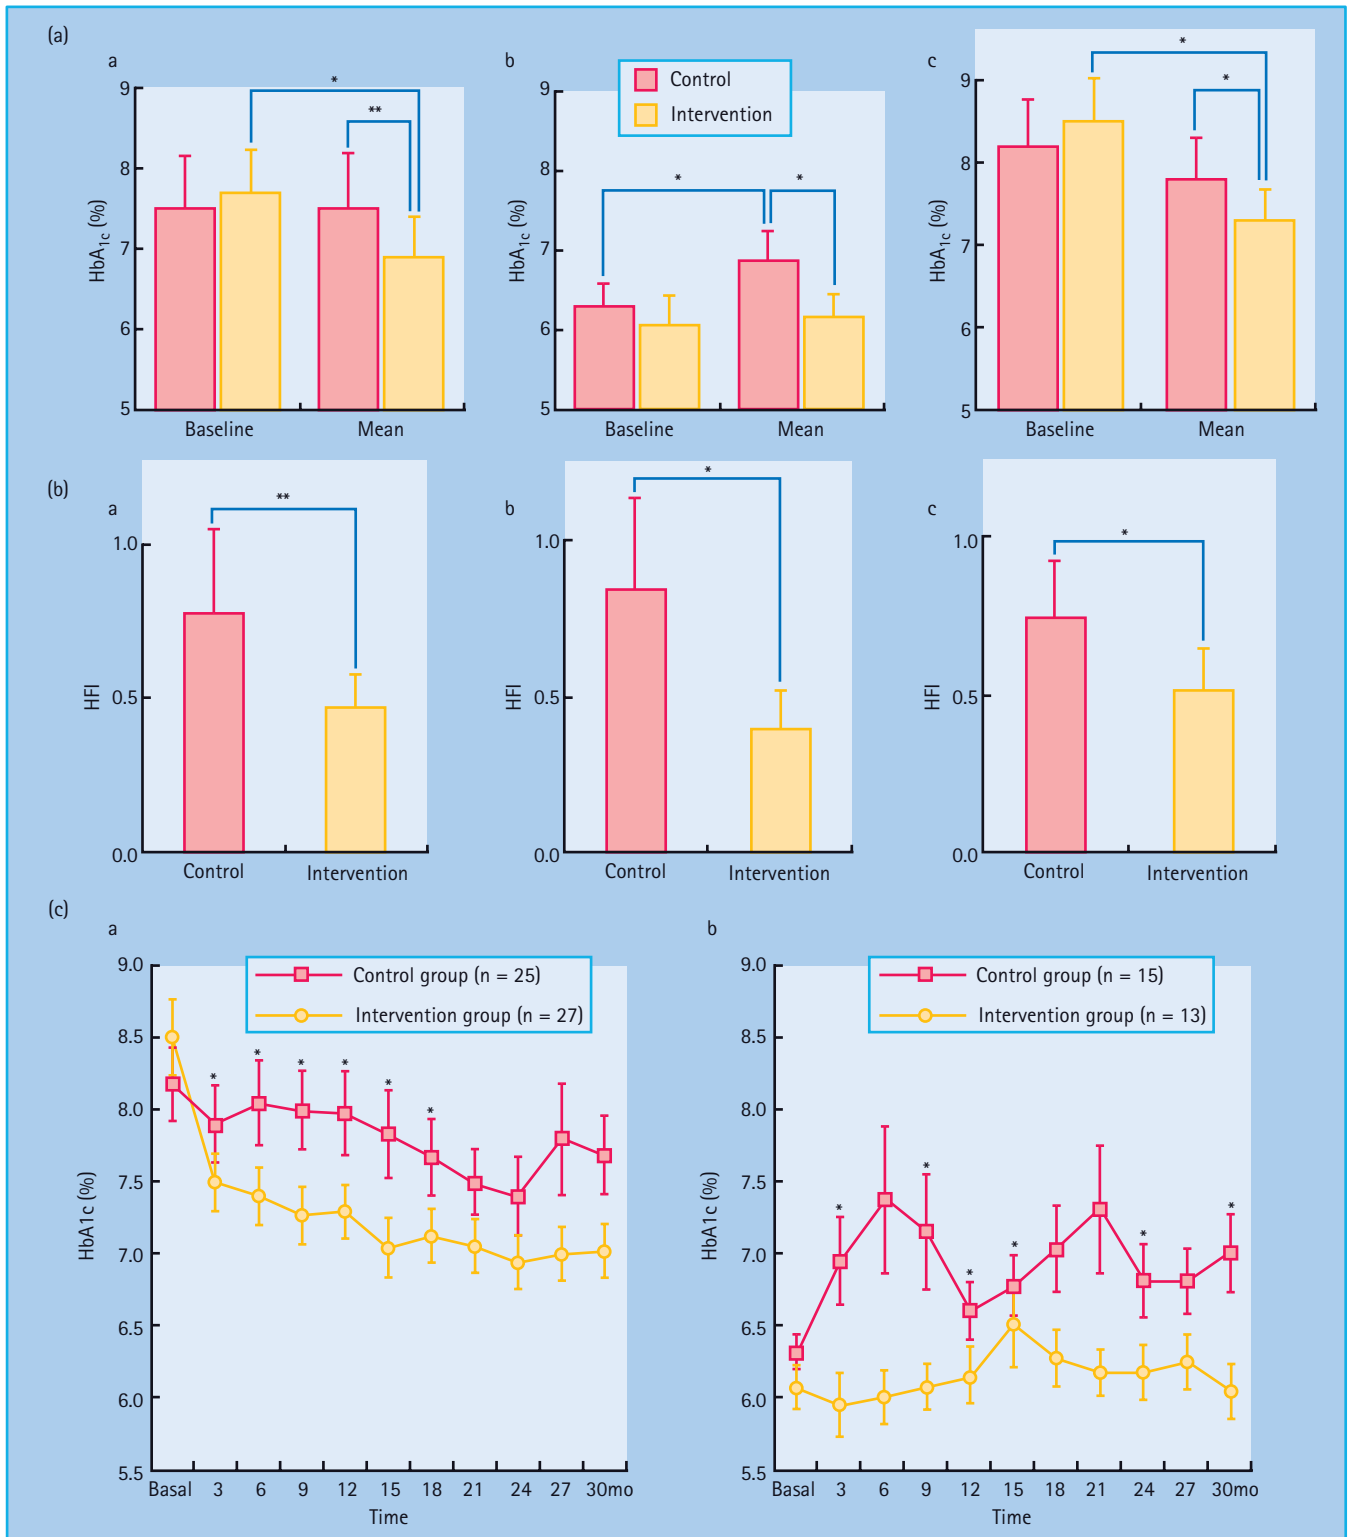

diabetes was effective in reducing HbA<sub>1c</sub> (Figure 58.7). Uniquely, this system not only provides periodic advice and feedback, but also allows continuous support for glucose control, frequent encouragement, problem assessment and individualized education about diet, exercise and drug modification, thereby providing a comprehensive caring system for patients with diabetes. Montori *et al.* [50] used a telecare system using a modem for patients with T1DM receiving intensive insulin therapy. When the patient deviated from the desired glycemic control, the glucose analysis software assisted nurses to interpret the patient's

status and provide feedback to the patient. Even more specialized systems have been developed for women with gestational diabetes [51].

### Merged feedback systems to enhance patient self-care

In order to develop a more efficient system, the time required from health care providers should be minimized, while preserving some communication between patients and health care providers when absolutely necessary. Recently, a system was piloted that will respond automatically when the glucose level is accept-

**Figure 58.7** The effects of intervention (Internet-based glucose monitoring system [iBGMS]) on changes of HbA<sub>1c</sub> and glucose stability. A: Baseline HbA<sub>1c</sub> and mean HbA<sub>1c</sub> during the study 30-month period. (a) All subjects, control (n = 40) vs intervention (n = 40). (b) Subjects with a basal HbA<sub>1c</sub> < 7%, control (n = 15) vs intervention (n = 13). (c) Subjects with a basal HbA<sub>1c</sub> ≥ 7%, control (n = 25) vs intervention (n = 27). B: Difference of HbA<sub>1c</sub> fluctuation index (HFI) between the control and intervention groups. (a) All subjects. (b) Subjects with a

basal HbA<sub>1c</sub> < 7%. (c) Subjects with a basal HbA<sub>1c</sub> ≥ 7%. C: Fluctuating line of HbA<sub>1c</sub> for the 30 months. (a) Subjects with a basal HbA<sub>1c</sub> ≥ 7%. (b) Subjects with a basal HbA<sub>1c</sub> < 7%. At each follow-up point, ≥90% of patients took the test. \*P < 0.05; \*\*P < 0.01. DCCT aligned HbA<sub>1c</sub> of 7% is equivalent to IFCC HbA<sub>1c</sub> of 53 mmol/mol. Reproduced from Cho et al. [49] with permission from the American Diabetes Association.

able, but which will involve a health care provider for further evaluation when the result is abnormal. Cho *et al.* [52] reported the effect on labor savings of a semi-automatic response system for glucose control. The system, which had an algorithm-based glucose decision engine, reduced physicians' labor time by nearly 50% while preserving interactive communication between patients and physicians. Simple algorithm-based programs are inadequate to meet the complexity of clinical decision-making, however, and in the future artificial intelligence-based programs may be developed to handle more complex data.

#### Internet-based health education and primary prevention

The Internet has been used as a medium for a weight loss program to prevent diabetes [53] and as part of a walking program for patients with T2DM. The latter had a more significant effect on patients' physical activity and reduction of depressive symptoms, compared with the conventional method of sharing physical activity information [54]. An Internet and mobile phone intervention was found to improve cardiovascular risk factors for both T1DM and T2DM groups [55]. Additionally, a mobile diabetes education and care system brought beneficial effects in children and young people with T1DM in a rural area [56].

#### Automatic data uploading system for more convenience

An automatic data uploading system has been introduced in South Korea to achieve more convenient IT-based communication system. This system allows for self-monitored glucose data measured with a home glucometer (OneTouchUltra, Lifescan, USA) to be sent to the patient's web chart via Internet by simply connecting it to a personal computer. Physicians can view the automatically uploaded glucose data on the web chart and send messages to the patient.

#### Electronic patient records and decision support

The electronic health record is a longitudinal electronic document of a patient's health information generated by one or more encounters in any care delivery setting. This information may include patient demographics, progress notes, problems, medications, vital signs, past medical history, immunizations, laboratory data, radiology reports, etc. The electronic health record automates and streamlines the clinician's workflow, it has the ability to generate a complete record of a clinical patient encounter – as well as supporting other care-related activities directly or indirectly via interface – including evidence-based decision support, quality management and outcomes reporting [57].

Various clinical decision supporting systems have been developed, which are able to provide diagnostic and therapeutic services to both clinicians and patients by using electronically recorded health data. Advanced development in IT not only guarantees efficient communication between an individual and a medical institution, but also makes possible for the medical institutions themselves to share information efficiently. Massin *et al.* [58] sent retinal images (non-mydratric photography) of people with diabetes to a reading center for diagnosis and follow-up of

diabetic retinopathy. Recently, efforts to standardize medical terminology and interfaces among devices and communication systems have been made.

#### Management and health information systems

A variety of personal health information systems have been developed and some are currently used for disease management, including diabetes. Several countries with good IT infrastructure already have commercialized various diabetes management systems. Mycareteam uses web-based software to facilitate diabetes management by allowing interactive communication between patients and their physicians or family members ([www.mycareteam.com](http://www.mycareteam.com), Mycareteam Inc, USA). A similar web-based service system in which patients can communicate with the diabetes-specialist care team consisting of a nurse, nutritionist and exercise therapist was introduced to improve glycemic control of women with pregnancy-associated diabetes ([www.cared.co.kr](http://www.cared.co.kr), C&I Healthcare Co., Republic of Korea). Growing numbers of health care companies in the USA are using IT tools for their care solutions instead of traditional telephone-based services. Alere provides a diabetes management program mainly focusing on education and ensuring that patients adhere to the physician's directions and clinical guidelines using web-based tool and telephone interactions ([www.alere.com](http://www.alere.com), USA). By establishing evidence showing an improvement in the quality of disease care, eventual medical cost reduction and improvement in patients' satisfaction, the IT-based health care market could increase.

#### Addressing economic hurdles

In the first instance, it is essential to determine the cost-effectiveness of IT. Cho *et al.* [59] reported a simulation study indicating that the IBGMS could save \$27 666 of direct cost per person for 35 years compared to a conventional face-to-face interview system in an outpatient clinic. Johnson *et al.* [60] reported that individuals were willing to pay \$1500 over 3 years to participate in a lifestyle intervention program similar to the diabetes prevention program. This indicates that individuals with a high risk of diabetes are willing to pay more than individuals with lower perceived risk. An IT-based patient care system sounds tempting but, once again, the key to its feasibility lies in cost-effectiveness even in high resource settings.

#### Addressing difficulties in IT use

Although Internet access is increasing worldwide, there is still a limited pool of people who can use IT without difficulties. Thus, an Internet-based diabetes care system must address and overcome its limitations before application. Watson *et al.* [61] reported that patients with diabetes with no experience of the Internet or media communication are enthusiastic about adopting future health information technology for their diabetes care. Furthermore, Jackson *et al.* [62] showed that among African-Americans with a lack of computer skills, 66% were willing to learn and 89% were willing to use a computer program to manage their diabetes, if it were offered free of charge. From this evidence,

the potential users for IT-based diabetic care should not be underestimated [61].

### Advances in the near future

It is believed that the dramatic development of IT and its application to health management systems will have a crucial role. Simple IT management models for controlling blood glucose levels for patients with diabetes will definitely evolve into much more complex models, in which various technologies are integrated in order to provide the complex management required. Technologic gadgets may be directly connected to a communication system to transmit a patient's current status and past data. For example, a physical activity monitor (Lifecoder, Suzuken, Japan; Actical, Philips, USA) could be integrated into the health information system for monitoring real-time physical activity.

These innovative technologies can also be applied to other chronic diseases such as hypertension and rheumatoid arthritis. It is important to develop software that can integrate efficiently and process the constant flow of incoming data. To achieve this, we must keep in mind that simple algorithm-based programs are not enough to meet the challenges of medicine; rather, artificial intelligence-based programs will be necessary to handle the complex data and to provide economic benefits by lowering the human labor and costs. Communication systems that are not hindered by time and space are also needed. Information technology should never be seen as an end in itself, but as a tool to complement other aspects of holistic patient-centered diabetes care.

### Keypoints

- Insulin replacement therapy is considered the only effective and feasible treatment for type 1 diabetes mellitus (T1DM) as only insulin is capable of reversing the metabolic disturbances and restoring a near-normal quality of life in patients with T1DM.
- Despite rigorous measures and major advances in health care provided for patients with T1DM, increased morbidity and mortality are still common from complications, which commonly develop within 10–12 years after clinical onset.
- Advances in the understanding of the natural history of T1DM and increased abilities to predict the disease have made it possible to design and implement prevention and intervention clinical trials.
- Clinical trials are aimed at: (a) preventing the initiation of islet autoimmunity (primary prevention); (b) reducing autoimmune  $\beta$ -cell killing and progression to clinical diabetes (secondary prevention); or (c) suppressing or modulating the immune response in order to halt  $\beta$ -cell killing and enhance  $\beta$ -cell regeneration (tertiary prevention or intervention).
- Several trials were implemented or are currently ongoing with dietary manipulation, parenteral or oral insulin or immune-suppressing or immune-modulating agents with the aim of preventing the disease or retarding its progression.
- The search for safe, effective and feasible drugs to prevent or cure T1DM is still ongoing. So far, immune modulation with alum-formulated GAD65 has been shown to be the most promising intervention to reduce the loss of  $\beta$ -cells. Anti-CD3 monoclonal autoantibodies also showed some benefits in patients with newly diagnosed T1DM.

### Introduction

The pathophysiologic mechanisms in type 1 diabetes mellitus (T1DM) are proposed to progress over several stages, in which autoimmunity is triggered in genetically predisposed individuals and in which  $\beta$ -cell killing by cellular immunity is activated, leading to insulin deficiency [1]. The autoimmune insult, which leads to selective killing of  $\beta$ -cells, may take months to years to develop. Throughout this autoimmune prodrome several genetic, autoimmune and biochemical markers may predict the disease prior to clinical onset. Once the clinical disease is established, the patient will be dependent on exogenous insulin and will require strict control to sustain euglycemia and minimize complications. Shortly after clinical onset of diabetes and initiation of insulin treatment, the remaining  $\beta$ -cells often increase their capacity to produce insulin, thereby decreasing the need for insulin treatment. This period of low insulin requirement, known as “partial remission” or the “honeymoon” period, may last for months or even years and is advantageous for the patient because it simplifies treatment and improves metabolic control, leading to less risk of long-term complications [2]. The “honeymoon” period seems

to be longer and appears more frequently in older children and adults than in children diagnosed at a younger age [3].

Several trials seeking to prevent or delay the clinical onset of T1DM in genetically predisposed individuals as well as attempting to spare or even improve residual  $\beta$ -cell function in recently diagnosed patients are planned, implemented or currently ongoing.

### Short history of type 1 diabetes prevention trials

Several approaches to modulate the immune system have been tested to prolong the partial remission in newly diagnosed patients. In the 1980s, plasmapheresis was performed in patients newly diagnosed with T1DM. A tendency of improved residual  $\beta$ -cell function and metabolic control was observed [4]. Later, several attempts with immune-modulating drugs were carried out. In order to suppress the immune response against the  $\beta$ -cells, small doses of cyclosporine were administered in a pilot study to autoantibody-positive first-degree relatives (FDR) of patients with T1DM with decreased first-phase insulin release (FPIR). The drug increased the FPIR, suggesting that cyclosporine may delay the onset of T1DM in glucose-intolerant siblings [5]. Cyclosporine was further tested in the Canadian–European Randomized Control Trial [6] as well as in series of controlled or uncontrolled smaller studies [5,7]. It was found that cyclosporine temporarily

reduced insulin requirement and enhanced endogenous  $\beta$ -cell function in patients with newly diagnosed T1DM [6]. Although cyclosporine had some effect on preserving  $\beta$ -cell function, further clinical trials were abandoned because of severe kidney lesions [6,8]. Other immunosuppressive drugs such as azathioprine were also tested, either alone [9] or with prednisolone [10]. These immunosuppression trials had verified the immunopathogenic basis of T1DM, indicated by improved indicators of  $\beta$ -cell function in some trials; however, the outcomes were hard to maintain because of concerns about serious side effects [5,7].

Concerns about safety and sustainability of therapeutic effects directed attention towards the search for other preventive agents, with the focus on initiating preventive trials based on the stages of disease progression; however, our understanding of the natural history of T1DM made it possible to identify highly predictive markers (genetic, immunologic and metabolic) and recognize putative etiologic factors and possible intervention methods.

Several studies tested non-antigen-specific agents as possible preventive agents. The Bacille Calmette–Guérin (BCG) vaccine was found to prevent T1DM in experimental animals such as the non-obese diabetic (NOD) mice [11] and the bio-breeding (BB) rat [12]; however, similar results were not achieved in a group of human pilot studies [13,14]. The histamine antagonist, ketotifen [15], used orally in a pilot study in islet cell antibody (ICA) positive children with low FPIR showed no significant effect. Nicotinamide (vitamin B<sub>3</sub>) protected  $\beta$ -cells in rodent studies [16] and so the effect of nicotinamide was tested in the European Nicotinamide Diabetes Intervention Trial (ENDIT) [17]. Nicotinamide was administered orally to ICA-positive FDR of patients with T1DM but the drug did not prevent progression to diabetes. High doses of nicotinamide were tested in other efficacy studies such as the DENIS [18] but this study also failed to show beneficial effects among high-risk children. Additionally, a group

of pilot studies tested the combination of nicotinamide with cyclosporine [19], vitamin E [20] or intensive insulin regimen [21], none of which showed a preventive effect. These studies showed that nicotinamide could not protect against the loss of  $\beta$ -cells in high-risk subjects and overall no significant beneficial effects were detected.

Insulin, as an antigen-specific agent, has been tested through different routes, parenteral [22], oral [23] or intranasal [24,25] in genetically predisposed individuals, FDR and patients with T1DM in several trials. These trials showed no effect on disease progression or the rate of  $\beta$ -cell loss; however, subanalysis from the oral arm of the Diabetes Prevention Trial-1 (DPT-1) revealed a statistically significant delay in onset of T1DM in subjects with high titer insulin autoantibodies (IAA). A repeat study of the oral insulin trial has therefore been initiated.

Several prevention and intervention trials with long follow-up durations, some even including a combination of therapies, are now ongoing or planned. These trials use different approaches, with goals of preventing the triggering of autoimmunity (primary prevention), halting  $\beta$ -cell destruction (secondary prevention) or preserving remaining  $\beta$ -cells and enhancing their regeneration (tertiary prevention). This chapter presents an evidence-based review of the main ongoing drug clinical trials in subjects at-risk for or in those with newly diagnosed T1DM.

## Prediction

Since the late 1970s, several studies have indicated that it is possible to predict T1DM among FDR through testing for human leukocyte antigen (HLA) class II genes and IAA. Several such studies utilized HLA genotyping, islet autoantibody analyses and biochemical indicators, as predictive markers are currently ongoing (Table 59.1). These prospective screening studies, may

**Table 59.1** Some of the recent or ongoing screening studies for T1DM in first-degree relatives or high-risk children in the general population.

Study	Screening period	Screening population	Country

The Environmental Determinants of Diabetes in the Young (TEDDY)	2004–	Multicenter study of high-risk children in general population	Sweden (Skåne), Finland, Germany, USA (Colorado, Florida, Georgia, Washington)

allow us to define the environmental factors that may trigger islet autoimmunity or accelerate the development of T1DM in subjects with islet autoimmunity. These studies should make it possible to follow the disease process from initiation to the clinical onset of T1DM to help us understand the course of events during  $\beta$ -cell autoimmunity. At the same time, our knowledge about patterns of disease markers during subclinical disease and the predictive value of islet cell autoantibodies should be improved.

Predicting a disease at an early stage of pathologic insult is a prerequisite for attempts to prevent disease progression and initiating interventions to ameliorate symptoms and reduce complications. T1DM fulfils the criteria for predictable disease:

**1** Genetic markers, specifically HLA class II genes, assist in recognizing individuals at higher risk who are eligible for autoimmune testing and follow-up [26].

**2** T1DM has a prolonged prodrome of islet autoimmunity during which cellular and humoral immune markers may be present as early as the perinatal period [27] and remain detectable for months up to several years before onset.

**3** Standardized and validated assays have been developed to detect multiple islet autoantibodies with high degrees of diagnostic sensitivity and specificity [28].

**4** The extent of  $\beta$ -cell loss and the remaining function may be indirectly evaluated by assessing FPIR and C-peptide levels, for example [29].

Combining these markers provides highly predictive tools that may help to identify individuals at risk and initiate prevention or intervention at an appropriate point in time.

Currently, exogenous insulin injection is the only therapeutic measure that is able to correct hyperglycemia and enables patients with T1DM to live an almost normal life. Nevertheless, complications are common and may develop within 10–12 years after onset even with adequate metabolic control [30,31]. Prediction of T1DM may provide a window of opportunity to initiate prevention programs to reduce or ideally to prevent  $\beta$ -cell destruction. Identifying susceptible individuals prior to the clinical onset may allow an early and symptom-free diagnosis of diabetes and prevent an otherwise acute T1DM. This is crucially important to prevent the life-threatening condition of diabetic ketoacidosis (DKA) [32], which is commonly seen in children <4 years of age and associated with high morbidity and mortality.

### Genetic markers

Much of our knowledge about prediction of T1DM has been generated from studies on FDR of patients with T1DM. These studies have revealed that T1DM can be predicted in siblings of patients with diabetes with analysis of HLA genotypes, number of islet autoantibodies and the titer of IA-2Ab [33]. HLA-identical siblings are at greater risk of developing autoantibodies and T1DM than are non-identical siblings.

Almost 50% of T1DM risk among FDR of Caucasian patients with T1DM is attributed to HLA [34]. One or both of the high-risk class II DQ8 and DQ2 haplotypes were found in more than 90% of patients diagnosed before the age of 30. Additionally,

nearly 50% of siblings who carry high-risk HLA genes develop islet autoimmunity by the age of 3 years [35]. By contrast, only 15% of children developing T1DM have FDR with the disease. Therefore, screening of the general population is necessary in order to find a majority of children who are susceptible to T1DM. The diagnostic sensitivity of large-scale genetic screening is low because only 10% of subjects with disease-associated HLA genes develop the disease [36]. Nevertheless, several studies such as the BABYDIAB [37], DAISY [38], DiPiS and TEDDY [39], involving genetically susceptible individuals, continue to improve our understanding of the etiopathologic mechanisms of T1DM. Furthermore, the frequencies of DR-DQ alleles within the high-risk haplotypes DR3-DQ2 (*DRB1\*03-DQA1\*0501-B1\*0201*) and DR4-DQ8 (*DRB1\*04-DQA1\*0301-B1\*0302*) vary among different populations [40]. Indeed, T1DM in Asians is associated with HLA haplotypes other than those in Caucasians, indicating that screening strategies may need to be tailored to the population at hand [41]. Longitudinal studies will identify the relationship between HLA variants and the contribution of environmental factors to risk of T1DM. Other non-HLA genetic markers such as *INS-VNTR*, *PTPN22*, *IL2RA* and many others have also been identified [42]. The role of these non-HLA genetic factors in the pathogenesis of islet autoimmunity needs to be clarified, but the relative risk of these genetic factors is shown to be less than that of the HLA genes [42]. HLA and some of the non-HLA genes may be associated with the presence of islet autoantibodies and progression to persistent autoimmunity [43–47]. Combining genetic and autoimmune markers does not improve diagnostic sensitivity of autoantibody testing although the overall positive predictive value may increase.

### Autoimmune markers: islet cell autoantibodies

The appearance of diabetes-associated autoantibodies is the first measurable sign of the autoimmune process that eventually leads to T1DM. In 1974, autoantibodies to pancreatic cells were described for the first time [48,49], providing evidence for T1DM being an autoimmune disease. These autoantibodies were named islet cell autoantibodies (ICA) and were detected by immunofluorescence in patients with T1DM. Later, ICA were detected in one patient a year before T1DM onset and in one twin without diabetes who later developed the disease [48], providing the first evidence of an ongoing autoimmune process before the clinical onset of T1DM. ICA are not specific for  $\beta$ -cells and probably represents several different specific autoantigens.

The first autoantigen demonstrated was a Mr64K protein immunoprecipitated by sera from patients with T1DM [50], which was later demonstrated to have glutamic acid decarboxylase (GAD) activity [51], but found not to be a previously recognized isoform of glutamic acid decarboxylase (GAD65) [52]. GAD65 converts glutamic acid to  $\gamma$ -aminobutyric acid (GABA), an inhibitory transmitter in the CNS. GAD65 is primarily present in specific neurons in addition to the pancreatic islet  $\beta$ -cells. Autoantibodies to GAD65 (GAD65Ab) are present in 55–60% of children with T1DM at onset of the disease.

In 1983 autoantibodies to insulin (IAA) were found to be present in patients with diabetes before insulin treatment [53]. This finding suggested that IAA had a role in the autoimmune process of diabetes. IAA are not detected by the immunofluorescence test for ICA. IAA are present in about 35–40% of children with T1DM at onset of the disease.

A third autoantigen, also found to contribute to the ICA reaction, is the insulinoma-associated protein 2 (IA-2), identified in 1996 [54]. IA-2 is a non-functional member of the protein tyrosine phosphatase family. It is localized to the membrane of the secretory vesicles in endocrine and neuronal cells [55]. IA-2 is expressed in both islet  $\alpha$  and  $\beta$ -cells, but the function is still unknown because it lacks enzymatic activity. Autoantibodies to IA-2 (IA-2Ab) are directed to the intracellular protein domains [55]. IA-2Ab are present in about 70% of children with T1DM at onset of the disease.

Most recently, autoantibodies to a fourth islet autoantigen, zinc transporter 8 (ZnT8Ab), were reported in patients recently diagnosed with T1DM [56]. This autoantigen is highly  $\beta$ -cell specific. ZnT8 is a protein located in the membrane of the secretory vesicles of the  $\beta$ -cells acting as a zinc ion transporter. Recently, ZnT8Ab have been found in 60–65% of patients with T1DM, compared to <2% in controls [56]. ZnT8Ab are independent markers of islet cell autoimmunity and were detected in otherwise IAA-negative individuals. Furthermore, ZnT8Ab were found to appear and precede disease onset in prospectively studied FDR of patients with T1DM and high-risk individuals from the general population.

Some patients are positive for ICA, but negative for both GAD65Ab and IA-2Ab, suggesting that there are additional, as yet undiscovered, antigens covered by ICA. Some of those patients may have ZnT8Ab. More than 90% of patients with T1DM have previously been reported to have ICA, GAD65Ab, IA-2Ab or IAA at diagnosis. The corresponding number for the general population is about 1% [57]. With the addition of ZnT8Ab to the combined analysis of GAD65Ab, IA-2Ab and IAA, up to 95% of all individuals developing T1DM are positive for at least one autoantibody.

In addition, several other proteins have been proposed as candidate autoantigens (see Chapter 9). Further studies are needed to establish the possible importance of these additional autoantigens for T1DM risk. It is possible that all diabetes-associated autoantibodies have not yet been discovered.

Individuals with clinical T1DM and absence of autoantibodies at diagnosis may still have had an ongoing autoimmune process leading to  $\beta$ -cell destruction. It has been found that 25% of children with T1DM with negative autoantibodies at diagnosis of the disease had autoantibodies present in their cord blood [58].

In genetically predisposed children, detecting islet autoantibodies as early as 3 months of age was associated with high seroconversion rates, where IAA and GAD65Ab often preceded ICA and IA-2Ab appeared last [59,60]. These autoantibodies seem to appear sequentially, with the appearance of additional autoantibodies usually taking place within a year after the detection of the

first one [36,61]. While a single autoantibody may be harmless and often represents non-progressive  $\beta$ -cell autoimmunity, the appearance of multiple autoantibodies most often reflects a progressive process [62–66]. The number of detectable autoantibodies is related to the risk of T1DM, both in FDR and in the general population. In studies of family members of patients with T1DM, 60–100% of individuals with three or more autoantibodies develop clinical T1DM over the next 5–6 years and population-based studies indicate that the risk is similar in the general population [67–69]. The autoantibody pattern differs among age groups. It has been suggested that GAD65Ab is a marker of general non-specific autoimmunity, while IA-2Ab and IAA are more specific markers for  $\beta$ -cell death [70]. The recently discovered ZnT8Ab has been reported to appear generally after 3 years of age and thereafter to increase in frequency with age up to adolescence [56].

Titers of the islet autoantibodies need to be taken into consideration for prediction. Higher titers may better predict risk of persistent autoimmunity and T1DM [33,62,64,66], especially in combination with a high-risk HLA genotype [64,71]. Persistent detection of high titer autoantibodies may mirror the intensity of the autoimmune reaction and the rate of progression to clinical diabetes [64].

In studies of the general population, GAD65Ab and IA-2A have been shown to be of equal predictive value as they are in FDR siblings, but for each separate autoantibody a higher cumulative risk was observed among the siblings. Double autoantibody positivity confers a similar cumulative risk among siblings and the general population [69], with additional predictive information provided by the level of the autoantibodies [64]. In one study of school children, the positive predictive value of multiple autoantibodies in the general population was 25–75%, with a sensitivity of 58–100%, not taking HLA genotypes into account [67].

### Biochemical (metabolic) markers

Children progressing to T1DM have been shown to have several autoantibodies, high titers of ICA, IA-2Ab and GAD65Ab and decreased FPIR in response to an intravenous glucose tolerance test (IVGTT). A combination of islet autoantibodies and FPIR might therefore potentially predict diabetes [62]. In one study, siblings of children with diabetes were also examined at the time when the index case was diagnosed. Islet autoantibodies alone predicted T1DM in 36%, but when FPIR was taken into account the rate of prediction increased to 56%, with a median observation time of 3.6 years. A young age, a strong humoral response and reduced FPIR seemed to characterize individuals with a progressive process [62]. Additionally, reduced FPIR levels (<50 mU/L) among autoantibody-positive subjects (mainly ICA or IAA) may predict T1DM among FDR by up to 92% over 10 years [29]. C-peptide may predict  $\beta$ -cell functional loss near diagnosis because C-peptide levels may diminish significantly 6 months prior to onset [72]. Therefore, combining these two tests may detect metabolic disturbances and predict the disease prior

to clinical onset, especially when monitored in parallel with autoimmune markers. Children developing diabetes in the DPT-1 study had a gradually deteriorating glucose tolerance with declining 2-hour C-peptide levels after an oral glucose tolerance test (OGTT) [73]. These data were seen over a period of at least 2 years before onset of disease, despite the fact that fasting C-peptide levels remained stable [73]. Moreover, among ICA-positive subjects recruited in the DPT-1 trial, an alternative OGTT index (using area-under-the-curve glucose, 60 and 90-minute glucose, instead of 2-hour glucose) was shown to have better predictive criteria than the standard OGTT, especially when combined with C-peptide measurement from the alternative OGTT [74].

Body mass index (BMI) has also been reported to give additional information in T1DM prediction [75]. It has also been reported that a normal but rising HbA<sub>1c</sub>, a measure that is proportional to the average blood glucose in the previous 120 days, predicts clinical onset of diabetes in autoantibody-positive children [76].

### Other markers

The search for additional biomarkers to predict T1DM is ongoing. Cytokines, chemokines and adhesion molecules are proposed as important inflammatory mediators in the pathogenesis of T1DM (for review see Purohit and She [77]). Antigen-specific T-lymphocytes are also proposed markers for T1DM prediction, but standardized tests to detect these markers have yet to be developed.

---

## Prevention and intervention

Several clinical trials aiming to prevent T1DM have been initiated during the past two decades; some have been completed and others are still ongoing. The general aim of prevention is either to prevent islet autoimmunity from happening or retard the autoimmune destruction of  $\beta$ -cells, or alternatively to preserve remaining  $\beta$ -cell secretory capability before clinical diagnosis. The aim of intervention is to interfere with the natural history of T1DM after the clinical diagnosis. The idea of intervention is to stop or halt the killing of  $\beta$ -cells and preserve  $\beta$ -cell secretory function in patients who have already developed clinical diabetes. Therefore, scientists continue to test new drugs with attempts to halt one or both of these stages. The rationale behind reported prevention and intervention has often been obtained from studies on laboratory animals such as the NOD mouse and BB rat [78–80]. Significant differences exist, however, between these animals and humans; therefore a successful intervention in these animals may not have the exact same effects in humans. Moreover, factors such as the duration of the intervention, the stage of enrolment and drug dosage and safety may influence the outcome. These factors, in addition to the complexity of the etiopathogenesis of T1DM, may explain why little success has been achieved so far in prevention or intervention of T1DM.

All three levels of disease prevention (primary, secondary and tertiary) may be applicable to T1DM.

### Primary prevention trials

Primary prevention trials aim to prevent the initiation of autoimmune responses among infants with genetic susceptibility (high-risk HLA genes) or history of T1DM among FDR. Several attempts to prevent T1DM in relatives of patients with the disease have been performed over the years. Such trials are often implemented for longer follow-up durations, especially during the main window of autoimmunity triggering (from birth to 6 years) [81]. Primary prevention trials tend to test the effects of safe, mainly non-antigen-specific agents in relation to environmental risk determinants, of which nutritional factors are important. Results from observational studies encouraged trials that use dietary manipulation to prevent T1DM (Table 59.2).

### Non-antigen specific primary prevention trials

#### *Gluten-free diet*

A gluten-free diet was given to islet autoantibody-positive children without any significant preventive effect neither on the risk of T1DM nor on the titers of T1DM-associated autoantibodies [82].

#### *Cow's milk*

There are several suggestions that cow's milk may be associated with higher risk of T1DM [83]. Dietary manipulation using hydrolyzed casein milk formula provided evidence of preventive effect on the risk of T1DM [84,85]. The TRIGR trial is an international effort involving 17 countries to verify if hydrolyzed casein milk formula can reduce T1DM risk among infants at risk (genetically predisposed infants with history of T1DM among FDR), if used instead of cow's milk. Following a period of 6–8 months' breastfeeding, infants are randomized into either receiving hydrolyzed casein-based or conventional cow's milk formulas. This trial is still ongoing and the results of autoantibody analyses are expected in 2012 and the results of T1DM in 2016 [86].

#### *Vitamin D*

Supplementary vitamin D has been suggested to protect against T1DM [87], possibly through the effects on the T lymphocytes and through suppression of cytokine production [88]. Lower concentrations of vitamin D have been reported in blood from children with T1DM, and lower vitamin D levels during pregnancy have been suggested to increase the risk for the child to develop T1DM [88,89]. Vitamin D (cholecalciferol) is currently tested in an ongoing randomized feasibility pilot study in Manitoba, Canada, to test if high doses of vitamin D (2000 IU/day) prevent T1DM among genetically susceptible infants  $\leq 4$  weeks of age [90].

### Nutritional Intervention to Prevent Diabetes study

Supplementation with cod liver oil, an important source of vitamin D and omega-3 fatty acids, during the first year of life led to reduced risk of T1DM in Norwegian children, but no risk

**Table 59.2** Primary prevention trials in T1DM. Adapted from Staeva-Vieira *et al.* [94].

Trial name	Agent	Type of trial	Description	Outcome
<b>Non-antigen-specific trials</b>				
PREVFIN	Gluten-free diet	Pilot	Exclusion of dietary gluten	No effects Ended in 2002
TRIGR	Hydrolyzed casein formulas vs cow's milk	R/PC, DB	To recruited 2800 type infants with FDR and T1DM Implemented in 17 countries	Ongoing NCT00179777
NIP	Oral omega-3 DHA	R/DB Pilot	Infants <5 months and mothers in third trimester (+ve family history) Follow-up until age of 9 years	Primary results awaited NCT00333554
Vitamin D	Cholecalciferol 2000 IU/day	R/OL Pilot	Genetically susceptible infants up to 4 weeks old (Manitoba, Canada)	Phase 1: Results awaited NCT00141986
<b>Antigen-specific trials</b>				
Pre-POINT	Oral/nasal insulin	R, PC	Genetically predisposed FDR infants (18 months to 7 years) No islet autoimmunity	Recruitment started in Germany and USA in 2010 Duration: 3–18 months

DB, double blinded; DHA, docosahexanoic acid; FDR, First-degree relatives; OL, open label; PC, placebo controlled; R, randomized. For further details, see clinical trial identifier: <http://www.clinicaltrials.gov/ct2/search>.

reduction was found with other kinds of vitamin D supplementation, suggesting that omega-3 fatty acids were responsible for the effect [91]. In a recent study it was reported that the intake of omega-3 and omega-6 fatty acids were inversely associated with the development of IAA, GAD65Ab and IA-2Ab in children with genetic risk of T1DM [92].

The Nutritional Intervention to Prevent Diabetes (NIP-Diabetes) is a small pilot study to test a proposed preventive effect of oral docosahexanoic acid (DHA) against islet autoimmunity (trial identifier NCT00333554) [93]. Participants included in this trial were infants ≤5 months of age and expected babies of pregnant mothers in their third trimester (>24 weeks) who were genetically predisposed (DR3 or 4) and had family history of T1DM among FDR. DHA is taken in late pregnancy and early infancy and all those infants are followed up for markers of autoimmunity and T1DM (for review see Staeva-Vieira *et al.* [94]).

### Antigen-specific primary prevention trials

#### Pre-POINT Trial

The primary intervention with oral and/or nasal insulin for prevention of T1DM in infants at high genetic risk to develop diabetes (Pre-POINT) is a trial to identify the dose and the type of insulin that can prevent progression to T1DM. Pre-POINT is an ongoing trial, which has two arms: oral and intranasal. This international effort recruits genetically predisposed FDR infants aged 18 months to 7 years with no islet autoimmunity. In this trial, oral insulin dose is almost 10 times higher than that used in the DPT-1 trial (<http://www.diabetes-point.org/nav2uk.html>).

### Secondary prevention trials

Secondary prevention trials are mainly intended for genetically predisposed children in whom autoimmunity has already devel-

oped and also for young adults with multiple islet autoantibodies. These trials aim to reduce  $\beta$ -cell killing by autoimmunity and prevent progression to clinical diabetes [95]. Secondary prevention trials may be divided into two groups: non-antigen-specific (Table 59.3) and antigen-specific trials (Table 59.4).

### Non-antigen-specific secondary prevention trials

Non-antigen-specific agents were tested in a group of secondary prevention trials including cyclosporine [5,7], BCG vaccine [13], ketotifen [15] and nicotinamide, as in ENDIT [17] and DENIS studies [18]. Although these agents were successful in laboratory animals such as the NOD mice, they failed to show similar benefits in human trials. In regards to immunosuppressive agents, the adverse effects outweighed the temporary benefits observed on indicators of  $\beta$ -cell function [8].

### Antigen-specific secondary prevention trials

It is known that an early diabetes diagnosis with mild or no symptoms is associated with good residual capacity of the  $\beta$ -cells to produce insulin and a longer “honeymoon” period [96]. Therefore, it was suggested that insulin therapy in individuals with subclinical diabetes could reduce the  $\beta$ -cell load and be advantageous. Insulin was used in prevention trials as an antigen-specific agent using different routes including parenteral, oral and intranasal insulin. Earlier pilot studies [97,98], which tested parenteral insulin (subcutaneously and intravenously) as prophylaxis among ICA-positive FDR, introduced evidence of delaying disease progression, but the randomized and controlled DPT-1 (parenteral arm) [22] failed to reproduce these results.

It is suggested that insulin given in small doses, either orally or nasally, could induce antigen-specific T-cell tolerance to insulin, which by releasing inhibitory cytokines in the target organ would suppress the autoimmune process against  $\beta$ -cells. This principle

**Table 59.3** Non-antigen-specific secondary prevention trials in T1DM. Adapted from Staeva-Vieira *et al.* [94].

Trial name	Agent	Type of trial	Description	Outcome
Cyclosporine	Cyclosporine orally 7.5 mg/kg/day/year	Pilot	FDR with immunologic and metabolic predisposition	Delayed progression, but no prevention
BCG vaccine	BCG vaccine intradermally	Pilot	A group of pilot studies	No effect
Ketotifen	Ketotifen orally	Pilot	ICA +ve subjects with low FPIR	No effect
ENDIT	Nicotinamide Orally 1.2 g/m <sup>2</sup> /day	R/PC, DB	ICA +ve FDR of young diabetes onset (<20 years)	No effect
DENIS	Nicotinamide Orally 1.2 g/m <sup>2</sup> /day	R, PC	ICA +ve FDR at risk of type 1 diabetes within 3 years	No effect
Nicotinamide combinations	Nicotinamide orally + intensive insulin or cyclosporine or vitamin E	Pilot	Various combinations used with nicotinamide	No effect

BCG, Bacille Calmette–Guérin; DB, double blinded; FDR, first-degree relatives; FPIR, first-phase insulin release; ICA, islet cell autoantibodies; PC, placebo controlled; R, randomized.

For further details, see clinical trial identifier: <http://www.clinicaltrials.gov/ct2/search>.

**Table 59.4** Antigen-specific secondary prevention trials in T1DM. Adapted from Staeva-Vieira *et al.* [94].

Trial name	Agent	Type of trial	Description	Outcome
DPT-1	Parenteral human ultralente insulin s.c. 0.25 U/kg/day + 1 annual infusion	RC/ET	Large multicenter study: FDR with >50% disease risk in 5 years	No effect
DPT-1	Oral insulin 7.5 mg/day	R/PC, DB, ET	Large multicenter study: FDR with 26–50% disease risk in 5 years Follow-up with OGTT for 6 months	No effect (subanalysis showed delay of onset in subjects with IAA >80 U/mL) Phase III is ongoing
DIPP	Intranasal insulin	R/DB/PC PA, ET	Genetically predisposed infants. Tested for ICA, IAA, GAD65Ab and IA-2Ab and IVGTT	No effect after follow-up to 15 years of age
INIT I	Intranasal insulin	OL	Tested effect on autoimmunity among children and young adults	No effect
INIT II	Intranasal insulin 1.6 and 16 mg	R/DB/PC PA, ET	Children and young adults at risk of type 1 diabetes Followed for $\beta$ -cell function and AAb & OGTT/6 months	Ongoing NCT00336674

AAb, autoantibodies; DB, double blinded; ET, efficacy trial; FDR, first-degree relative; GAD 65Ab, glutamine acid decarboxylase autoantibodies; IAA, insulin autoantibody; IA-2Ab, autoantibody to insulinoma-associated antigen 2; ICA, islet cell autoantibodies; IVGTT, intravenous glucose tolerance test; OGTT, oral glucose tolerance test; OL, open label; PA, parallel assignment; PC, placebo controlled; R, randomized; RC, randomized controlled.

For further details, see clinical trial identifier: <http://www.clinicaltrials.gov/ct2/search>

has previously been tried in various other autoimmune diseases, with small or inconsistent beneficial effects. The theory is that peptides from orally ingested antigens encounter the lymphoid tissue in the mucosa, which serves to protect the host from reacting against ingested proteins.

### Oral insulin

The oral arm of the DPT-1 trial examined a preventive effect of oral insulin (7.5 mg/day) [23]. This placebo-controlled study

tested 372 high-risk first and second-degree relatives who were positive for ICA and IAA, but with normal FPIR on IVGTT and glucose tolerance on OGTT. Although the overall results of the DPT-1 showed no significant effect, subanalysis of these data showed a benefit in subjects with IAA >80 U/mL, in whom diabetes was delayed by 4–5 years [23]. This indicates that oral insulin may have a protective effect when given to individuals at risk and having high titers of IAA. No serious study-related adverse events were recorded with oral insulin and the levels of

IAA in the patients did not increase with the administration of oral insulin [99]. Further studies of orally administered insulin in subjects with high titers of IAA are ongoing such as the ongoing repeat of the oral arm of DPT-1 (NCT00419562).

### **Nasal insulin**

Prophylactic administration of insulin nasally has shown to prevent T1DM in NOD mice. In humans, insulin has also been used nasally to induce autoimmune tolerance in prevention trials such as the Intranasal Insulin Trial (INIT) phases I and II and Type 1 Diabetes Prediction and Prevention trial (DIPP). The INIT is a double-blinded cross-over pilot study that recruited T1DM FDR in Australia. INIT-I was completed in 2004 with no significant effect on  $\beta$ -cell function but it showed some indications of mucosal tolerance to insulin [24]. INIT-II (NCT00336674) is an ongoing randomized double-blinded placebo-controlled trial using nasal insulin (1.6 or 16 mg) that aims to assess the effects of nasal insulin on islet autoimmunity. The DIPP study of Finland is a double-blinded prevention trial that used nasal insulin in children with genetic risk and positive ICA and IAA. In 224 children short-acting insulin or placebo was administered intranasally once a day, but no protective effect was seen [25].

In animal studies, oral insulin has shown various results in protecting from T1DM. In BB rats, oral insulin failed to prevent the disease and actually seemed to accelerate the autoimmune process [100,101]. In contrast, studies in the NOD mouse did reveal a protective effect of the drug [102]. Taken together, there is limited evidence that preclinical studies in the NOD mouse and the BB rat can be immediately translated into successful trials in humans.

### **Intervention (tertiary prevention) trials**

Tertiary prevention or intervention trials mainly recruit patients with new-onset T1DM, using interventions intended to preserve  $\beta$ -cells and also to maintain their regeneration [103]. In these studies researchers are trying to suppress or modulate the immune response in order to stop the autoimmune process, which leads to  $\beta$ -cell death and eventually T1DM, or to reduce the  $\beta$ -cell stress, for example by early-introduced insulin therapy. An intensive insulin regimen in patients with new-onset T1DM is proposed to preserve the remaining  $\beta$ -cells and enhance their functionality [104]. Intensive insulin treatment should therefore be used as the basic therapy for all newly diagnosed patients with T1DM who are randomized into intervention trials.

Unlike prevention trials, tertiary interventions mainly test less safe agents over shorter duration of time on subjects who have already developed clinical diabetes. The intervention drug has typically been evaluated in animal studies, and then assessed in small pilot studies to ensure an acceptable route of administration and to verify a safety profile. Intervention trials commonly consider C-peptides as the main outcome for  $\beta$ -cell function, which may reflect the extent of  $\beta$ -cell preservation. Certain trials test combination therapies in which various drug modalities with different modes of action are used in pubertal patients with new-onset T1DM (commonly two drugs in each trial).

Therapeutic agents used in tertiary interventions may also be classified into non-antigen-specific (Table 59.5) or antigen-specific (Table 59.6).

### **Non-antigen-specific intervention trials**

In this set of trials non-antigen-specific drugs are used including immunosuppressive or immunomodulatory agents (Table 59.5). Systemic immunosuppressive drugs such as cyclosporine [7,105] and azathioprine [106] induced remission with signs of improved  $\beta$ -cell function in patients with new-onset T1DM. In spite of that, serious side effects limited prolonged clinical use.

### **Nicotinamide**

Nicotinamide was also used among patients with new-onset T1DM in a group of intervention trials [107–109]. Some of these trials proposed a beneficial effect of nicotinamide reflected in improved C-peptide levels among intervention groups compared with controls [109]. This may indicate that nicotinamide possesses certain therapeutic effects related to  $\beta$ -cell function after onset, but not during the autoimmune prodrome, because prevention trials did not prove a beneficial effect of nicotinamide among high-risk individuals [17,18].

Other agents such as the BCG vaccine [14,110] and diazoxide [111] failed to produce sustained beneficial effect on preserving  $\beta$ -cell function.

### **Anti-CD3 monoclonal antibodies**

Non-specific systemic immunotherapy to modulate T cells has also been attempted with some promising outcomes among this group of drugs. Anti-CD3 monoclonal antibodies (anti-CD3 MoAb), such as teplizumab, have shown some positive effects in postponing the autoimmune destruction of  $\beta$ -cells with preservation of their functionality and enhancement of endogenous insulin [112–114]. Humanized anti-CD3 MoAb were used in order to avoid depleting T-lymphocyte populations. Two variants of these antibodies, mutated Fc region (hOKT3 $\gamma$ 1(Ala-Ala) and glycosylated Fc region ChAglyCD3(TRX4)) were used in two already completed trials [112,113]. These trials showed that anti-CD3 MoAb were able to enhance C-peptide levels and improve clinical variables for up to 2 years but they did not induce sustained tolerance of  $\beta$ -cell autoantigens [114]. This effect appears to be transient because the drug only delayed the decline in C-peptide concentration. Despite remission and metabolic enhancement, there were serious adverse effects including bone marrow suppression with cytokine release syndrome or subsequent serious infections or reactivation of Epstein–Barr virus infection with this treatment [113]. Nevertheless, the obtained results encouraged initiating phase II of the anti-CD3 trial (NCT00378508) and planning a third phase.

### **Antithymocyte globulin**

Antithymocyte globulin (ATG) was found to induce short-term benefits in laboratory animals such as the NOD mice, primarily through inducing immunoregulation rather than depleting T-lymphocytes [115]. In humans, ATG is thought to decrease

**Table 59.5** Non-antigen-specific intervention trials in T1DM. Adapted from Staeva-Vieira *et al.* [94].

Trial name	Agent	Type of trial	Description	Outcome
Cyclosporine	Cyclosporine-A	R, PC	A group of trials	Remission but with serious side effects
ChAgly CD3	Humanized non-mitogenic CD3 monoclonal Ab 8 mg/day IV/6 days	R, DB, PC, PA, ET	Starts at diagnosis of patients with new onset T1DM 12–45 years	Completed, results awaited NCT00627146
Teplizumab	Anti-CD3 monoclonal Ab hOKT3γ1 (Ala-Ala)	R, DB, PC, PA, ET	Phase II: Single 14 course for 4–12 months after diagnosis of new-onset T1DM, to test effects on insulin secretion	Ongoing NCT00378508
ATG	Antithymocyte globulin	R, SB, PA, ET	Test the effect of ATG plus intensive insulin versus intensive insulin therapy only	Ongoing NCT00190502
STRAT	Anti-thymocyte globulin (ATG) Daily 4-day escalating dose	R, DB, PC, PA, ET	Phase II: Given within 12 weeks of diagnosis to assess effects on insulin secretion (C-peptide) over 12 months	Ongoing ITN028AI
Rituximab	Anti-CD20 monoclonal Ab weekly IV/4 weeks	R, DB, PC, PA, Safety/ET	Phases II & III: 8–45 years patients with T1DM, followed every 3 months/2 years (C-peptide, insulin and HbA <sub>1c</sub> )	Results awaited NCT00279305
Abatacept (CTLA-4)	Cytotoxic T-lymphocyte antigen-4, IV	R, DB, PC, PA, ET	The effect of CTLA-4 on insulin production (C-peptide secretion) over 2 years	Ongoing, not recruiting NCT00505375
HrIFN-α	Oral human recombinant interferon α	R, DB, PC, PA	Phase II: test the effect on counter-regulatory anti-inflammatory cytokines	Ongoing, not recruiting NCT00005665
Anakinra, Kineret®	IL-1 receptor antagonist	E, OL	Whether Anakinra protects β-cells by blocking the IL-1β receptor in children with T1DM	Ongoing NCT00645840
Anakinra, Kineret®	IL-1 receptor antagonist	R, DB, PC, PA, ET	The effect of IL-1β receptor antagonism on insulin secretion in young adults with T1DM	Ongoing NCT00711503

ATG, antithymocyte globulin; DB, double blinded; E, exploratory; ET, efficacy trial; IL, interleukin; OL, open label; PA, parallel assignment; PC, placebo controlled; R, randomized; SB, single blinded.

For further details, see clinical trial identifier: <http://www.clinicaltrials.gov/ct2/search>.

**Table 59.6** Antigen-specific intervention trials in T1DM. Adapted from Staeva-Vieira *et al.* [94].

Trial name	Agent	Type of trial	Description	Outcome
DiaPep77 (HSP60)	Subcutaneous peptide heat shock protein 60	R, PC, DB, PA, ET	An immunomodulatory peptide proposed to protect internal production of insulin through halting β-cell killing	Preserved β-cell over 12–18 months in adults. No similar effect in children Phase III (DIA-AID) is ongoing NCT00615264
Alum-GAD (Diamyd®)	Alhydrogel-formulated GAD65 20 μg s.c.	R, PC, DB, PA, ET	Immuno-modulation effect in LADA (Phase IIa) and 10–18 years old with new-onset T1DM (Phase IIb)	Preserved β-cell and C-peptide levels in patients with <6 months onset Phase III ongoing NCT00723411
NBI-6024	Altered peptide ligand insulin B:9–23 vaccine s.c.	R, DB, PC, PA, ET	Multinational trial used a genetically engineered peptide in adolescents (10–17 years) and adults (18–35 years) with new onset T1DM	Completed NCT00873561
BHT-3021	Pro-insulin-based DNA vaccine weekly i.m. inj./12 weeks	R, DB, PC, OL, CO	Assesses safety in ≥18-year-old patients with T1DM: 12 months blinded treatment, 12 months cross-over and 12 months follow-up	Ongoing NCT00453375

CO, cross-over; DB, double blinded; ET, efficacy trial; i.m. inj., intramuscular injection; LADA, latent autoimmune diabetes of adults; OL, open label; PA, parallel assignment; PC, placebo controlled; R, randomized; RC, randomized controlled; s.c. subcutaneous.

For further details, see clinical trial identifier: <http://www.clinicaltrials.gov/ct2/search>.

insulin requirement in patients with new-onset T1DM; however, serious adverse effects such as transient thrombocytopenia are major drawbacks to be considered. Currently, polyclonal anti-T-lymphocyte globulin is being tested in an ongoing randomized placebo control trial that aims to prevent progression of autoimmune  $\beta$ -cell destruction in patients with new-onset T1DM (NCT00190502).

#### **Anti-CD20 monoclonal antibodies**

Anti-CD20 MoAbs are potential non-specific immunoregulatory agents. These monoclonal antibodies induced regulatory B lymphocytes in humanized mice [116]. It is proposed that monoclonal antibodies exert an immunoregulatory effect through reducing B lymphocytes and decreasing their antigen-presentation abilities, cytokine release and antibody production [116]. In humans, anti-CD20 MoAb (rituximab) is currently used in a randomized double-blinded placebo-controlled trial (NCT00279305, phases II and III) to examine whether rituximab can preserve residual insulin and halt  $\beta$ -cell function loss.

#### **Abatacept**

The cytotoxic T-lymphocyte antigen 4 (CTLA-4) is thought to be involved in modulating immune responses through inducing co-stimulatory signals, which are important for T-lymphocyte activation [117]. CTLA4 immunoglobulin (CTLA4-Ig) is proposed to regulate, but not delete, T-lymphocytes through inhibiting their stimulatory activation pathway [118], and is therefore considered relatively safer than other immunosuppressive agents. CTLA4-Ig (abatacept) was recently used in a randomized placebo controlled trial to assess the effects of CTLA4-Ig on progression of new-onset T1DM in patients aged 6–45 years (NCT00505375).

#### **Human recombinant interferon $\alpha$**

Several other non-antigen specific interventions are currently ongoing. A randomized double-blinded trial assessing whether orally ingested human recombinant interferon  $\alpha$  (hrIFN- $\alpha$ ) may prolong the “honeymoon” period in patients with newly diagnosed T1DM aged 3–25 years (NCT00005665) examines whether oral hrIFN- $\alpha$  enhances counter-regulatory anti-inflammatory cytokines such as interleukin-4 (IL-4), IL-10 and peripheral IFN- $\alpha$ , thereby maintaining residual living  $\beta$ -cells.

#### **Interleukin-1 receptor antagonist**

Two trials were recently launched to test the anti-inflammatory effect of IL-1 receptor antagonist (Anakinra, Kineret®) on maintaining  $\beta$ -cell function and preserving insulin secretion in children (NCT00645840) and young adults (NCT00711503). Based on results from preclinical T1DM studies and studies in rheumatoid arthritis [119], these trials propose that immune regulation in T1DM may be obtained through blocking the IL-1 $\beta$  receptor, which has an important role in  $\beta$ -cell killing.

#### **Antigen-specific intervention trials**

Specific pancreatic antigens have been examined as safe agents to modulate the autoimmune response through inducing immuno-

logic tolerance towards islet antigens. In experimental animals, several antigen-specific molecules are able to induce immunologic tolerance and protection against T1DM [120] using a whole islet protein, peptides taken from islet antigen, or DNA-based vaccines [121]. In humans, only few potential antigen-specific agents may have promising results such as peptide heat shock protein 60 (DiaPep277) and alum-formulated GAD65. The induction of immunologic tolerance using antigen-specific agents is thought to be achieved through the stimulation of antigen-specific regulatory T lymphocyte ( $T_{reg}$ ); however, standardized specific tools for detecting and measuring these  $T_{reg}$  cells are not yet available. A group of intervention trials is currently under way to examine the effect of certain antigen-specific drugs in new-onset T1DM (Table 59.6).

#### **DiaPep277**

The humanized DiaPep277 was found to provide protection for  $\beta$ -cells and enhance the levels of C-peptide in a group of trials [122–124]. DiaPep277 was reported to possess a high safety profile; however, the deterioration in  $\beta$ -cell function over an 18-month duration after initiating the intervention was more apparent in children ( $\leq 15$  years) than in adults [123,124]. A trial with similar design involving newly diagnosed children found no similar beneficial effect on  $\beta$ -cell function and C-peptide levels [125]. DiaPep277 is currently tested in a randomized double-blinded placebo-controlled trial involving patients with new-onset T1DM aged 16–45 years (NCT00615264 phase III).

#### **Alum-GAD65**

Another way of trying to induce tolerance to an antigen is to give the antigen subcutaneously in small and repeated doses together with aluminium hydroxide. This adjuvant is commonly used in vaccines. Aluminium salts preferentially induce a humoral (Th2) rather than cellular (Th1) immune response. Because the autoimmune process leading to T1DM is thought to be a mainly cellular (Th1) immune response, aluminium salts could steer the process against a humoral (Th2) response and minimize the likelihood of exacerbating cell-mediated  $\beta$ -cell destruction. This concept is used in the trials of vaccination with Alhydrogel-formulated GAD65 (Diamyd®).

A dose-finding placebo-controlled Phase IIa safety study in 47 patients with latent autoimmune diabetes in adults (LADA) indicated that 20  $\mu$ g Diamyd reduced  $\beta$ -cell destruction without any serious adverse events. In Phase IIb clinical trial, the efficacy and safety of Diamyd were investigated in children 10–18 years of age, recently diagnosed with T1DM [126]. A total of 70 GAD65 antibody-positive children with a recent diagnosis ( $< 18$  months duration) of T1DM were included in the study. All had remaining  $\beta$ -cell capacity measured by C-peptide levels. A total of 35 children received two doses of 20  $\mu$ g Diamyd and 35 children received placebo. C-peptide levels were measured after mixed meal tolerance tests 3, 9, 15, 21 and 30 months after the first drug injection. Significant differences between groups were found after mixed meal stimulation and fasting C-peptide was different at 30 months

only. Furthermore, in a subgroup of children who had been diagnosed with diabetes no longer than 6 months at study-start, the fasting C-peptide levels declined less in children who had received Diamyd compared with the levels in children who received placebo. This indicates that Diamyd may prevent further  $\beta$ -cell destruction in recently diagnosed children, without any serious adverse events. Thus, the study has provided support for the clinical safety of Diamyd and statistically significant and clinically relevant positive effect on the preservation of  $\beta$ -cell function in children diagnosed within 6 months before study start [126]. A Phase III randomized double-blinded placebo-controlled multicenter study is ongoing to evaluate the efficacy and safety of Diamyd further, with a larger number of children diagnosed no longer than 3 months before inclusion in the study.

Studies of the NOD mice indicated that GAD65 prevents the autoimmune destruction of the pancreatic  $\beta$ -cells and T1DM [127–132].

### ***Insulin peptides***

It has been observed in animal studies that intermittent immunization with insulin or insulin- $\beta$  chain coupled with incomplete Freund adjuvant may prevent T1DM progression in NOD mice [133]. Another approach used altered peptide ligand, based on the immunodominant T1DM insulin- $\beta$  chain:9-23 vaccine (NBI-6024), which was tested in humans based on earlier results from experimental animals [134,135]. This region of insulin- $\beta$  chain has been shown as a specific T-lymphocyte target antigen in the NOD mouse [134]. A genetically engineered vaccine was prepared based on this peptide region and administered subcutaneously to adolescents and adults with a recent history of T1DM. The Phase I trial showed that NBI-6024 was able to shift the IFN- $\gamma$ -producing T-helper (Th1) lymphocyte into the Th2 regulatory lymphocyte [135]; however, no preventive effect or metabolic control was observed with this NBI-6024 (NCT00873561).

Pro-insulin-based DNA vaccine (BHT-3021) is an antigen-specific drug which is currently being tested in adults older than 18 years with new-onset T1DM. This randomized blinded placebo-controlled trial is a multicenter study that will test the safety of this drug (NCT00453375).

### **Combination therapies**

The search for a single drug that can modulate the natural history of T1DM continues; however, it is not yet clear to what extent a single agent may be able to modify or retard the progression of T1DM. Therefore, combinations of drugs have also been suggested for patients with new-onset diabetes.

The current direction of research is to combine two immunomodulatory agents: non-specific antibody-based immunotherapy such as anti-CD3 MoAb and specific antigen-based immunoregulatory agent such as proinsulin peptide [136]. This combination may permit reduction of the dose or the duration of one or both drugs to maximize benefits or minimize adverse effects. Bresson and von Herrath suggested two main goals for combination therapy of T1DM [121]. First, ensure rapid inter-

ruption of the aggressive autoimmune response with minimum adverse effects. Second, enhance  $\beta$ -cell regeneration to the level of sustaining normal glucose levels independent of exogenous insulin therapy [121].

Among combination therapies aiming at immunoregulation are IL-2 (proleukin) and sirolimus (rapamycin), which are being combined and used in an ongoing open-label uncontrolled safety trial. Participants are adults, 18–45 years old, who were diagnosed with T1DM within 4 years (NCT00525889). This trial was based on results obtained in NOD mice when this therapy combination induced sustained  $\beta$ -cell protection and prevented T1DM progression after omitting the drugs [137]. The synergetic effects of these drugs are thought to be through enhancing shifting Th1 lymphocyte into the protective Th2 regulatory lymphocyte.

A second proposed combination involves anti-CD3 and a proinsulin peptide (B24–C36) nasally. This combination was found to induce proinsulin-specific  $T_{reg}$  cells and enhance remission in two experimental animals more than the effect of each single drug alone [136].

Alternatively, an ongoing randomized double-blinded placebo-controlled trial tests two immunosuppressive agents, mycophenolate mofetil (MMF/CellCept) and the anti-IL2 receptor monoclonal antibody, daclizumab (DZB/Zenapax) (NCT00100178). This trial will assess whether this combination preserves the remaining viable  $\beta$ -cells and enhances their regeneration in subjects 8–45 years of age who were diagnosed within a 3-month-period. (For further details on prevention and intervention trials see <http://www.ClinicalTrials.gov>.)

---

## **Future directions**

Future drug therapy of T1DM will depend on the success of ongoing and planned intervention trials. Since 1976, patients with newly diagnosed T1DM have been given immunosuppressive agents but none of these have preserved  $\beta$ -cell function. Transient effects have been reported but the benefits have been limited because they had to continue the insulin replacement therapy. Immunomodulation alone, or possibly combined with immunosuppressive therapy, seems to be promising in reducing the loss of C-peptides after diagnosis. It is often questioned whether immunomodulation with a single autoantigen is sufficient. Provided the treatment is safe, it cannot be excluded that the simultaneous administration of GAD65, IA-2 and proinsulin may be more efficacious than GAD65 alone.

The route of administration needs further exploration. Oral insulin has already been tested and it would be interesting to test the efficacy of oral GAD65. Furthermore, it would be interesting to test alum-GAD65 together with alum-formulated proinsulin. Studies of the function of the human immune system lags behind that of the mouse and rat. Safe immune tolerance trials may provide a novel approach to dissect the mechanisms by which the human immune system responds to immune therapy with autoantigens.

Since 2001, TrialNet, an international network of clinical research groups supported by the National Institutes of Health, has established an infrastructure for trials for predicting and preventing T1DM. Within this network, relatives of patients with T1DM will be screened for disease risk and then either followed or randomized into clinical trials. Individuals developing multiple autoantibodies will be eligible for ongoing prevention studies. Networks such as TrialNet will enable different investigators and clinics to cooperate in the attempts to predict and prevent T1DM.

**Keypoints**

- The heterogeneous and progressive nature of type 2 diabetes presents an ongoing requirement for additional and novel blood glucose-lowering agents.
- Longer-acting (once daily and once weekly injected) analogs of the incretin hormone glucagon-like peptide 1 (GLP-1) and new dipeptidyl peptidase 4 inhibitors are being developed.
- Proof of principle studies have shown potential for non-peptide molecules to act as GLP-1 receptor agonists and insulin mimetics.
- Potentiators of insulin action include specific phosphatase inhibitors and other types of compounds that increase insulin receptor and early post-receptor signaling.
- Selective peroxisome proliferator-activated receptor modulators, glucagon receptor antagonists and cellular glucocorticoid inhibitors have shown potential.
- Agents that directly increase glucose disposal (e.g. glucokinase activators) or reduce glucose output (e.g. fructose 1,6-bisphosphatase inhibitors) are receiving attention.
- Sodium-glucose co-transporter 2 inhibitors can facilitate glycaemic control through increased renal glucose elimination.

**Introduction**

Current strategies for managing type 2 diabetes mellitus (T2DM) are described in Part 6. This chapter reviews new therapeutic approaches to address the metabolic disturbances of T2DM. The main focus is on drugs that have recently become available for clinical use or have entered clinical trials, and established agents that have found new applications in patients with diabetes. Some agents in preclinical development that have particular theoretical promise are also considered.

There is a continuing need for new and improved agents to treat diabetes as available therapies do not reinstate normal glucose homeostasis or eliminate the threat of long-term complications. Indeed, patients with T2DM incur chronic tissue damage and suffer premature death, even with assiduous use of the available therapies [1–3]. Lifestyle measures, notably diet and exercise, remain the foundation therapy [4], while pharmacologic interventions are added to provide further recourse against the multiple, heterogeneous and progressive endocrine and metabolic disturbances of the disease [5]. Recent trial outcomes have re-emphasized the importance of comprehensive risk factor management in which early, effective, individualized and sustained glycaemic control can defer the onset and reduce the severity of

complications [1,2]. In particular, “glycaemic memory” requires good glycaemic control early after diagnosis to minimize the complications of hyperglycemia much later in the disease process [1,2,6].

**Development of new antidiabetic agents**

As diabetes must usually be treated for the remainder of the patient’s life, any new antidiabetic drug must be safe, well-tolerated, conveniently administered and carry minimal risk of serious hypoglycemia. It should offer durable efficacy and preferably other advantages – for example, a novel mode of action or favorable pharmacokinetics that suit a particular group such as the elderly. Ideally, a new agent will be suited to combination therapy with at least some of the existing agents, and confer benefits against conditions that are commonly associated with diabetes, such as abdominal obesity, dyslipidemia, hypertension and other vascular diseases or risk factors. A new drug might correct at least one of the major underlying endocrine or metabolic disturbances such as counter insulin resistance, improve  $\beta$ -cell function, reduce hyperglucagonemia or act directly to decrease glucotoxicity or lipotoxicity.

The development of a drug from a new chemical entity through to marketing approval involves many stages of rigorous preclinical and clinical evaluation (Table 60.1). The process can take 10–15 years and cost US\$ 500–2000 million [7]. If there is evidence of increased adverse cardiovascular outcomes during the

**Table 60.1** Stages in the development of a new drug.**Preclinical stages***New chemical entity*

- Identification, extraction/synthesis, chemical characterization and patenting of compounds
- Genotoxicity testing: screening for biological activity *in vitro* and *in vivo* in animals
- Preclinical pharmacology, mode of action, pharmacodynamics (activity, safety, tolerance), pharmacokinetics (bioavailability, distribution, metabolism, elimination) and toxicity in  $\geq$  two mammalian species

**Clinical stages***Investigational new drug application: permission to begin clinical studies*

## Phase 1

- First administration to small number of healthy human volunteers
- Dose ranging, vital signs, pharmacodynamics, pharmacokinetics, drug interactions, safety

## Phase 2

- First trials in small numbers of patients
- Dose ranging, efficacy, further pharmacodynamics, pharmacokinetics and safety

## Phase 3

- Trials in larger numbers of patients
- Multicenter trials, comparative trials with other treatments, efficacy, further pharmacodynamics and safety (including meta-analysis of cardiovascular outcomes)

*New drug application: permission to market as a drug*

## Phase 4

- Use in medical practice
- Additional trials (similar to phase 3), post-marketing surveillance, adverse drug reactions, use in special subgroups (e.g. elderly people)

pre-authorization studies, depending on the circumstances, either additional pre-authorization or post-authorization trials will be required. To extend the period of marketing exclusivity it is not unusual for companies to seek additional indications and develop new formulations post-authorization. Because many patients with T2DM require combination therapy, there is also considerable interest in the production of single-tablet fixed-dose combinations [8].

## Classification of new antidiabetic agents

Blood glucose-lowering agents may be either hypoglycemic or antihyperglycemic [9]. Both reduce hyperglycemia, but hypoglycemic agents can lower blood glucose concentrations below the euglycemic range, and therefore carry the risk of clinical hypoglycemia. Such agents include potent inhibitors of hepatic glucose output, insulin secretagogues that act at low glucose concentrations, potent insulin-mimetic drugs and agents that impair counter-regulatory mechanisms. By contrast, antihyperglycemic agents, when used as monotherapy, do not lower blood glucose

**Table 60.2** Established blood glucose-lowering agents and some other agents with blood glucose-lowering activity.

Agents	Main mode of action
<b>Agents used in the treatment of diabetes</b>	
Metformin (biguanide)	Counters insulin resistance
Sulfonylureas	Stimulate insulin secretion
Prandial insulin releasers (meglitinides)	Stimulate insulin secretion (rapid/short acting)
Thiazolidinediones (glitazones)	Increase insulin sensitivity (PPAR $\gamma$ agonists)
GLP-1 analogs	Potentiate insulin secretion
DPP-4 inhibitors (gliptins)	Potentiate insulin secretion
$\alpha$ -Glucosidase inhibitors	Inhibit carbohydrate digestion
Pramlintide	Satiety, slow gastric emptying, decrease glucagon
Insulin	Decrease glucose production, increase glucose disposal, storage and utilization
<b>Other agents with blood glucose-lowering activity</b>	
Acipimox	Decrease lipolysis, reduce NEFAs
Alcohol	Inhibit gluconeogenesis
Niacin	Decrease lipolysis, reduce NEFAs
Quinine	Stimulate insulin secretion
Salicylates	Stimulate insulin secretion
$\beta$ -Adrenoceptor blockers*	Inhibit adrenergic counter-regulatory response

DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide 1; NEFA, non-esterified fatty acids; PPAR $\gamma$ , peroxisome proliferator-activated receptor  $\gamma$ .

\*  $\beta$ -Adrenoceptor blockers usually raise glucose concentrations, but they can contribute to hypoglycemia by inhibiting the acute counter-regulatory response and impairing hypoglycemia awareness.

into the range of overt hypoglycemia. These drugs include the inhibitors of carbohydrate digestion and intestinal glucose absorption, anti-obesity agents, weaker suppressors of hepatic glucose output or counter-regulation, mild or glucose-dependent insulin secretagogues, most insulin-sensitizing agents and modulators of lipid metabolism.

The major glucose-lowering drugs currently used to treat diabetes, and some other agents with glucose-lowering activity, are shown in Table 60.2. Examples of other types of compounds under investigation as potential glucose-lowering drugs are listed in Table 60.3 [10,11] and illustrated in Figure 60.1.

## Inhibitors of intestinal carbohydrate digestion and absorption

Delaying the digestion and absorption of dietary carbohydrate in the intestine reduces post-prandial hyperglycemia and may have some “carry-over” benefit to reduce basal glycemia. Efficacy is variable but generally modest, although this approach is usually suitable for combination with most other antidiabetic therapies

**Figure 60.1** Potential sites of action of blood glucose-lowering agents. DPP-4, dipeptidyl peptidase 4; GK, glucokinase; GLP-1, glucagon-like peptide 1; SGLT-2, sodium-glucose co-transporter 2; TZD, thiazolidinedione.

**Table 60.3** Examples of some new or investigational blood glucose-lowering agents.

Type of agent	Action	Example
$\alpha$ -glucosidase inhibitors	Inhibit carbohydrate digestion	Voglibose
Insulin secretagogues	Stimulate insulin secretion	Mitiglinide
Insulin secretion potentiators	Enhance nutrient-stimulated insulin secretion	GLP-1 analogs, DPP-4 inhibitors
Insulin mimetics	Insulin-like effects on glucose metabolism	IGF-I
Insulin action potentiators	Enhance actions of insulin	Selective PPAR modulators
Counter-regulatory hormone inhibitors	Suppress secretion/action of counter-regulatory hormones	Glucagon receptor antagonists, cellular glucocorticoid inhibitors
Direct glucose regulators	Increase glucose metabolism	GK activators, F16Pase inhibitors
Lipid regulators	Inhibit oxidation of fatty acids	CPT-1 inhibitors
SGLT2 inhibitors	Increase renal glucose elimination	"Flozins"

CPT-1, carnitine palmitoyl transferase-1; DPP-4, dipeptidyl peptidase 4; F16Pase, fructose 1,6-bisphosphatase; GK, glucokinase; GLP-1, glucagon-like peptide-1; IGF-I, insulin-like growth factor I; PPAR, peroxisome proliferator-activated receptor; SGLT2, secondary active sodium glucose co-transporter 2.

including insulin. Extending the period of digestion in this way can also reduce interprandial hypoglycemia in insulin-treated patients. Included here are dietary fiber supplements and inhibitors of digestive enzymes (Table 60.4).

### Dietary fiber supplements

Most dietary fiber comprises plant polysaccharides that are not digested or fermented in the large bowel; some are soluble and form bulky viscous gels and gums, while others are coarse and insoluble (Table 60.4). Soluble fiber appears to be more effective than insoluble in reducing post-prandial hyperglycemia and hyperinsulinemia. Fibers can act as a barrier to diffusion within the lumen of the small intestine, where complex starchy carbohydrates are digested. Carbohydrates become entrapped within the matrix, impeding access of digestive enzymes, and restricting the diffusion of liberated saccharides across the unstirred layers of gut contents to the intestinal epithelium [12]. Various fiber

supplements have appeared intermittently on the pharmacy shelves. These include common food thickeners such as soluble guar gum (E412), a galactomannan from the Indian cluster bean (*Cyamopsis tetragonoloba*; Figure 60.2) and fruit pectins. The prandial blood glucose-lowering effect of these supplements is usually small, especially if patients are already consuming a balanced diet containing fruit and vegetables [13].

### Inhibitors of carbohydrate digestion

Slowing the digestion of complex carbohydrates by inhibiting amylases and glucosidases can reduce post-prandial hyperglycemia, particularly in individuals consuming a high starch diet such as rice (Figure 60.3). Inhibitors of  $\alpha$ -amylases impair the

hydrolysis of starch, but such agents have been too unpredictable for routine therapeutic use. Reversible competitive inhibitors of brush-border  $\alpha$ -glucosidases such as acarbose, miglitol and voglibose are more predictable (Figure 60.4). These still require appropriate titration against the amount of complex carbohydrate in the diet to prevent undigested sugars from entering the large bowel, where bacterial fermentation can produce carbon dioxide and osmotically active glucose, causing flatulence and diarrhea as side effects [14]. There do not appear to be new  $\alpha$ -glucosidase inhibitors in clinical development.

### Insulin secretagogues

Several defects in islet  $\beta$ -cell function occur early in the pathogenesis of T2DM: the acute first-phase insulin secretory response to glucose becomes reduced and eventually lost, processing of proinsulin to insulin is impaired, the normal pulsatile rhythm of basal insulin secretion is disturbed, and the second phase of insulin secretion is often extended, albeit diminished in magnitude, as the period of post-prandial hyperglycemia is prolonged (see Chapter 10). In advanced stages of T2DM,  $\beta$ -cell mass and insulin biosynthesis are also compromised. An ideal insulin secretagogue would restore  $\beta$ -cell sensitivity to glucose, and support adequate biosynthesis, processing and secretion of insulin in response to other nutrients, hormones and neural factors. Insulin secretagogues can be categorized into initiators (e.g. sulfonylureas), which stimulate insulin secretion on their own or require only low glucose concentrations, and potentiators (e.g. GLP-1 analogs), which enhance the effect of rising glucose and other secretagogues but do not induce insulin release without glucose.

**Figure 60.2** Guar, a galactomannan polysaccharide from the Indian cluster bean, *Cyamopsis tetragonoloba*, used as a dietary fiber supplement.

**Figure 60.3** Starch digestion and its inhibitors.  $\alpha(1-6)$ -glucosidic linkages are cleaved by  $\alpha(1-6)$  glucosidases, and  $\alpha(1-4)$  linkages by  $\alpha$ -amylase.  $\alpha$ -Glucosidase inhibitors such as acarbose act by competitive, reversible inhibition of intestinal brush-border  $\alpha$ -glucosidase enzymes. This slows the rate of carbohydrate digestion.

**Figure 60.4**  $\alpha$ -Glucosidase inhibitors in present use are acarbose and miglitol. Voglibose is available in some countries. These agents have different affinities for specific  $\alpha$ -glucosidases: the binding affinity of acarbose is glucoamylase > sucrase > maltase > dextrinase; miglitol and voglibose potently inhibit sucrase, while voglibose shows more potent inhibition of other  $\alpha$ -glucosidases than acarbose. Acarbose also weakly inhibits  $\alpha$ -amylase.

**Figure 60.5** The ATP-sensitive ( $K_{ATP}$ ) channel in the  $\beta$ -cell membrane consists of a large sulfonylurea 1 (SUR1) subunit (17 transmembrane domains) and a smaller pore-forming unit that acts as an inwardly rectifying K channel, Kir6.2. The cytosolic surface of the SUR1 subunit has separate binding sites for sulfonylureas (S), benzamido compounds (B) and the nucleotides, ADP and ATP (N). Four complete channel units self-associate to form an octameric complex in the membrane.

## Initiators of insulin secretion

Currently available sulfonylureas and meglitinides are oral insulin secretagogues that initiate insulin secretion (see Chapter 29). They bind to either the sulfonylurea site or the benzamide site

(meglitinides) on the sulfonylurea receptor 1 (SUR1) in the plasma membrane of the  $\beta$ -cell. The SUR1 is part of the ATP-sensitive potassium channel ( $K_{ATP}$  channel), which consists of an octameric complex of four Kir6.2 pores (inwardly rectifying potassium channels) surrounded by four SUR1 molecules (Figure 60.5). Binding of ligands to the sulfonylurea or benzamide sites

**Figure 60.6** Sulphonylureas and benzamido compounds stimulate insulin release mainly by binding to sites on the sulphonylurea receptor 1 (SUR1) of the adenosine triphosphate (ATP)-sensitive potassium channels ( $K_{ATP}$  channels). This closes the Kir6.2 pores of the  $K_{ATP}$  channels, causing localized depolarization, opening of voltage-dependent calcium channels, increasing  $Ca^{2+}$  influx, and activation of calcium-dependent proteins that promote exocytosis of insulin granules. Imidazoline derivatives can act on  $I_1$  and  $I_2$  receptors, as well as other (unclassified) receptors and directly on the Kir6.2 pores to enhance insulin secretion. Succinate esters fuel glucose metabolism.

on SUR1 elicits the same response as binding of ATP to the nucleotide-binding domains of the channel, namely closure of the Kir6.2 pore [15]. This prevents  $K^+$  efflux, which leads to localized depolarization of the plasma membrane. In turn, this opens voltage-gated (L-type) calcium channels, allowing influx of  $Ca^{2+}$  ions, which increases the cytosolic calcium ion concentration. Calcium-sensitive proteins are thereby activated, triggering the exocytosis of insulin-containing secretory granules (Figure 60.6). SUR1–Kir6.2 channels have also been identified within the membranes of mitochondria and possibly other organelles, suggesting that sulphonylureas and meglitinides could act at these and other sites in the cell as part of their insulin-releasing action.

Several novel insulin secretagogues have been reported to act by closing the  $K_{ATP}$  channels. The meglitinide derivative mitiglinide (KAD-1229) appears to bind at the benzamide site on SUR1 (Figure 60.6), and this agent has proceeded in clinical development [16]. Several other types of compounds have been shown to interact with  $K_{ATP}$  channels, but these do not appear to have proceeded beyond early clinical studies (Figure 60.7). These include

the morpholinoguanidine BTS67582 [17] and certain imidazolines such as S22068 [18]. Other imidazoline compounds, which bind to  $I_1$ ,  $I_2$  and probably other receptors, may also close  $K_{ATP}$  channels as part of their mechanisms to stimulate insulin secretion [19]; however, there are imidazolines such as BL11282 that stimulate glucose-induced (but not basal) insulin secretion by effects on protein kinases without closing  $K_{ATP}$  channels [20]. Various  $\alpha_2$ -adrenergic receptor antagonists such as phentolamine, which can reduce the tonic suppression of insulin secretion mediated through  $\alpha_2$ -adrenergic activation, may also act to close  $K_{ATP}$  channels.

Although closure of  $K_{ATP}$  channels initiates insulin secretion, it does not promote insulin biosynthesis. Agents that increase nutrient metabolism, and close  $K_{ATP}$  channels through increased ATP production, additionally enhance proinsulin biosynthesis. This capability is illustrated by esters of succinic acid which provide a metabolisable substrate to the mitochondria [21]. These compounds have low enteral bioavailability and a short duration of action, and they also fuel gluconeogenesis in the liver. A related approach could be to stimulate mitochondrial succinyl-

**Figure 60.7** Structures of some established and novel insulin secretagogues. Glibenclamide (glyburide) has both a sulfonylurea and a benzamide moiety. Meglitinide derivatives exhibit a benzamide moiety. BTS 67582 is a morpholinoguanidine, while S-22068 and BL11282 are examples of imidazole compounds.

coenzyme A (CoA) synthetase to generate ATP and guanosine triphosphate (GTP) [22].

Because the islet  $\beta$ -cell takes up glucose approximately in proportion to the circulating glucose concentration and phosphorylates the glucose via glucokinase (GK; EC 2.7.1.1), the  $\beta$ -cell is amenable to stimulation of glycolysis with agents that enhance the activity of GK [23]. Although this effect is actually potentiating the action of glucose (Figure 60.8), it can operate at low glucose concentrations, so it has been categorized here as an initiator. Several specific small molecule activators of GK have been shown to increase insulin secretion and improve glucose homeostasis in models of T2DM. These include allosteric activators and molecules that prevent association of GK with or cause dissociation of GK from inhibitory protein complexes [24–29]. Several of these agents are now in clinical trial, and it will be interesting to see if this approach can benefit other aspects of islet function and be regulated to avoid hypoglycemia. Because liver cells express GK and take up glucose approximately in proportion

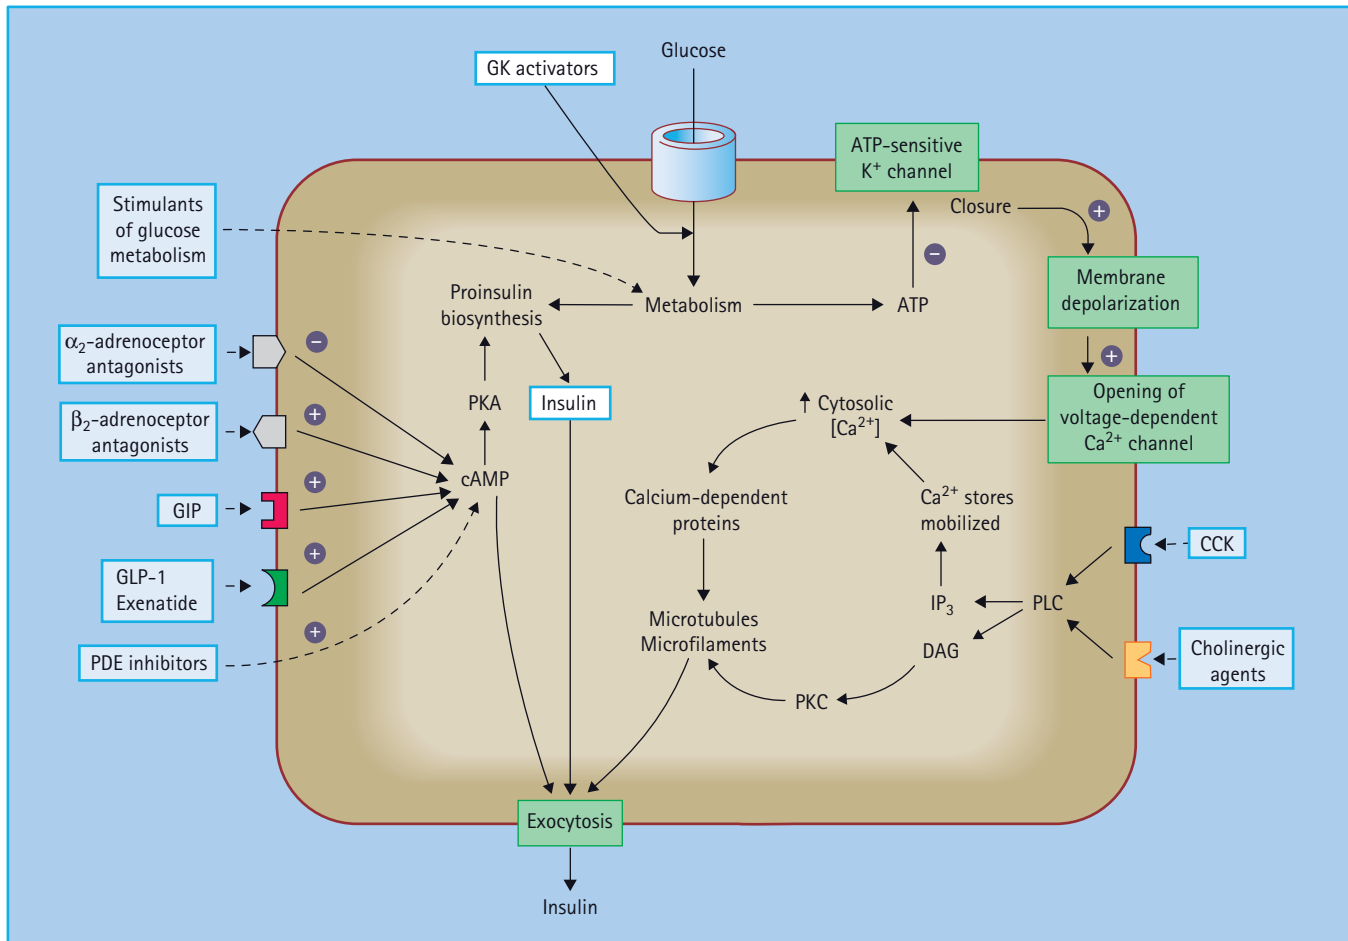

to the circulating concentration, GK activators will also stimulate hepatic glucose utilization and reduce hepatic glucose production, adding to their blood glucose-lowering potency.

### Potentiators of insulin secretion

Potential opportunities to increase nutrient-induced insulin secretion are shown in Figure 60.8. In principle, these agents should predominantly decrease post-prandial hyperglycemia and carry less risk of interprandial hypoglycemia.

### Incretins

Insulin secretion is enhanced by several hormones released from the gut during feeding – so-called incretin hormones. The main incretins are glucagon-like peptide 1 (7–36) amide (GLP-1) and gastric inhibitory polypeptide (GIP; also known as glucose-dependent insulinotropic peptide). These hormones activate specific G-protein coupled receptors in the  $\beta$ -cell membrane and potentiate nutrient-induced insulin secretion and insulin biosyn-

**Figure 60.8** Sites on the pancreatic  $\beta$ -cell that offer potential targets to potentiate nutrient-induced insulin secretion. cAMP, cyclic adenosine monophosphate; CCK, cholecystokinin; DAG, diacylglycerol; GIP, gastric inhibitory polypeptide, also known as glucose-dependent insulinotropic peptide; GK, glucokinase; IP<sub>3</sub>, inositol-1,4,5-trisphosphate; PDE, phosphodiesterase; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C. Activated  $\beta_2$ -adrenoceptors and GIP and glucagon-like peptide-1 (GLP-1) receptors stimulate insulin secretion, as do antagonists of the inhibitory  $\alpha_2$ -adrenoceptors.

**Figure 60.9** Incretin hormones GLP-1 and GIP have been shown to increase  $\beta$ -cell mass in animal models. Possible mechanisms include increased  $\beta$ -cell proliferation and differentiation, slowing of  $\beta$ -cell apoptosis and increased  $\beta$ -cell neogenesis from ductal progenitor cells.

thesis, at least partly through increased cyclic adenosine monophosphate (cAMP) and production of protein kinase A (PKA) [30,31]. Both hormones have also been shown to promote  $\beta$ -cell mass in animal models, possibly slowing  $\beta$ -cell apoptosis and

increasing  $\beta$ -cell neogenesis by increased expression of the transcription factor PDX-1 (pancreatic duodenal homeobox 1), which promotes proliferation and differentiation of ductal progenitor cells (Figure 60.9). GLP-1 has been favored as a treatment

for T2DM because it also suppresses glucagon secretion in a glucose-dependent manner, slows gastric emptying and exerts a satiety effect that can facilitate weight loss [32]. Moreover, GLP-1 concentrations appear to be reduced in T2DM but the ability of the peptide to enhance insulin release is maintained (Table 60.5). Thus, when injected subcutaneously immediately before a meal, GLP-1 can substantially reduce the post-prandial rise in blood glucose concentrations in T2DM (Figure 60.10). However, the rapid degradation of GLP-1, mostly by the enzyme dipeptidyl peptidase 4 (DPP-4) and the renal clearance of GLP-1 (plasma half-life < 2 minutes) makes the peptide itself an inconvenient form of therapy [33].

DPP-4 cleaves off an N-terminal dipeptide where there is an alanine residue (as in GLP-1) or a proline residue at the N2 position. Exenatide (exendin-4) is a GLP-1 analog with a glycine residue at the N2 position (Figure 60.11), making it resistant to degradation by DPP-4, and extending the half-life to several

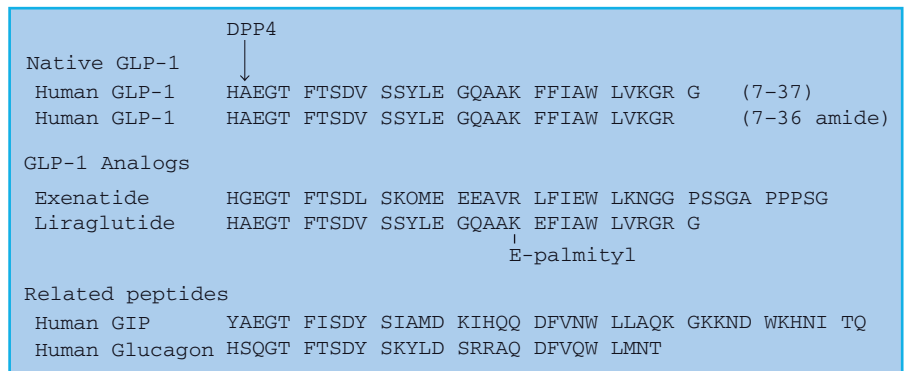

**Table 60.5** Effects of the incretin hormones glucagon-like peptide 1 (7–36) amide (GLP-1) and gastric inhibitory polypeptide (GIP; also known as glucose-dependent insulinotropic peptide).

	GIP	GLP-1

Compound	Name	Company	Structure
NN2211	Liraglutide* (Victoza)	NovoNordisk	GLP-1 analog linked to palmitoyl fatty acid, t <sub>1/2</sub> 12–13 hours (once daily, s.c.)
Exendin-4	Exenatide-LAR	Amylin/Lilly	Long-acting release exendin (once weekly, s.c.)
?	Albiglutide (Syncria)	GSK	Complex of dimeric GLP-1 bound to albumin (once weekly, s.c.)
LY548806	?	Lilly	DPP-4 resistant GLP-1 analog
LY315902	?	Lilly	GLP-1 analog linked to a fatty acid
BIM-51077, R1583	Taspoglutide	Ipsen/Roche	Long-acting GLP-1 analog (once weekly, s.c.)
CJC-1131	?	ConjuChem	GLP-1 analog linked to a chemical complex
ZP10A, AVE0010	Lixisenatide	Zealand/ Sanofi- Aventis	GLP-1 analog

Other GLP-1 preparations in development include GLP1-INT (GLP-1 analog; Transition Therap/NovoNordisk) and MKC253 (GLP-1-technospheres for inhalation, MannKind Corp).

\* Liraglutide was launched in Europe in July 2009.

hours. Because exenatide retains the glucose-lowering efficacy of GLP-1 it has become established as an incretin therapy, injected subcutaneously twice daily before the main meals [34]. The glucose-dependent nature of the insulin-releasing and glucagon-suppressing effects is reflected in the limited risk of hypoglycemia, while the satiety effect has assisted weight loss and favored use in obese patients.

Among other GLP-1 analogs (Table 60.6), liraglutide (NN2211) recognized regulatory approval in Europe in July 2009. Liraglutide is GLP-1 (7-37) with Lys34 replaced by Arg34, and Lys26 attached via a glutamate residue to a C16 hexadecanoyl (palmitoyl) fatty acid chain. The fatty acid chain facilitates association into heptamers and attachment of the molecule to albumin, protecting it from degradation by DPP-4 and enabling once daily injection [35].

A once-weekly depot formulation of exenatide, new long-acting GLP-1 analogs, slow-release formulations and different administration routes (e.g. transdermal, buccal and inhaled) are receiving clinical assessment [32]. Hybrid peptides are also being explored to increase glucose-lowering efficacy, for example DAPD, a peptide that is a GLP-1 receptor agonist and a glucagon receptor antagonist [36]. To circumvent the need for injections, non-peptide GLP-1 receptor agonists (e.g. Boc5) have been identified. These bind to the GLP-1 receptor on islet  $\beta$ -cells and enhance glucose-dependent insulin secretion [37,38].

Although GIP potentiates nutrient-induced insulin secretion it also increases glucagon release and promotes lipid deposition [39]. Moreover, GIP receptor knockout (KO) mice and the administration of GIP receptor antagonists (both peptide and non-peptide) have been shown to prevent the development of obesity, improve glucose homeostasis and reduce insulin resistance in animal models [40–44]. This is consistent with evidence from bariatric surgery: a reduced supply of nutrients through the proximal small intestine (location of GIP-secreting K-cells) rapidly improves glycemic control in obese patients with diabetes [45]. Thus, GIP antagonism by pharmacologic means or “metabolic surgery” may provide a new antidiabetic mechanism [46].

### DPP-4 inhibitors

Inhibiting the enzyme DPP-4 (EC 3.4.14.5) prevents the rapid inactivation of the endogenous incretins GLP-1 and GIP, thereby raising their circulating concentrations and increasing nutrient-stimulated insulin release and other effects of these incretins (Table 60.5). DPP-4 is found “loose” in the circulation and tethered to cell membranes, especially endothelia in capillaries of the gastrointestinal tract, a location that facilitates the degradation of incretins. The protease activity of DPP-4 degrades a range of biologically active peptides in addition to incretins, including substance P, bradykinin, peptide YY, neuropeptide Y, pituitary adenylate cyclase-activating peptide, insulin-like growth factor I (IGF-I) and various interleukins and monocyte chemo-attractant proteins [33,47]. Despite affecting this wide range of peptides, to date, specific DPP-4 inhibitors have not shown significant adverse effects during substantial clinical use [32]. Also, DPP-4 is the lymphocyte cell surface protein CD26 required for the co-stimulation response to recall antigens, but its immunologic role does not appear to be interrupted by small molecule inhibitors of its peptidase activity.

Currently available DPP-4 inhibitors (gliptins) include sitagliptin, vildagliptin and saxagliptin (see Chapter 30). These agents improve glycemic control similarly to GLP-1 analogs but there are subtle differences that may partly reflect the concomitantly increased GIP, and the likelihood that raised endogenous incretin concentrations will not achieve the high concentrations of exogenously administered GLP-1 analogs. In consequence, DPP-4 inhibitors are unlikely to cause initial nausea through delayed gastric emptying, and they may exert a lesser satiety effect resulting in little change of body weight. Among the DPP-4 inhibitors in clinical development (Table 60.7), trials with alogliptin are well advanced (Figure 60.12). These agents have shown high specificity for DPP-4 inhibition, and preliminary information indicates that therapeutic concentrations cause almost complete inhibition of DPP-4 activity for about 12 hours, producing similar glucose-lowering efficacy to existing gliptins [32].

### Phosphodiesterase inhibitors and other approaches

The  $\beta$ -cell expresses several phosphodiesterases (PDEs) that degrade cAMP and so reduce insulin release. Selective and

transient inhibition of these enzymes in  $\beta$ -cells, especially isoform PDE-3B, which exerts most influence on glucose-induced insulin secretion, could be a possible intervention [48], but the problem of specifically targeting the  $\beta$ -cells has yet to be overcome. Other theoretical approaches to potentiate insulin secretion (Figure 60.8), such as antagonism of  $\alpha_2$ -adrenoceptors and activators of phospholipase C (PLC), have not been possible to target specifically at the  $\beta$ -cell.

### Insulin-mimetic drugs

Insulin resistance (impaired insulin action) is a typical feature of T2DM, but it is highly heterogeneous, initially progressive (excepting some monogenic forms), and susceptible to many different genetic and environmental factors [49,50]. Most patients with T2DM probably incur multiple defects that impinge on insulin receptor function and/or various post-receptor signaling pathways, as well as independent disturbances in the activities of substrate transporters and metabolic enzymes consequent to glucotoxicity and lipotoxicity [51]. Indeed, insulin has important genomic effects that determine the expression levels of many cellular components that are directly and indirectly involved in metabolic homeostasis. Defects of insulin receptor structure are uncommon, and reductions in insulin receptor number are not usually rate limiting. Thus, the therapeutic challenge of insulin resistance appears to require interventions at diverse intracellular targets [52].

In theory, agents that address defects of insulin receptor signaling or early post-receptor lesions might be expected to produce a broader spectrum of benefits, but if the rate-limiting defects occur at more distal locations their therapeutic efficacy will be compromised. Potential target sites to obviate cellular defects of insulin action are shown in Figure 60.13.

**Figure 60.13** Pathways of intracellular insulin signaling showing some of the potential sites for therapeutic intervention. Adapted from Bailey [52]. ## Insulin receptor activation

Evidence that an orally active, non-peptide molecule can mimic the gluco-regulatory actions of insulin was obtained with L-783,281 (demethylasterriquinone; Figure 60.14), a metabolite from cultures of a *Pseudomassaria* fungus [53]. L-783,281 initiated phosphorylation and tyrosine kinase activity of the  $\beta$ -subunit of the human insulin receptor expressed in Chinese hamster ovary (CHO) cells [54]. This induced tyrosine phosphorylation and activation of insulin receptor substrate 1 (IRS1), increased activity of phosphatidylinositol 3-kinase (PI3K) and increased phosphorylation of Akt (protein kinase B). Studies with mutated subunits of the insulin receptor showed that L-783,281 interacted selectively with the  $\beta$ -subunit (without requiring insulin to bind

to the  $\alpha$ -subunit), and its activity could not be attributed to inhibition of protein tyrosine phosphatases. Low (3–6)  $\mu$ mol/L concentrations of L-783,281 elicited about 50% of the maximum tyrosine kinase activity (TKA) generated by insulin in CHO cells, and initiated a range of insulin-like effects in normal tissues including increased glucose uptake by isolated rodent adipocytes and skeletal muscle [53]. Oral administration of L-783,281 (5–25 mg/kg/day) lowered blood glucose in insulin-resistant obese-diabetic *db/db* mice providing proof of therapeutic concept, although other features of this particular compound are not suited to clinical development.

## Insulin-like growth factor I

IGF-I can weakly mimic the effects of insulin through low affinity binding to the insulin receptor [55]. Cross-talk between the IGF-I

**Figure 60.14** Structures of compounds that improve insulin action by direct interaction with insulin receptors: L-783,281 and TLK16998.

receptor and early post-receptor components of the insulin-signaling cascades can ameliorate rare cases of severe insulin resistance caused by genetic defects of the insulin receptor. IGF-I can assist glycemic control in type 1 diabetes mellitus (T1DM) and T2DM, but such therapy is generally discounted by potential proliferative effects and other unwanted side effects of IGF-I. Circulating IGF-I is mostly bound to IGF binding proteins, especially IGFBP-3, and the side effects probably reflect an increase in unbound IGF-I after injection. To address this, mixtures of recombinant human IGF-I and recombinant human IGFBP-3 have been employed [56].

### Insulin receptor potentiation

Insulin receptor signaling after initial activation by insulin binding at the  $\alpha$ -subunit can be enhanced and/or prolonged by several different mechanisms (Figure 60.13). For example, a non-peptide molecule TLK16998 (Figure 60.14) that does not interact with the insulin receptor  $\alpha$ -subunit increased insulin-induced phosphorylation of the insulin receptor  $\beta$ -subunit [54,57]. TLK16998 also potentiated  $\beta$ -subunit phosphorylation initiated

by L-783,281. In cultured mouse 3T3-L1 adipocytes, low  $\mu\text{mol/L}$  concentrations of TLK16998 increased insulin-induced phosphorylation of IRS-1 and PI3K, increased translocation of GLUT-4 glucose transporters into the plasma membrane and increased glucose uptake during submaximal stimulation by insulin. TLK16998 (30 mg/kg by intraperitoneal injection) also lowered glucose concentrations in insulin resistant obese-diabetic *db/db* mice [57].

### C peptide

Insulin C-peptide, which is secreted from pancreatic  $\beta$ -cells along with insulin, appears to bind to G-protein coupled receptors in several insulin-sensitive tissues. In cultured L6 muscle cells, physiologic concentrations of C-peptide (0.3–3.0 nmol/L) increase glycogen synthesis during submaximal (but not maximal) stimulation with insulin, accompanied by increased insulin receptor tyrosine kinase activity and phosphorylation of IRS1 [58]. Activation of PI3K, mitogen activated protein kinase (MAPK) and glycogen synthase kinase 3 (GSK3) was also noted, suggesting that the ability of C-peptide to potentiate insulin receptor signaling might modestly be exploitable as a possible approach to improve insulin action in C-peptide deficient states.

### Protein tyrosine phosphatase 1B

Several protein tyrosine phosphatases (PTPs), most notably PTP1B, dephosphorylate the insulin receptor  $\beta$ -subunit, terminating insulin-induced receptor TKA [59]. These phosphatases also dephosphorylate and deactivate IRS1 and IRS2. The therapeutic potential of inhibiting PTP1B has been demonstrated by PTP-1B KO mice which are highly sensitive to insulin [60]. These mice also show an increased metabolic rate and resistance to diet-induced obesity. Antisense oligonucleotides against PTP1B increased insulin sensitivity in *ob/ob* mice, associated with increased phosphorylation of the insulin receptor, IRS1/2 and GSK3, and increased activity of PI3K and Akt [61]. Selective inhibitors of PTP-1B, including certain benzonaphthofurans, thiophenes and acylsulfonamido compounds, improved glycemic control in insulin-resistant diabetic animals and have been considered as templates for potential new therapies [62–64]. PTP-1B inhibitors could also assist weight control by increasing the satiety effect of leptin, because hypothalamic PTP1B normally reduces leptin receptor signaling [65]. Inhibition of PTP1B might also improve endothelial function by improving insulin-induced endothelial nitric oxide synthase (eNOS) production [66]. Vanadium salts inhibit protein tyrosine phosphatases including PTP1B, and have been shown to enhance the actions of insulin and possibly leptin.

### Other insulin receptor potentiators

Various substances that increase the number of insulin receptors and/or appear to improve insulin receptor function have been mooted as possible therapeutic leads but have not given rise to new therapeutic entities. These include N-terminal fragments of human growth hormone (GH) and mosapride, a benzamide derivative that activates serotonin 5HT-4 receptors and promotes gastrointestinal motility [52,67].

## Insulin receptor and early post-receptor potentiation

The divergent pathways of post-receptor insulin signaling contain many potential rate-limiting steps for insulin action. Most of these pathways are not specific to insulin and impact activities as disparate as cell differentiation and apoptosis. They also include a controlling influence exerted through the feedback of more distal signaling components on more proximal steps [50,51].

### Protein kinase C

The IRS–PI3K route of insulin signaling (Figure 60.13) increases the formation of phosphatidylinositol-3,4,5 trisphosphate (PIP3) and phosphoinositide-dependent kinases PDK1/2. These signaling intermediates activate some isoforms of protein kinase C (PKC), which exert a negative feedback on insulin receptor and probably early post-receptor phosphorylation steps [68,69]. Inhibition of specific isoforms of PKC provides a potential means to improve insulin action, although appropriately selective inhib-

**Figure 60.15** Structure of the PKC- $\beta$  inhibitor LY333531 (ruboxistaurin), the inositol derivative 3-methoxy analog of D-*chiro*-inositol (pinitol).

itors have proved difficult. The PKC- $\beta$  inhibitor LY333531 (ruboxistaurin; Figure 60.15) is in clinical trial as a potential treatment for diabetic retinal and glomerular microvascular disease [70]. Excess fatty acids, diacylglycerol and chronic hyperglycemia also appear to reduce early insulin signaling via activation of PKC isoforms.

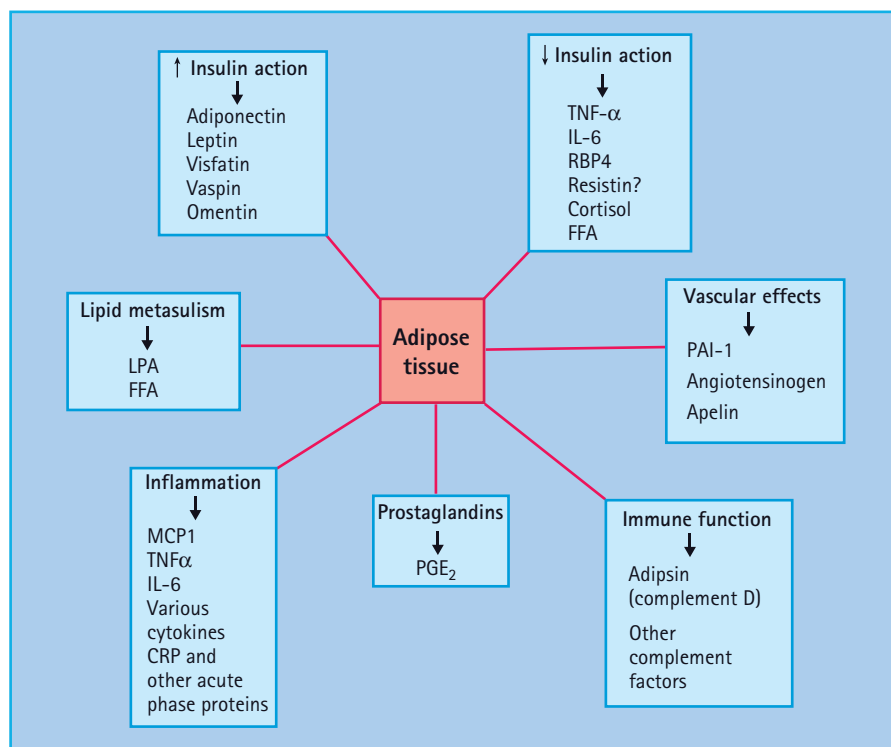

### Other signaling feedbacks

Serine phosphorylation of the insulin receptor  $\beta$ -subunit and IRS proteins, which inhibits their signaling activity, is brought about by several serine kinases such as inhibitor kappa-B kinase- $\beta$  (IKK $\beta$ ) and c-Jun N-terminal kinase (JNK; Figure 60.13). These kinases contribute to the insulin resistance produced by the cytokine tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) [71,72]. The potential opportunity to prevent these routes of insulin resistance is indicated by the ability of salicylates, which inhibit IKK $\beta$ , and a cell-permeable inhibitor of JNK to relieve insulin resistance in part [73,74].

The insulin signaling intermediate Akt appears to participate in a negative feedback effect on the signaling pathway. Akt activates the mammalian target of rapamycin (mTOR) which promotes phosphorylation of serine residues on IRS proteins [75]. The membrane ectoenzyme glycoprotein-1 (PC-1/NNP1) binds to the insulin receptor and prevents the conformational changes required for receptor autophosphorylation [76]. These interactions present potential sites for therapeutic intervention.

### Potentiation of phosphatidylinositol-3 kinase

PI3K promotes phosphorylation of phosphatidylinositol 4,5-bisphosphate (PIP2) to the 3,4,5-trisphosphate (PIP3). This step is often reduced in insulin-resistant states [77], but direct targeting of PI3K is difficult because the regulatory (p85) subunit suppresses the catalytic (p110) subunit [78]; however, increasing the availability of precursor inositol substrates and prevention of product breakdown might offer therapeutic mechanisms.

**Figure 60.16** Examples of the autocrine, paracrine and endocrine products of adipose tissue that influence insulin action, metabolic control and vascular, inflammatory and immune processes that could impinge on diabetic control. CRP, C-reactive protein; FFA, free fatty acid; IL-6, interleukin 6; LPL, lipoprotein lipase; MCP1, monocyte chemoattractant protein 1; PAI-1, plasminogen activator inhibitor 1; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; RBP4, retinol-binding protein 4; TNF- $\alpha$ , tumor necrosis factor  $\alpha$ .

### Inositol derivatives

Inositol derivatives such as *D-chiro*-inositol (INS-1) and the 3-methoxy analog of *D-chiro*-inositol (pinitol; Figure 60.15) improve muscle glucose uptake and reduce hyperglycemia in diabetic animal models and patients with T2DM [79,80]. *D-chiro*-inositol-galactosamine (INS-2) also increased insulin action in diabetic rats, possibly involving direct activation of pyruvate dehydrogenase phosphatase (protein phosphatase 2C [PP2C]) [81].

### PTEN and other inositol phosphatases

Preventing the dephosphorylation of PIP<sub>3</sub> has been identified as a possible approach to improve insulin action (Figure 60.13). The phosphatase PTEN, which dephosphorylates PIP<sub>3</sub>, can be inhibited by an antisense oligonucleotide: when administered (ip, once weekly) to *db/db* and *ob/ob* mice, the oligonucleotide increased signaling downstream of PIP<sub>3</sub>, improved insulin sensitivity and improved glycemic control [82]. Also, an adipose tissue specific PTEN knockout mouse was lean and insulin sensitive with high energy expenditure and increased biogenesis of adipocyte mitochondria [83]; however, substantial disruption of PTEN carries a risk of tumor formation [84]. PIP<sub>3</sub> is 5'-dephosphorylated to form phosphatidylinositol 3,4-bisphosphate by the SH2-inositol phosphatases (SHIP-1 and SHIP-2). Partial disruption of the SHIP-2 gene in mice improves insulin sensitivity [85], suggesting another potential target to enhance the effectiveness of PI3K.

### Adipokines

Adipose tissue is a source of many autocrine, paracrine and endocrine factors that affect insulin action (Figure 60.16), and obesity is a well-recognized risk factor for insulin resistance and T2DM [86,87]. Thus, some of these factors have been assessed as potential therapeutic targets.

### Proinflammatory cytokines

Proinflammatory cytokines produced by adipose tissue, notably TNF- $\alpha$  and interleukin 6 (IL-6), contribute to insulin resistance. They activate or induce JNK, IKK $\beta$  and the suppressor of cytokine signaling-3 (SOCS-3), each of which can disrupt TKA of the  $\beta$ -subunit of the insulin receptor (Figure 60.13); however, preliminary evaluation of a TNF- $\alpha$  antibody in patients with T2DM showed little effect on insulin sensitivity, and the risk of susceptibility to infection has called this approach into question [52].

### Adipocyte hormones

#### Leptin

Leptin is an adipocyte hormone that exerts centrally mediated satiety and thermogenic effects, as well as direct effects on cellular nutrient metabolism. Administration of large doses of leptin can produce weight loss and improve insulin action, but the development of leptin resistance and leptin antibodies has compromised long-term efficacy [88]. Leptin analogs and non-peptide receptor agonists remain under consideration.

**Figure 60.17** Structures of some compounds that potentiate insulin action: bromocriptine, lipoic acid, isoferulic acid, masoprocol and resveratrol.

### Resistin

Resistin (FIZZ3), an adipocyte hormone, reduces insulin sensitivity in obese rodents, and immuno-neutralization of resistin improved insulin sensitivity; however, resistin is expressed at low levels by human adipocytes, and may be involved in inflammatory processes, limiting its potential as a therapeutic target [89].

### Adiponectin

Adiponectin (Acrp30), produced exclusively and in large amounts by adipocytes, improves insulin sensitivity with increased insulin receptor tyrosine phosphorylation and activation of adenosine monophosphate-activated protein kinase (AMPK) [90]. It also has anti-inflammatory activity and improves vascular reactivity. Adiponectin concentrations become reduced as adipose mass increases, and therapeutic approaches to raise adiponectin levels, develop analogs and non-peptide receptor agonists are under investigation. Part of the insulin-sensitizing effect of thiazolidinediones may reflect increased adiponectin production.

### Visfatin

Visfatin (PBEF), mainly from visceral adipocytes, was initially reported to activate insulin receptors. Subsequently, however, no correlation was observed between plasma visfatin concentrations and insulin sensitivity in human subjects [91].

### Retinol-binding protein

Retinol-binding protein 4 (RBP4) is one of several retinoid-binding proteins produced by adipocytes and liver that transports

retinoids in plasma. Increased RBP4 has been noted in insulin resistant states, while RBP4 gene knockout increases insulin sensitivity [92], suggesting that a reduction of RBP4 might be considered to reduce insulin resistance.

### Vaspin

Vaspin (visceral adipose tissue-derived serpin) is an adipocyte serine protease inhibitor which improved insulin sensitivity and glucose homeostasis in obese insulin-resistant rodents, and might therefore offer a therapeutic lead [93].

### Omentin

Omentin, a peptide from visceral adipose tissue, increased insulin-stimulated glucose uptake by adipocytes [94], and might indicate a potential therapeutic approach.

## Other potentiators of insulin action

### Bromocriptine

The dopamine D2 receptor agonist bromocriptine (Figure 60.17), used in the treatment of Parkinson disease, galactorrhea and prolactinomas, has long been known to improve insulin sensitivity and glycemic control in T2DM [95,96]. Bromocriptine as monotherapy or an adjunct to other antidiabetic agents for up to 1 year has reduced HbA<sub>1c</sub> by 0.5–1.2% (5–13 mmol/mol), lowered triglyceride and non-esterified fatty acid concentrations, reduced some cardiovascular events, not caused serious hypoglycemia,

and facilitated weight loss. However, side effects including nausea, hypotension and psychiatric symptoms should be appreciated. Bromocriptine has recently received marketing authorization to treat diabetes in the USA.

### Lipoic acid, isoferulic acid and angiotensin-converting enzyme inhibitors

The antioxidant  $\alpha$ -lipoic acid (Figure 60.17), used in some countries to treat diabetic neuropathy, increases insulin sensitivity and improves glycemic control, probably brought about in part by its action as a co-factor for dehydrogenases involved in glycolysis and the Krebs cycle. Additionally,  $\alpha$ -lipoic acid increases insulin receptor TKA and IRS1 tyrosine phosphorylation, with increased signaling via PI3K and increased GLUT-4 translocation into the plasma membrane [11]. Isoferulic acid increases expression of GLUT-4 and decreases gluconeogenesis by reducing phosphoenolpyruvate carboxykinase (PEPCK) [11].

Modest improvements of insulin sensitivity have been recorded during treatment with angiotensin-converting enzyme (ACE) inhibitors, possibly because of improved hemodynamics resulting from increased bradykinin. ACE is one of the circulating enzymes that normally degrades bradykinin. ACE inhibitors may also help to counter the effects of insulin resistance by reducing inflammation and increasing vascular reactivity [97].

### Plant-derived compounds

Plant extracts and herbal preparations remain commonplace as treatments for diabetes, especially in low and middle income countries, and plant-derived compounds have provided templates for the synthesis of potential antidiabetic agents [98]. For example, the herbal use of *Bougainvillea spectabilis* led to studies on the antidiabetic action of pinitol [79], and the traditional use creosote bush (*Larrea tridentate*) prompted studies on the glucose-lowering effect of masoprocol [99].

Many current pharmaceuticals have their origins in traditional herbal medicines, and phytochemical approaches continue to attract interest. Recent attention has been given to resveratrol (Figure 60.17), a phytophenol (3,4,5 trihydroxystilbene) found in many plants, especially red grape skins [100]. It appears to offer cardioprotective properties, improving the lipid profile, increasing eNOS-dependent vasorelaxation and exerting antioxidant and anti-inflammatory effects. Resveratrol and related phytophenols may improve insulin action and prevent diet-induced obesity by increasing mitochondrial biogenesis through activation of the sirtuin SIRT1 and by increased activity of the PPAR co-activator PGC-1 $\alpha$  [101].

### Anti-obesity agents

Appetite control, reduced and delayed nutrient absorption and weight loss are well appreciated to reduce insulin resistance and hyperglycemia in the overweight and obese T2DM. Several centrally acting appetite-suppressing and satiety-inducing anti-obesity agents also exert peripheral effects that improve some actions of insulin and assist glycemic control in overweight patients.

### Sibutramine

Sibutramine, which is a serotonin-noradrenaline reuptake inhibitor that induces satiety, acts in part through the primary amine metabolite M2. This metabolite increases glucose uptake by muscle tissue independently of weight loss after treatment *in vivo* [102]. Sibutramine was withdrawn in Europe in January 2010.

### Rimonabant

Rimonabant (SR141716), an endocannabinoid receptor-1 (CB1) antagonist that suppresses appetite, was recently withdrawn because of neural side effects soon after introduction in some countries as an anti-obesity agent. In overweight and obese diabetic individuals rimonabant induced a greater reduction in HbA<sub>1c</sub> than expected for the extent of weight loss, possibly explained in part by increased adiponectin production [103].

### $\beta_3$ -Adrenoceptor agonists

$\beta_3$ -Adrenoceptor agonists act on  $\beta_3$ -adrenoceptors, expressed mainly by brown and white adipose tissue, to assist weight loss by stimulating lipolysis and thermogenesis. Several selective agonists were developed for rodents, but minor differences in the structure of the human form of the receptor rendered these agents relatively ineffective in humans. Various  $\beta_3$ -adrenoceptor agonists have been shown to stimulate insulin release, improve insulin-mediated glucose disposal and improve glycemic control in obese diabetic rodents, but adequate efficacy and a very high level of selectivity have yet to be demonstrated in humans.

---

### Peroxisome proliferator-activated receptor $\gamma$ agonists

Current thiazolidinediones (pioglitazone and rosiglitazone) exert their “insulin-sensitizing” effects largely by stimulating the peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ; Figure 60.18). Stimulation of this nuclear receptor increases transcription of a selection of insulin-sensitive genes and other genes (Table 60.8; see Chapter 29): these collectively increase adipogenesis, enhance insulin sensitivity, improve glycemic control and exert anti-inflammatory and vascular effects [104,105]. Additional thiazolidinediones that stimulate PPAR $\gamma$  continue in development (e.g. rivoglitazone), and non-thiazolidinedione PPAR $\gamma$  agonists have been reported (Figure 60.19) [105]. The latter might alter conformation of the PPAR $\gamma$  binding epitope or other regions of the receptor such that different coactivators are recruited, affecting the selection of genes transcribed and the profile of biologic effects. Thus, non-thiazolidinedione PPAR $\gamma$  agonists that partially modulate PPAR $\gamma$ , such as halofenate/metaglidasen and FK614, do not activate exactly the same set of genes as a full PPAR $\gamma$  agonist [106]. Through selective modulation of PPAR $\gamma$  binding it should be possible to retain desired therapeutic effects and reduce undesirable side effects [105]. A similar outcome might be achieved by stimulating genes for selected co-activators of PPAR $\gamma$  such as PGC-1 $\alpha$  [107].

**Figure 60.18** Mechanism of action of a thiazolidinedione in an adipocyte. Thiazolidinediones are peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) agonists. They bind to the nuclear PPAR $\gamma$  receptor, which forms a heterodimer with the retinoid X receptor (RXR). Ligand binding releases repressors, attracts co-activators and exposes the active site of the receptors which binds with a specific DNA nucleotide sequence (AGGTCAAGGTC) termed the peroxisome proliferator response element (PPRE). RNA polymerase is recruited and

transcription of mRNA takes place for genes that carry the PPRE sequence in a promoter region. The mRNA is translated into the enzymes and transporters that bring about the biologic effects of thiazolidinediones in the cell. These include the fatty acid transporter protein (FATP), adipocyte fatty acid binding protein (aP2), acyl-CoA synthase, lipoprotein lipase and glucose transporter 4 (GLUT 4). Stimulation of PPAR $\gamma$  also activates genes encoding proteins with anti-inflammatory and vascular effects.

### Other peroxisome proliferator-activated receptor agonists

To take advantage of the blood lipid-lowering and anti-inflammatory effects of low affinity binding to PPAR $\alpha$  various thiazolidinediones and non-thiazolidinedione molecules have been described with binding affinities for both PPAR $\gamma$  and PPAR $\alpha$  – so-called dual PPAR $\alpha/\gamma$  agonists (glitazars) [105]. The two glitazars most advanced in development (muraglitazar, tesaglitazar) were discontinued because of side effects [108].

Genetic overexpression or selective stimulation of PPAR $\delta$  (e.g. with GW501516 and L-165041) improves insulin sensitivity, increases fatty acid oxidation, raises thermogenesis and prevents weight gain [109]. Thus, a selective PPAR $\delta$  agonist or an agent with desired levels of selectivity for PPAR $\alpha$ ,  $\gamma$  and  $\delta$  (termed a panPPAR agonist or SPPARM – selective PPAR modulator) could offer therapeutic advantages [105]. Various selective modulators of RXR have been reported to reduce hyperglycemia in

animal models, but these tend to have diverse effects including hypertriglyceridemia and interference with thyroid function. Because certain RXR agonists can reduce appetite, increase production of mitochondrial uncoupling proteins and decrease weight gain, combinations of these agents with PPAR $\gamma$  (PPAR $\gamma$ -RXR agonists) have received preclinical consideration [110].

### Vitamins and minerals

#### Vitamins

The pathogenic effect of excess reactive oxygen species has become an accepted part of glucotoxicity, lipotoxicity and insulin resistance, and it is appreciated that anti-oxidant defenses are often depleted in diabetic states [111]. Whether supplementation of the anti-oxidant vitamins C (ascorbic acid), E ( $\alpha$ -tocopherol) and  $\beta$ -carotene can measurably benefit insulin sensitivity and reduce cardiovascular risk remains in contention [112]. Adequate concentrations of vitamin D and vitamin D receptor function

**Table 60.8** Stimulation of peroxisome proliferator-activated receptor  $\gamma$  increases transcription of a selection of insulin-sensitive and other genes affecting adipogenesis, insulin sensitivity, nutrient metabolism, anti-inflammatory and vascular reactions (so-called "pleiotropic" effect).

Lipoprotein lipase (LPL)  
 Fatty acid transporter protein (FATP/CD36)  
 Adipocyte fatty acid binding protein (aP2)  
 Acyl-CoA synthetase (ACS)  
 Malic enzyme  
 Glycerol kinase (adipocytes ?)  
 PEPCK (adipocytes),  $\uparrow$  perilipin  
 $\uparrow$  GLUT-4 (derepression),  $\uparrow$  GLUT-2  
 $\downarrow$  Resistin,  $\downarrow$  RBP4  
 $\uparrow$  Adiponectin ( $\uparrow$  leptin,  $\uparrow$  IRS2 ?)  
 $\downarrow$  TNF- $\alpha$   
 $\downarrow$  CRP and some proinflammatory cytokines,  $\downarrow$  NF $\kappa$ B,  $\downarrow$  IFG- $\gamma$  (T cells)  
 $\downarrow$  PAI-1,  $\downarrow$  MMP-9  
 $\uparrow$  UCP1 (?)

$\uparrow$  increase;  $\downarrow$  decrease; ? unconfirmed.

CRP, C reactive protein; GLUT-4, glucose transporter 4; IFG- $\gamma$ , interferon gamma; IRS, insulin receptor substrate; MMP-9, matrix metalloproteinase-9; NK $\kappa$ B, nuclear factor  $\kappa$ B; PAI-1, plasminogen activator inhibitor-1; PEPCK, phosphoenolpyruvate carboxy kinase; RBP, retinal binding protein; TNF- $\alpha$ , tumor necrosis factor  $\alpha$ ; UCP1, uncoupling protein 1.

appear to be necessary for normal insulin production and secretion, and may be required for normal insulin action. Diabetic patients are often deficient in circulating vitamin D<sub>3</sub> (cholecalciferol), and preliminary data suggest that vitamin D supplementation in deficient individuals might benefit glycemic control [113]. Thiamine (vitamin B<sub>1</sub>) is a co-factor for pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase, and facilitates glucose metabolism, while large amounts of biotin (vitamin H) have been claimed to improve glycemic control and insulin sensitivity in T2DM [52,114]. When interpreting vitamin supplement studies it is pertinent to note that correcting a deficiency is more likely to offer benefit than adding excess in individuals with normal values.

### Minerals

Reduced and deficiency levels of several minerals, particularly magnesium, chromium and zinc, are not uncommon amongst older patients with diabetes, and replacement supplements may improve glycemic control in such cases [115]. Supplementation of magnesium (necessary for phosphate transfer and kinase reactions) can enhance insulin action in hypomagnesemic patients [116], and trivalent chromium supplements often improve glycemic control without increasing insulin concentrations in chromium-deficient patients [117]. Insulin-like antidiabetic effects have been reported for zinc, lithium, selenium, molybdenum, tungsten, mercury and cadmium, but the therapeutic index is generally narrow and toxicity risks have limited clinical investigations [115]. Zinc (essential for insulin hexamer formation)

**Figure 60.19** Structures of the thiazolidinediones pioglitazone, rosiglitazone, rivoglitazone and the non-thiazolidinedione partial PPAR $\gamma$  agonist metaglidasen.

appears to assist both the secretion and action of insulin, while molybdenum and tungsten salts act predominantly to decrease hepatic glucose output [13,59,115]. Improved insulin sensitivity with lithium may be offset by decreased insulin secretion resulting in variable effects on glycemic control in T2DM [115].

Vanadium salts have attracted considerable interest because modest vanadium supplements have improved glycemic control and reduced insulin requirements in diabetic animals and in patients with T1DM and T2DM [115,118]. Improved insulin sensitivity has been attributed at least in part to inhibition of protein tyrosine phosphatases, especially PTP-1B, and suppression of glucose 6-phosphatase. Additional effects to reduce appetite and reduce the rate of intestinal glucose absorption may also contribute to the antidiabetic effect of vanadium salts. To address issues of poor absorption and toxicity, low-dose peroxovanadiums, pervanadates and organic vanadium complexes have received attention [119], and an intermittent treatment schedule might be considered because the antidiabetic effects of vanadium salts can persist for weeks after treatment is stopped.

### Counter-regulatory hormones

The major counter-regulatory hormones (glucagon, epinephrine, glucocorticoids and GH) raise blood glucose concentrations by increasing hepatic glycogenolysis and gluconeogenesis (see Chapter 13). As hepatic glucose production is inappropriately raised in diabetes, agents that interfere with the secretion or

action of counter-regulatory hormones could potentially be therapeutically useful; however, those with highly potent or prolonged actions are undesirable, as they might impair the life-sustaining protection of the liver to produce glucose in response to severe hypoglycemia. Indeed, patients in advanced stages of T2DM often show delayed or deficient counter-regulatory responses to hypoglycemia.

### Glucagon antagonists

The concept of reducing hyperglycemia by suppressing glucagon action is illustrated by the use of glucagon antibodies [120], and various peptide antagonists of the glucagon receptor have been described, mostly based on deletion of His1 and replacement of Asp9 with Glu [121]. There are also hybrid peptides that show glucagon receptor antagonism and GLP-1 receptor agonism [36]. Many small molecule glucagon receptor antagonists have been reported. An isopropylfluorobiphenyl (Bay 27-9955) that competitively blocked glucagon binding to its receptor has not proceeded in development [122], but other potent inhibitors such as Cpd1, NNC 25-0926 and MB09975N are being investigated [123,124]. An alternative approach has been to uncouple the glucagon receptor from activation of adenylate cyclase (e.g. with skyrin, a fungal bisanthroquinone) [125]. Inhibitors of glucagon secretion (e.g. MB39890A and somatostatin analogs) have been developed, but have not been sufficiently selective [121]. Thus, the somatostatin analog octreotide (Figure 60.20), suppresses glucagon secretion and delays intestinal glucose absorption as well as preventing GH secretion, but it also inhibits insulin secretion, rendering it unhelpful in T2DM, but potentially useful for glycemic control with insulin in patients with T1DM [121].

### Glucocorticoid antagonists

Raised glucocorticoid concentrations can precipitate and aggravate truncal obesity, insulin resistance and hyperglycemia, while maneuvers to reduce glucocorticoid action can prevent and reverse these effects. To avoid lowering overall glucocorticoid production, and to minimize disturbances to the hypothalamic-pituitary-adrenal system, tissue specific inhibition of glucocorticoid action has been investigated. Some inhibitors of glucocorticoid receptor binding show modest degrees of hepatic selectivity [126], but more specific targeting of the liver has been achieved

when glucocorticoid receptor inhibitors are conjugated to bile salts. This retains the inhibitor mostly within the entero-hepatic circulation, reducing hyperglycemia and improving hepatic insulin sensitivity in animal models [127].

Another approach to the cellular targeting of glucocorticoid suppression takes advantage of the normal cellular conversion of less active cortisone to more active cortisol (Figure 60.21). This

**Figure 60.20** Structure of native somatostatin-14, its synthetic octapeptide analog, octreotide, and a non-peptide glucagon receptor antagonist Cpd 1.

**Figure 60.21** Cellular conversion of less active cortisone to more active cortisol through the reductase activity of the enzyme 11β-hydroxysteroid dehydrogenase-1 (11β-HSD1).

reaction is mediated through the predominantly reductase activity of the enzyme  $11\beta$ -hydroxysteroid dehydrogenase-1 ( $11\beta$ -HSD1) which is strongly expressed in liver and adipose tissue [128]. Selective inhibitors of  $11\beta$ -HSD1 have been shown to improve insulin sensitivity, glycemic control and plasma lipids in obese-diabetic rodents [129]. Excess glucocorticoids are often associated with some degree of islet hypertrophy, and because  $11\beta$ -HSD1 is expressed by pancreatic  $\beta$ -cells, possible effects of  $11\beta$ -HSD1 inhibitors on  $\beta$ -cells require detailed evaluation.

There is a substantial literature documenting that administration of the adrenal androgen dehydroepiandrosterone (DHEA) and an etiocholanolone metabolite (Figure 60.22) can decrease adiposity, improve glycemic control and reduce insulin resistance in obese diabetic animal models [130]. These agents may act in part to elevate tyrosine phosphorylation of IRS proteins and increase translocation of the glucose transporters GLUT-1 and GLUT-4 to the cell membrane [131].

### Direct modifiers of glucose metabolism

Many substances directly stimulate glucose uptake and utilization or suppress glucose production. Their metabolic impact is often difficult to control, and their wider effects have precluded therapeutic application for T2DM. Included here are agents that create some insulin-like effects such as deoxyfrenolicin, vitamin  $K_5$ , spermine, diamides and peroxides (Figure 60.23) [115]. Okadaic acid and phorbol esters initially imitate certain effects of insulin,

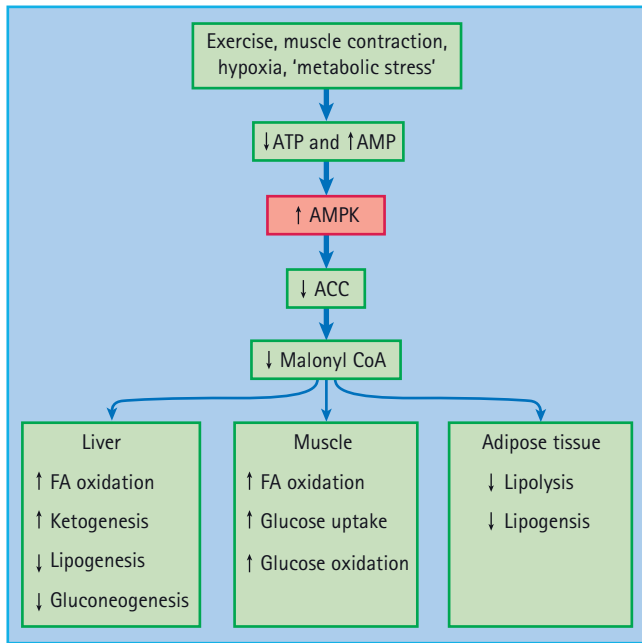

but then prevent tissues from responding further to insulin. Dichloroacetate and its esters increase glucose oxidation by stimulating pyruvate dehydrogenase, and suppress hepatic glucose production by inhibiting pyruvate carboxylase, but may adversely affect neural function through the production of glyoxylate and oxalate [115].

**Figure 60.22** Structures of dehydroepiandrosterone (DHEA) and etiocholanolone.

**Figure 60.23** Structures of deoxyfrenolicin, vitamin  $K_5$ , spermine, okadaic acid and dichloroacetate.

**Figure 60.24** Metabolic effects of the energy-regulating enzyme adenosine monophosphate-activated protein kinase (AMPK). ACC, acetyl CoA carboxylase; FA, fatty acid.

### Adenosine monophosphate-activated protein kinase activators

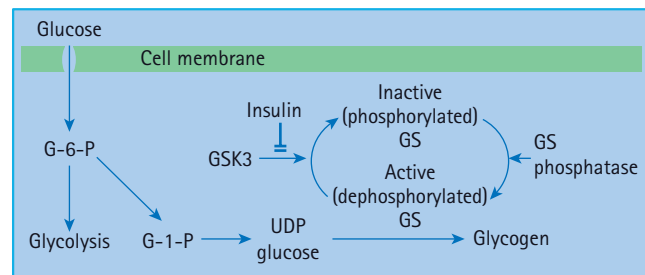

Adenosine monophosphate-activated protein kinase (AMPK) is a key energy-regulating enzyme that is activated when the energy status of cells declines and/or energy demand escalates [132]. When ATP and creatine phosphate become depleted, for example during exercise, AMP concentrations become raised. Rising AMP concentrations activate AMPK, promoting energy production by increasing the uptake and oxidation of glucose and fatty acids, leading to the restoration of ATP (Figure 60.24). AMPK may also reduce expression of PEPCK (key gluconeogenic enzyme), and depending upon associated regulatory factors, suppress cell proliferation [133]. Metformin, adiponectin and thiazolidinediones have been shown to activate AMPK amongst other actions that contribute to their glucose-lowering effects [134]. Various analogs of AMP such as AICAR (5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside) have been shown to activate AMPK and improve glycemic control in insulin-resistant diabetic animals (Figure 60.25) [135, 136], and other activators (e.g. DRL-16536) are being developed.

### Glycogen synthase kinase inhibitors

Glycogen synthesis is impaired in T2DM, caused in part by reduced activity of glycogen synthase. Glycogen synthase is normally deactivated through phosphorylation by a serine/threonine kinase – GSK3. Glycogen synthesis proceeds when GSK3 is inactivated by insulin via the PI3K-Akt pathway, but expression and activity of GSK3 are increased in insulin-resistant diabetic states.

**Figure 60.25** Structure of AICAR, 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside.

**Figure 60.26** Glycogen synthase kinase-3 (GSK3) regulation of glycogen synthase (GS). G-6-P glucose 6-phosphate; G-1-P, glucose 1-phosphate; UDPG, uridine diphosphate glucose.

Small molecule inhibitors of GSK3 have been shown to lower blood glucose and increase insulin-stimulated glucose uptake and glycogenesis by skeletal muscle of insulin-resistant diabetic animals [137,138]. There are two isoforms and several splice variants of GSK3 that have various roles in the signaling of pathways as diverse as cytoskeletal regulation, protein degradation and apoptosis, making it difficult to target glycogen metabolism specifically (Figure 60.26).

### Glucokinase activators

Because liver cells, like islet β-cells, can take up glucose approximately in proportion to the circulating glucose concentration, the rate of hepatic glucose disposal is determined mostly through the rate of glucose phosphorylation by GK. Allosteric activators of GK and molecules that prevent GK from binding with its inhibitory regulatory protein have been shown to increase hepatic glucose metabolism and reduce blood glucose concentrations in normal and diabetic rodents [24–29,139]. Clinical studies will establish whether the combined effects of increased hepatic glucose disposal and increased insulin secretion can be titrated to avoid overt hypoglycemia.

### Inhibitors of hepatic glucose production

Any therapeutic approach that suppresses gluconeogenesis and/or glycogenolysis should be partial, readily reversible and should not seriously compromise vital actions of counter-regulatory

hormones and neural signals in times of rapid and severe hypoglycemia.

### Glycogen phosphorylase inhibitors

Glycogen phosphorylase inhibitors have received considerable preclinical attention as possible agents to reduce hyperglycemia by preventing the breakdown of glycogen. The agents studied include inhibitors of the active site, the AMP site and other sites on the enzyme [139–141]. An example is the dihydropyridine derivative BAY R3401, a prodrug that is metabolized to an active agent that binds at the AMP site causing allosteric inhibition and dephosphorylation of active glycogen phosphorylase *a* into the inactive *b* form [141]. While most glycogen phosphorylase inhibitors have been shown to improve glycemic control in animal models of T2DM, there have been few reports of clinical studies, and the limited evidence available suggests only modest or unsustained efficacy.

### Glucose 6-phosphatase inhibitors

Glucose 6-phosphatase inhibitors have been considered an attractive approach to address hyperglycemia because they can interrupt the last step in glucose output from both glycogenolysis and gluconeogenesis. Inhibitors of the catalytic subunit and the translocator protein for glucose 6-phosphatase have been shown to reduce hepatic glucose output and lower blood glucose; however, this approach carries a high risk of hypoglycemia. Also, cellular accumulation of glucose 6-phosphate causes excess deposition of glycogen and induction of lipogenic genes which predispose to fatty liver [139].

### Fructose 1,6-bisphosphatase (F16BPase) inhibitors

Fructose 1,6-bisphosphatase (F16BPase) inhibitors prevent the dephosphorylation of fructose 1,6-bisphosphate to fructose 6-phosphate as the penultimate step in gluconeogenesis before glucose 6-phosphate. Various F16BPase inhibitors have been described, generally causing only a partial reduction of hepatic glucose output because of increased compensatory glycogenolysis, which helps to guard against hypoglycemia [139]. Although excessive use of a F16BPase inhibitor might cause accumulation of lactate and triglyceride, appropriate titration of such agents in early clinical trials (e.g. MB07803) has given encouraging results.

## Modifiers of lipid metabolism

The commonly observed dyslipidemia of T2DM, particularly raised very low density lipoprotein (VLDL), triglyceride and non-esterified fatty acid (NEFA) levels, contribute to insulin resistance and hyperglycemia in several ways [51,142]. These include direct effects of fatty acids and their metabolites to impair cellular insulin signaling pathways, and alterations in fuel selection mediated through the Randle (glucose–fatty acid) cycle. Agents that modify lipid metabolism could therefore benefit glycemic control in T2DM. For example, thiazolidinedione PPAR $\gamma$  agonists act in

**Figure 60.27** Structures of the antilipolytic agents, nicotinic acid and acipimox.

part through an alteration in fatty acid metabolism, and lipid-lowering fibrates, which act via PPAR $\alpha$  agonism, can modestly assist glycemic control in some patients. Other agents that lower plasma triglycerides, such as the fenfluramine analog benfluorex and the long-chain dicarboxylic acid, Medica 16, can lower blood glucose concentrations [121]. Reducing circulating NEFA concentrations with conventional antilipolytic agents such as nicotinic acid (niacin) and its analog acipimox (Figure 60.27) can acutely improve glucose tolerance in T2DM, but the effect is not consistent or sustained [121].

Inhibition of fatty acid oxidation interrupts the supply of energy for hepatic gluconeogenesis and enhances the use of glucose as a source of energy in skeletal muscle. Most inhibitors of fatty acid oxidation act by inhibiting carnitine palmitoyltransferase 1 (CPT-1), the rate-limiting enzyme for transfer of long-chain fatty acyl-CoA into the mitochondria. Irreversible inhibitors of CPT-1 such as the oxirane carboxylates (e.g. etomoxir) and the alkylglycidates (e.g. methyl palmoxirate) have effectively lowered glucose concentrations in diabetic animals, mainly through their antigluconeogenic action, but clinical studies have indicated vulnerability to hypoglycemia. Similar concerns have emerged with agents that inhibit intramitochondrial enzymes of fatty acid oxidation [121].

### Sodium-glucose co-transporter 2 inhibitors

Glucose is filtered through the renal glomeruli and (almost) all that has been filtered is reabsorbed in the proximal tubules. Reabsorption is mediated mostly via the sodium-glucose co-transporter 2 (SGLT2) system (Figure 60.28). SGLT2 is expressed only in the first segment of the tubules and enables low affinity secondary active glucose transport into the tubular epithelial cells [143]. Thus, specific and appropriately titrated inhibition of these transporters provides an opportunity to reduce hyperglycemia by elimination of excess glucose in the urine. The potential of this approach has long been appreciated because non-specific inhibitors of sodium-glucose co-transporters such as phlorizin (Figure 60.29) from apple tree bark have been shown to reduce hyperglycemia in animals [144]. Non-specific inhibitors can also inhibit SGLT1 which is responsible for intestinal glucose absorption.

**Figure 60.28** After glucose is filtered at the glomerulus into the proximal convoluted tubule (PCT) it is reabsorbed mostly from the first segment of the PCT via the low affinity secondary active sodium glucose co-transporter 2 (SGLT2).

More recently, selective inhibitors of SGLT2 (termed “flozins”) have been developed, and these have reduced hyperglycemia in diabetic animals and proceeded into clinical trials [145]. Preliminary evidence suggests that dosages that partially prevent glucose reabsorption to allow elimination of up to about 100 g/day glucose can be used to facilitate glycemic control in patients with T2DM. In principle, reversible SGLT2 inhibitors could be

**Figure 60.29** Structure of phlorizin (non-specific SGLT1/2 inhibitor) and the selective SGLT2 inhibitor dapagliflozin.

used as adjunctive therapy with any other antidiabetic treatment, and the elimination of glucose should assist weight loss. By lowering glucotoxicity it is anticipated that insulin sensitivity may be improved. Because SGLT2 inhibition does not stimulate insulin secretion or interrupt the counter-regulatory system, serious hypoglycemia should be avoidable if the extent of SGLT2 inhibition is titrated appropriately. Possible adverse effects of osmotic diuresis during SGLT2 inhibition include risk of dehydration and electrolyte imbalance, as well as infection in the urinary tract and urino-genital region.

### Sirtuins

Sirtuins comprise a group of seven enzymes that are nicotinamide-adenine-dinucleotide (NAD)-dependent histone deacetylases and/or ADP-ribosyltransferases. They affect gene transcription through chromatin silencing, and mediate metabolic responses that have the potential to extend lifespan similar to chronic caloric restriction [146]. Sirtuin SIRT1 is widely expressed in mammalian tissues including liver, muscle and fat, and appears to promote mitochondrial biogenesis and activity in some tissues, increasing thermogenesis and reducing susceptibility to weight gain, diabetes and cardiovascular disease. AMPK enhances SIRT1 activity, resulting in increased activity of downstream transcription factors such as PGC-1 $\alpha$  and the fork-head protein FOXO1 which increase energy production [147]. SIRT1 in pancreatic  $\beta$ -cells may also facilitate insulin secretion. Several small molecule activators of SIRT1 have been described that are structurally unrelated to polyphenols (such as resveratrol). The activators increased mitochondrial capacity, enhanced insulin sensitivity and reduced plasma glucose in animal models [148].

### Stem Cell Therapy in Diabetes

*Shuibing Chen<sup>1</sup>, Jayaraj Rajagopal<sup>2,3</sup>, Qiao Zhou<sup>3</sup> & Douglas A. Melton<sup>1,3</sup>*

#### Keypoints

- Stem cells are self-renewing cells that possess the ability to generate daughter cells that produce large numbers of differentiated progeny. They can be divided into two broad categories: embryonic stem cells and adult stem cells.
- Embryonic stem cells are derived from the inner cell mass of mammalian blastocysts and can give rise to all of the differentiated tissues of the embryo proper, including the  $\beta$ -cells of the pancreas.
- Induced pluripotent stem cells are embryonic stem cell-like cells derived from adult cells such as skin fibroblasts in a process called reprogramming.
- Human embryonic stem cells and induced pluripotent stem cells have been shown to produce insulin-producing cells by stepwise approach in culture.
- Adult stem cells have been identified in many organs, where they participate in tissue repair and homeostasis. No definitively identified stem cell population has been described in pancreas.
- Lineage-tracing experiments suggest that  $\beta$ -cell mass is maintained primarily by replication of pre-existing  $\beta$ -cells during normal adult life in mice. After injury, stem/progenitor cells may be recruited to produce additional islet cells, but the identity of these pancreatic stem/progenitor cells remains unclear.
- Pancreatic exocrine cells can be directly converted to become  $\beta$ -cells *in vivo* in a process called lineage reprogramming.

## Introduction

The aim of stem cell therapy in the treatment of type 1 diabetes mellitus (T1DM) is to provide a source of cells that are identical or nearly identical to  $\beta$ -cells. Stem cells by definition are self-renewing, and in some cases they can be propagated clonally from a single cell. These properties allow a degree of reproducibility that is unusual for a cell-based therapeutic vehicle. It may be possible to engineer stem cells to evade immune recognition. It is also now possible to derive patient-specific induced pluripotent cells (iPS) that fully match individual patients immunologically. Encouraging progress has been made in recent years to derive insulin-producing cells from either embryonic stem cells or exocrine cells. Future efforts will be focused on continued improvement of the derivation efficiency and fidelity of  $\beta$ -cells, with the ultimate aim of producing sufficient numbers of transplantable mature  $\beta$ -cells that can rescue hyperglycemic conditions.

## General definitions: adult and embryonic stem cells

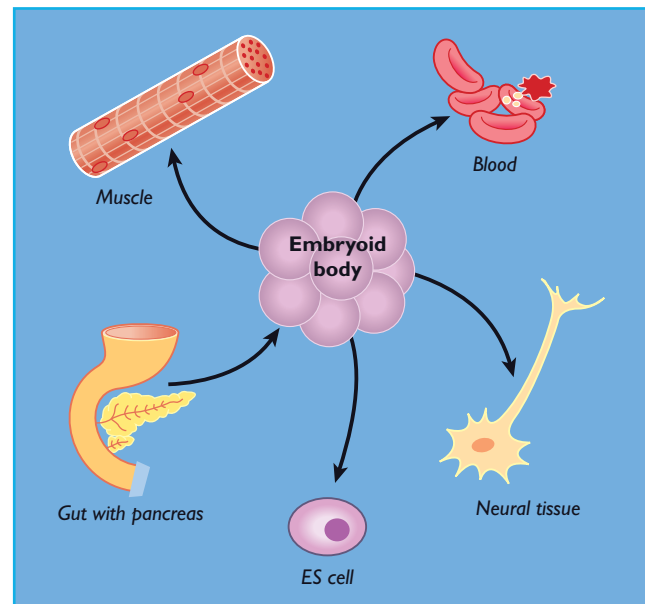

Stem cells are defined functionally. They are capable of self-renewal and possess the ability to generate daughter cells that

produce large numbers of differentiated progeny [1]. They can be divided into two broad categories: embryonic stem cells and adult stem cells. Embryonic stem cells are derived from the inner cell mass of the mammalian blastocyst (Figure 61.1) and are said to be pluripotent because they give rise to all of the fully differentiated tissues of the embryo proper, including the products of all three embryonic germ layers and thus the  $\beta$ -cells of the pancreas (Figure 61.2). Fortunately, conditions have been described that permit the long-term culture of these cells *in vitro* without chromosomal aberration or loss of potency to form diverse tissues (Figure 61.3) [2–6]. Indeed, cell lines can be created by the propagation of a single cell, ensuring homogeneous cell populations that can subsequently be used as starting material for  $\beta$ -cell differentiation experiments.

Adult stem cells are thought to be rare cells and are known to participate in the repair or regeneration of certain tissues, most notably in the bone marrow [7,8]. Furthermore, stem cell populations are involved in the tissue homeostasis of the liver, the brain, the skeletal muscle and the skin [9–13]. Adult stem cells, like their embryonic counterparts, are capable of self-renewal and retain the ability to generate large numbers of differentiated progeny, but they are traditionally thought to produce a more limited number of cell types. Although there is some evidence to suggest the existence of a pancreatic stem cell function, no cell type or marker of such a putative cell has been identified. In fact,

**Figure 61.1** Derivation of embryonic stem cells. After fertilization, the single-cell human or mouse zygote undergoes cleavage to produce a multicellular blastocyst. The blastocyst stage of mammalian development occurs well before cytodifferentiation and organogenesis. Cells from the inner cell mass, which normally give rise to the tissues of the embryo proper, can be cultured *in vitro* to produce embryonic stem cells. ES, embryonic stem.

**Figure 61.2** The pluripotent nature of embryonic stem (ES) cells. Embryonic stem cells can be cultured *in vitro* indefinitely. When allowed to aggregate in suspension culture, forming embryoid bodies, they differentiate into derivatives of all three embryonic germ layers. This includes ectodermal tissues such as neurons, mesodermal tissues such as muscle cells and blood, and endodermal tissues such as  $\beta$ -cells. Although there are many cell types in embryoid bodies, they are often disorganized and do not adopt the same patterned structure found in mature embryos and adults (e.g. actual muscle, ganglia, gut or islets).

**Figure 61.3** A human embryonic stem cell colony is composed of hundreds to thousands of homogeneous cells grown in a Petri dish along with hundreds of other similar stem cell colonies. One colony is shown here. These colonies are grown on mouse embryonic fibroblasts, which provide signals preventing embryonic stem cell differentiation. This allows repeated, near-indefinite subculture of embryonic stem cells. When removed from the murine feeder layer, the stem cells spontaneously differentiate into a wide variety of cell types (not shown).

**Figure 61.4** Potential stem-cell sources of  $\beta$ -cells. In theory, one can derive pancreatic  $\beta$ -cells from a number of different stem cell sources. Embryonic stem cells from the mammalian blastocyst have the broadest capacity for differentiation. Similarly, induced pluripotent cells (iPS) derived from skin fibroblasts may also give rise to all cell types in the body, including  $\beta$ -cells. Pancreatic stem cells may be the most direct path to  $\beta$ -cells, but their identity is still unclear. ES, embryonic stem.

**Figure 61.5** Stepwise differentiation from embryonic stem (ES) cells to  $\beta$ -cells. DE, definitive endoderm; PP, pancreatic progenitor; EP, endocrine progenitor; Ngn3, neurogenin 3; INS, insulin.

it is unclear whether the concept of an adult stem cell represents a single well-defined cell type or a common property of a heterogeneous population of different cells [1].

### Differentiating $\beta$ -cells from human embryonic stem cells

Embryonic stem (ES) cells, with a virtually endless replicative capacity and the potential to differentiate into most cell types, provide nearly unlimited starting material to generate differentiated cells for study and clinical therapy [14]. By mimicking signals used during embryonic pancreatic development, to the extent that they are known, a stepwise protocol is being explored to differentiate human ES cells into functional  $\beta$ -cells (Figure 61.4). This involves directing ES cells first to form definitive

endoderm, then  $Pdx1^+$  pancreatic progenitors, followed by the formation of endocrine progenitors and, finally, insulin<sup>+</sup>  $\beta$ -cells (Figure 61.5). Knowledge from pancreatic development provides candidate factors that promote the progression from one step to another, and marker genes that can be used to recognize the cells at each developmental stage.

Using a protocol based on the combination of candidate factors suggested by embryonic pancreatic development, significant advances have been made to produce insulin-producing cells from human ES cells [15–17]. Briefly, human ES cells were first treated with Wnt 3a and Activin A, which can result in approximately 70% of the cells expressing SOX17 [15], a marker of definitive endoderm. In the second step, manipulation of several signaling pathways that include suppression of sonic hedgehog (SHH) and bone morphogenetic protein (BMP), and activation of retinoic acid (RA) [16,17], allow the cells to progress into a

pancreatic and endocrine progenitor stage. This heterogeneous progenitor population can be further differentiated and matured into various pancreatic endocrine cell types including insulin-secreting cells either in Petri dish [16] or after being transplanted into mice [17]. The endocrine cells appear to organize into islet-like structures and gain the ability to ameliorate hyperglycemia.

As an alternative to growth factors as inducers, an unbiased chemical screen approach has been used to identify cell-permeable small molecules to direct human ES cells to pancreatic lineage. In the ideal case, as noted by many others, small molecule inducers would be less expensive, more easily controlled, and possibly more efficient than growth factors in directing differentiation. High content chemical screening has led to the identification of a small molecule, (-)-Indolactam V (ILV), that induces human ES cell differentiation to pancreatic progenitors. These pancreatic progenitors can contribute to insulin-secreting cells both *in vitro* and *in vivo* [18].

Despite recent successes with the human ES cell approach, major challenges remain. The efficiency and consistency of  $\beta$ -cell derivation from human ES cells require improvement. The resulting  $\beta$ -like-cells need to be extensively validated to confirm their function [16] and the possibility of tumor formation after transplantation [17] must be fully addressed. New reagents and methodologies of human ES cell differentiation will need to be developed to overcome these challenges.

Human ES cell lines are derived from blastocyst-stage embryos. Recently, significant progress has been made in reprogramming differentiated human skin fibroblasts to a pluripotent state by introducing defined transcription and other reprogramming factors [19–21]. The resulting pluripotent cells are called induced pluripotent stem cells (iPS cells). iPS cells derived from people with diabetes have recently been shown to differentiate into three germ layers [22]. These DiPS cells could provide an important reagent for modeling diabetes pathology and investigating new therapies.

---

## Evidence for the existence of pancreatic stem cells

In principle, tissue turnover in the adult can occur by the differentiation of adult stem cells (e.g. in skin and intestine), or by the replication of existing differentiated cells. In adult pancreas, there is strong evidence suggesting that new  $\beta$ -cells are generated primarily by the replication of pre-existing  $\beta$ -cells during normal adult homeostasis, as well as during  $\beta$ -cell regeneration induced by either partial removal of the pancreas or specific ablation of  $\beta$ -cells [23–27].

The evidence for the existence of adult pancreatic stem cells is indirect and comes from studies of regenerating pancreata. In these models, a chemical or surgical injury is induced in the adult pancreas. After chemical or surgical pancreatectomy in the islet, a burst of replicative activity in the pancreatic duct cells has also been reported. BrdU label disappears from the ducts and then

increases in pancreatic exocrine and endocrine tissue, suggesting that cells may be recruited from ducts to form islets and acini [28]. Groups of cells that appear to be budding from the ducts have been suggested to represent cells recruited from a ductal stem cell compartment. The early burst in epithelial duct proliferation following pancreatectomy is reported to be accompanied by an increase in Pdx1 protein in the replicating duct cells [29]. Pdx1 is a protein that is essential for exocrine and endocrine pancreas formation. In the regenerating hamster pancreas, there are nests of cells near ducts that express insulin and glucagon, suggesting that duct cells may differentiate into hormone-producing cells that subsequently migrate into the islets [30]. In addition, after chemical pancreatectomy with streptozocin (streptozotocin), a cell population that coexpress hormones appears in the islets themselves, including Pdx1–somatostatin cells and somatostatin–insulin cells. These double-positive cells have been noted in the developing pancreas, but their exact role in development of the  $\beta$ -cell lineage is unclear. Nonetheless, it has been suggested that the presence of such cells implies neogenesis from a stem cell compartment located within the islets themselves [31].

It has recently been demonstrated that following partial duct ligation, a progenitor population expressing neurogenin 3 (Ngn3), a marker of embryonic endocrine progenitors, appears in adult mice. These Ngn3<sup>+</sup> cells can further give rise to new islet cells, including  $\beta$ -cells after transplantation into cultured embryonic pancreata [32]. This study provides an example of the existence of  $\beta$ -cell progenitors in adult pancreas; however, it is not clear whether this event represents the mobilization of existing adult endocrine progenitor cells that already express low levels of Ngn3, activation of dormant stem-like cells, or conversion of other cells into endocrine cells following injury. In addition, the number of Ngn3<sup>+</sup> progenitors detected following injury is very low and the molecules triggering the regeneration event remains unknown.

Taken together, the work on regenerating pancreata suggests the possibility of an existing precursor or stem cell; however, no clearly identified subpopulation of cells that has the capacity for self-renewal and  $\beta$ -cell differentiation has yet been identified as the pancreatic stem cell compartment. If such a pancreatic stem cell compartment does exist, its physiologic significance, in terms of the number of new  $\beta$ -cells produced, needs to be compared with the demonstrable capacity of  $\beta$ -cells for self-duplication.

---

## Lineage reprogramming

In rare cases, adult cells of one lineage may be converted directly into cells of another lineage [33]. These phenomena are broadly defined as lineage reprogramming. For the pancreas, there is some experimental evidence suggesting that non- $\beta$ -cells, such as liver cells, pancreatic duct cells and exocrine cells, may be converted to  $\beta$ -like-cells in culture [34]. In most of these reported

cases, however, the extent to which the resulting cells resemble true  $\beta$ -cells is often unclear. The molecular mechanism of these reported conversion events also remain largely unknown.

Recently, it has been shown that mature exocrine cells of the pancreas can be reprogrammed to become  $\beta$ -like-cells *in vivo* with a simple combination of three transcription factors. The induced cells closely resemble endogenous islet  $\beta$ -cells in morphology, ultrastructure, molecular signatures and function [35]. There are several issues that need to be resolved before the *in vivo* lineage reprogramming approach can be applied to clinical therapy. For example, the induced  $\beta$ -cells persist as individual cells or small clusters and do not organize into islets. Moreover, viruses currently used to express the reprogramming factors would need to be replaced by safer reagents such as chemical compounds. Furthermore, given the difficulty of biopsying human pancreas,  $\beta$ -cell reprogramming should be accomplished directly *in vivo*, or alternatively, other more easily accessible starting cell populations, such as adult liver cells and skin fibroblasts, may be used to produce  $\beta$ -cells.

---

### Future issues regarding human transplantation of cell-based therapies

There are several promising strategies for the generation of  $\beta$ -cells, from human embryonic stem cells, putative adult stem cells or lineage reprogramming. Nonetheless, a number of issues must be resolved before cells derived by these methods can be used in human transplantation. Immune rejection is prime amongst these concerns. Although the recent success with non-steroid immunosuppression is encouraging, it may be possible to engineer stem cells to be immunologically silent. The development of iPS technology now allows derivation of patient-specific stem cells and immunologically fully matched  $\beta$ -cells. In addition, considerable work also needs to be done to eliminate the risk of neoplasia. We must demonstrate that cells derived from ES cells are not transformed and that they are free from contaminating undifferentiated cells that could go on to produce teratomas in graft recipients. Cells must also be shown to be free of pathogens. Because human ES cells are currently grown on murine feeder cell lines, pathogens associated with xenotransplantation must be considered. Finally, we must assess the stability of the  $\beta$ -cell phenotype in grafts and the longevity of cells once transplanted. Ideally, these transplants would include not only differentiated  $\beta$ -cells, but also pancreatic stem cells with long-term reconstituting activity.

## Future Directions: Islet Transplantation

Angela Koh, Peter Senior & A.M. James Shapiro

### Keypoints

- Islet transplantation is a promising treatment for patients with type 1 diabetes with severe hypoglycemia, hypoglycemia unawareness and/or glycemic lability.
- Successful islet transplantation can lead to insulin independence, but this is usually not maintained in the long term.
- Graft function is preserved for several years beyond the loss of insulin independence, resulting in better glycemic control in spite of a return to insulin use.
- Current immunosuppression protocols include the use of more potent induction agents which may lead to better long-term outcomes.
- The side effects of maintenance immunosuppression are better understood, and appropriate dose titration and/or change to alternative agents have led to fewer and more tolerable side effects.
- The long-term impact of islet transplantation on diabetes-related complications is not fully elucidated, but there appears to be stabilization of microvascular and macrovascular disease.

### Introduction

The discovery of insulin dramatically changed the outcome for patients with type 1 diabetes mellitus (T1DM) and the acute lethal complications of diabetes, such as diabetic ketoacidosis, could be effectively treated. The improved survival, however, allowed the development of the secondary complications of diabetes [1]. Typically, the patient with T1DM develops retinopathy, nephropathy, neuropathy or vascular disease over time. It was not until 1993 that definitive proof for the value of good glycemic control was established. The landmark Diabetes Control and Complications Trial (DCCT) study showed that the microvascular complications of diabetes could be delayed or avoided by good glycemic control, which required intensive insulin therapy [2]. Such therapy was associated with a hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) that

was 1% (11 mmol/mol) lower than that of the control group. It should be noted that the HbA<sub>1c</sub> was not normalized and in the intensively treated group remained at least 1% (11 mmol/mol) above the upper limit of normal. Similar evidence was provided by the UK Prospective Diabetes Study (UKPDS) in T2DM with microvascular disease, showing a significant improvement for a decline of 1% (11 mmol/mol) in the HbA<sub>1c</sub> [3]. Thus, glycemic control is essential if the microvascular complications of diabetes are to be prevented.

Controlling glycemia with exogenous insulin remains a challenge. Given the non-physiologic subcutaneous route of insulin administration, its inherent delay in absorption, the variability of serum levels obtained and the systemic versus portal venous delivery, it is perhaps remarkable how well the glucose levels are actually controlled. The newer insulin analogs have removed

some of the variability and delay in absorption, but even with intensive therapy it is difficult to achieve normoglycemia. Continuous subcutaneous insulin administration helps further, but neither earlier nor more recent studies have managed to normalize glucose values [4,5]. Carbohydrate counting and attention to diet improves the quest for normoglycemia but does not offer a complete solution. The largest study using all available tools to optimize therapy was still associated with an increased risk of hypoglycemia [2]. In the DCCT, the risk for severe hypoglycemia (defined as needing third-party assistance) was increased threefold. Concern about hypoglycemia remains the limiting factor in attempts to achieve optimal glycemic control.

Many efforts have been made to generate a closed-loop system for glucose control. The first successful efforts were with the Biostator®, which involved continuous monitoring of blood glucose and then an insulin infusion using a computer-derived algorithm [6]. Although effective for a short period of time, it was impractical being bulky and plagued with flow problems from the double lumen catheter being used for sensing the glucose level. Insulin infusion pumps especially using insulin analogs (such as lispro or insulin aspart) have helped but are not closed-loop systems and require frequent glucose monitoring and rarely result in normal glycemia without severe hypoglycemia. The goal of any closed-loop system is to have reliable glucose sensing linked to appropriate insulin delivery on a continuous basis. Mechanical closed-loop systems may in the future achieve this but have been fraught with problems despite early promise. Transplantation of islets of Langerhans or of the whole pancreas can achieve a physiologic closed-loop system today.

---

## Background history

Transplantation of pancreatic tissue was first tried in 1890 when a surgeon in England transplanted fragments of a sheep's pancreas into a boy with diabetic ketoacidosis [7]. The immune barriers, unknown at the time, were insurmountable, especially for a xenograft. The modern era of transplantation began in the 1960s when the use of steroids, especially when combined with azathioprine, allowed successful renal transplantation. The steroids block several cytokines and act as inhibitors of antigen presentation, and azathioprine is an inhibitor of purine synthesis and thus impedes the generation of active T cells. Cyclosporine A (CsA), a calcineurin inhibitor, which is associated with an impaired transcription in active T cells and thus blocks interleukin 2 (IL-2) activation, greatly improved transplantation graft survival [8]. In 1972, Ballinger and Lacy [9] demonstrated that chemical diabetes could be “cured” in mice with islet transplantation.

Many groups had been working in rodent and canine models to perfect islet isolation and maintain demonstrable  $\beta$ -cell insulin secretion [10,11]. Experiments in rats and mice showed that success in islet transplantations could be obtained in rodents [8] and the transplanted islets had a biphasic insulin secretory

response to glucose [12]. Islet allotransplantation in animals was also successfully performed [13,14] and it has been possible to isolate human islets that would function in diabetic nude mice [15,16].

The results of these studies highlighted the need for purified islets and the importance of the site of transplantation. Multicellular islet tissue comprises 1.5% by weight of the whole pancreas [17]. Careful digestion is necessary to achieve a purified preparation, and collagenase became the mainstay in the digestion [10]. Success with isolation from human pancreases was more problematic than in animal studies [18,19]. Methods used for the dissociation of islets from the exocrine tissue required a combination of mechanical and enzymatic techniques.

The site of transplantation was also an issue. The pancreatic bed, because of the risk of inducing acute pancreatitis, was not a preferred option. Liver, spleen, renal subcapsule and an omental pouch have been the primary locations tried [14,20–22]. Work with immune privileged sites, such as the testes, has been ongoing but has not been routinely adapted [23]. A site with portal drainage has the natural advantage of mimicking the normal route of insulin delivery and is most commonly used for human islet transplantation [24]. The splenic site was associated with infarction [25] and so the liver, renal and omental pouch have been the preferred areas for islet transplantation. Compared to the native islet bed, all sites have the disadvantages that oxygenation is lower [26] and the intra-islet blood pressure is elevated [27]. Vascularization of the liver is advantageous and may help in the angiogenesis of the islets while an advantage of the omental pouch or renal site is the ability to remove the islets for histologic examination. When the liver is used, an unresolved question is whether the venous drainage of the islets appear in the portal sinusoids or the systemic circulation. A possible drawback of the portal site is that it allows more exposure to high levels of immunosuppressive drugs and their potential toxicity as they are absorbed [28].

---

## Early human studies

The first human islet transplants were performed in the 1970s [29], with insulin independence rarely reported [30]. Up to 1998, approximately 260 patients with T1DM had received an islet transplant, with only 12% remaining insulin independent for more than 1 week [24]. The first two patients, transplanted as part of an early cohort transplanted in Edmonton in 1989 [31], received approximately 260 000 islets at the same time as a renal transplantation. Exogenous insulin was used intravenously for 14 days with intensive glucose monitoring in order to maintain euglycemia, which may help preserve  $\beta$ -cell function [32]. The immunosuppression therapy included corticosteroids, azathioprine, CsA, and Minnesota antilymphocyte globulin. Both patients demonstrated positive C-peptide status post-transplant, but both developed cytomegalovirus infection and lost islet mass, never achieving insulin independence. The subsequent five

patients had transplants using both fresh and cryopreserved islets so that the total islet mass given exceeded 10 000 islet equivalents per kilogram. One patient obtained insulin independence for 2 years [33]. One patient who was transplanted at this time had a liver transplant with partially purified islets infused. Complete portal vein thrombosis ensued necessitating an urgent repeat liver transplant [34]. Another patient attained insulin independence for a period of time but eventually all patients required insulin again. On long-term follow-up, two of these patients have continued C-peptide production, the longest being more than 9 years since her transplant; however, subsequent technical problems arose in Edmonton, particularly with the collagenase, and so purified islets could not be obtained and thus islet transplantation lapsed as an avenue for treating diabetes. Other major centers, particularly Miami/Pittsburg, St. Louis and Milan, also reported early success [35–38] and demonstrated that the transplanted cells may survive for a prolonged time [39,40].

---

## Pancreas transplantation

With improved immunosuppression the possibility of performing whole pancreas transplants, particularly at the time of renal transplantation for end-stage diabetic nephropathy, became a possibility [41]. Initial efforts were associated with peritonitis from exocrine drainage of the pancreatic duct. These problems were surmounted by using bladder drainage [42] such that success rates reached over 80% for 1-year graft survival accompanied by low mortality rates [43–46]. With newer techniques of anastomosis connecting the transplanted duodenum to an enteric drainage site [47], fewer problems were encountered (especially with the acidosis secondary to bicarbonate loss in the urine associated with the bladder anastomosis [48]). More than 25 000 whole pancreas transplants have been carried out worldwide. The 1-year graft survival rate has improved as a result of reduction in technical and immunologic failure rates [49]; however, the overall 10-year graft survival rate for deceased donor pancreas transplants has not substantially improved over time and was 48% for transplants between 1995 and 1999 [50]. Graft survival is better for simultaneous pancreas–kidney transplantation than either pancreas transplant alone or pancreas transplantation after kidney transplantation. The side effects are diminishing but it remains a technically challenging surgical procedure [51–53] with some morbidity and mortality. The excellent glycemic control [54] can lead to reversal of diabetic renal lesions [55], stabilization or improvement in neuropathy [56,57], vascular status [58,59] and stabilization but not necessarily improvement of retinopathy [60,61].

---

## Islet transplantation in the new millennium

The unimpressive results of islet transplantation in the late 1990s, as illustrated by low rates of insulin independence [39,62,63],

were related to the islet preparation (purity of preparations and adequate islet numbers) [64] and immunosuppression (potency and toxicity especially in terms of glucose tolerance), as has been reviewed by Hering and Ricordi [65]. The field of islet transplantation was rejuvenated with our report of seven consecutive cases, achieving insulin independence with islet transplantation using a steroid-free immunosuppression regimen (Edmonton protocol) [66]. Some of the factors associated with this success are discussed below.

### Islet isolation

Islet mass availability remained a central issue for success. An adequate islet mass contributed to the success of the Edmonton protocol, with >11 000 islet equivalents per kilogram recipient body weight being transplanted.

The normal pancreas has 1.0–1.7 million islets [67,68], yet early studies showed only 250 000 islets being recovered for allotransplantation. Minimizing warm and cold ischemia time and other donor issues are important [69,70]. Using the University of Wisconsin perfusate solution at the time of organ retrieval enhanced the yield [71]. In addition, the intraductal delivery of collagenase [18,19,72], particularly with improved collagenase preparations [73,74], further enhanced the number of islets obtained. Great strides were made in characterizing the collagenase necessary for purified islet isolation, resulting in much better preparations. The enzyme preparation Liberase was widely used for islet isolation and is a blend of primarily collagenase type 1 and 2, but also has collagenase 3 and 4, clostripain, thermolysin and proteases (trypsin, chymotrypsin and elastase), and is associated with a low endotoxin load [74].

Another major advance was the development of a metal chamber by Ricordi *et al.* [75] allowing disassociation of islets with mechanical digestion and the continuous removal and harvesting of the liberated islets [76]. Purification of islets using a refrigerated COBE centrifuge and Ficoll gradient is also important. While it leads to some loss of cells, it reduces the otherwise substantial risk of intraportal hypertension associated with the infusion of unpurified preparations [34,77]. The increased purification may also have a negative effect because ductal elements, which may be important as a source for islet neogenesis, are removed [78].

Short-term culture of the islets may lead to enhanced purity without excessive loss of islets. In addition, the newer methods of islet isolation have removed all xenoproteins from the process, and this could further reduce the risk of rejection.

### Immunosuppression

The importance of the appropriate immunosuppression regimen is demonstrated by the fact that with autotransplantation once 2500 islet equivalents per kilogram are provided then insulin independence can usually be achieved; however, three or four times this number of cells are required for insulin independence in the allotransplant environment [79]. In the Edmonton protocol, daclizumab was used for induction, followed by maintenance

immunosuppression therapy with sirolimus (target trough levels of 12–15 µg/L for 3 months, then 10–12 µg/L) and low-dose tacrolimus (target trough levels of 3–6 µg/L) [66]. Such a combination allowed the omission of steroids from the regimen, which was a major advantage in the setting of borderline islet mass by reducing β-cell toxicity. Effective blockade of IL-2 with sirolimus, which inhibits T-cell expression and activation, and daclizumab, an antibody to IL-2 receptors, allows inhibition of T-cell activation and provides potent immunosuppression. Sirolimus can result in lipid abnormalities but was not known to affect glucose tolerance [80,81]. Tacrolimus, a more potent calcineurin inhibitor than CsA, is associated with some diabetogenicity [9,82–84] by inhibiting insulin release [85] in a dose-dependent manner [86], a problem shared by its predecessor CsA [87,88]. Hence, part of the rationale for using sirolimus as the mainstay of immunosuppression with low dose tacrolimus was to reduce diabetogenicity of the maintenance immunosuppression regimen.

## Islet transplantation today

Following this initial success, more than 650 islet transplants have been performed worldwide using the Edmonton protocol or variants of it, and incorporating newer advances. Indeed, islet transplantation today is quite different from 10 years ago.

### Islet preparation

#### Pancreas preservation

The University of Wisconsin solution (UW) was effective in pancreas preservation, but prolonged storage before islet isolation led to reduced recovery of viable islets [89]. The two-layer system using perflurodecalin (PFC) and UW for whole pancreas preservation was thus advocated for rescuing ischemically damaged pancreases [90]. This was because of the ability to ensure adequate oxygenation to the pancreas during preservation, and the reduction of cold ischemic injury by promoting adenosine triphosphate production [90]. It was also found that preservation in PFC resulted in the upregulation of anti-apoptotic genes and the downregulation of pro-apoptotic genes [91].

Indeed, islet recovery from pancreases preserved with the two-layer system was double that of UW alone [90,92]. Furthermore, PFC preservation resulted in an islet yield from pancreases procured from marginal donors that was sufficient for clinical transplantation in more cases than with UW alone [92]; however, more recently it was shown that there was no significant difference in islet yield or transplantation outcome regardless of whether the two-layer method or UW alone was used [93]. The authors currently use histidine-tryptophan-ketoglutarate solution alone for pancreas preservation, which appears to be equally effective as UW.

#### Islet culture

Previously, islets were infused into recipients within 2 hours of isolation to reduce the risk of ischemic injury to the islets [66];

however, this gave little time for appropriate quality control measures to be completed and potential recipients had to live near the transplant center. The authors' current practice is to culture islets for up to 72 hours prior to transplantation. This has numerous advantages because the additional time when the islets are in culture allows for the administration of conditioning or other immunosuppressive therapies, can result in improved safety because transplants can be carried out when the entire transplant team is present and allows for better islet characterization before transplant [94]. In addition, the decrease in total tissue volume with culture may reduce the risk of portal vein thrombosis. Furthermore, the use of regional islet processing centers has been advocated as a means of standardizing the islet product, and hence improving transplant outcomes. Islet culture can result in better islet recovery after shipment [95], and islet culture has now become standard and routine practice at most islet transplant centers worldwide.

#### Enzyme preparation and digestion protocols

In 2007 it became apparent that the crude collagenase extract in Liberase®, a secretion product of *Clostridium histolyticum* bacteria, could have been contaminated with bovine brain infusion extract, as this extract contains high levels of lipid, carbon and nitrogen which apparently facilitates the proliferation and secretory capacity of the bacteria. The specific risk to an islet patient is the possibility of prion transmission from the cow brain extract through the enzyme and into the pancreas organ during digestion of the gland. The estimated risk is currently unknown, but a working number is currently less than one in ten million – in other words exceedingly remote. Since then, most islet isolation centers have switched to an alternative enzyme manufactured by Serva. This is a GMP (good manufacturing practice) grade enzyme where the potential risk of prion transmission should be dramatically lower as no bovine brain extracts are used in the manufacture process. Using high-pressure liquid chromatography and collagenase activity assay, we found that the Serva collagenase is less pure and less potent than Liberase. With modification of our digestion protocols, we have now managed to achieve a high rate of islet isolation success (defined as >300 000 IEQs, >70% viability and <5 mL packed tissue volume) that is superior to historical outcomes from the Liberase era (unpublished data). Specifically, we use different digestion protocols for younger (≤35 years) versus older donors. For younger donors, we use collagenase and neutral protease simultaneously, while for older donors, a higher amount of collagenase initially, followed by sequential digestion with a lower amount of neutral protease was found to be optimal. Others have found that islet isolation outcomes and islet function are similar with the two enzyme blends [96].

#### Transplant procedure

Once adequate pure islets are prepared the patient is brought to radiology and percutaneous access is established under midazolam and fentanyl sedation. After infiltration of local anesthetic a 22-gauge Cheba needle is advanced under fluoroscopic guid-

ance into the portal vein. Others have used computer tomography (CT) guidance or it is possible to gain access by the transjugular route or with laparoscopy [97]. A guidewire is then inserted into the main portal vein and a catheter is positioned with confirmation by portal venogram. Purified islets are then infused with frequent monitoring of portal pressure. If the portal pressure doubles or rises above 22 mmHg infusion is halted until it resolves, and if it does not resolve the infusion is discontinued. Initially, we used a 60-mL syringe but quickly adopted the use of an intravenous bag which is prepared in the laboratory [98]. This aids aseptic technique and may also pose less shear pressure on the islets and further provides some constant monitoring of portal pressure during islet infusion.

This percutaneous approach can result in the risk of bleeding from the liver, which was seen in the first report. Subsequently, Gelfoam® pledgets and coils were used to seal the catheter tract, and there was no more bleeding seen in the next 28 cases [99]; however, in 2003, there was a spate of post-procedural bleeding (defined as an acute fall in hemoglobin of 20%, associated with free fluid on ultrasound, the need for blood transfusion or surgical intervention for control of bleeding) [99,100]. Since then, the portal tributary cannulation site was plugged with coils, and the tract ablated using tissue glue (Tisseel®) with no further recurrence of bleeds in the next 35 procedures [100]. More recently, Avitene® paste dissolved in radiologic contrast and saline has been used instead to seal the catheter tract. When adequately deployed, this has eliminated bleeding risks and has the practical advantage of being clearly visible during deployment on fluoroscopy.

Before transplant, intravenous insulin and dextrose infusions are started to maintain euglycemia during transplant. Initially, insulin was discontinued after transplantation and was avoided unless hyperglycemia (serum glucose  $\geq 11.1$  mmol/L) occurred [66]. Subsequently, this threshold was lowered and insulin was given if pre-meal glucose was  $>6.0$  mmol/L or 2-hour post-meal glucose was  $>8.0$  mmol/L [99].

Recently, it was shown that maintaining euglycemia in the immediate post-transplant period could contribute to better graft survival [101]. Since mid 2005, it has been our policy to maintain euglycemia (serum glucose 4.0–7.0 mmol/L) following transplant by using intravenous insulin (minimum of 1 unit/hour) with dextrose infusions for the first 48 hours, and subcutaneous insulin thereafter.

Intravenous heparin is also infused to keep the pro-thrombin time 70–90 seconds for 48 hours after transplantation to promote engraftment by reducing the immediate blood mediated inflammatory reaction (IBMIR). Heparin is withheld if there is inadequate tract plugging with Avitene ( $<3$  cm in length) until imaging confirms the absence of bleeding.

After the heparin infusion is discontinued, subcutaneous low molecular weight heparin (30 mg enoxaparin twice daily) is administered for 7 days and 81 mg/day aspirin for 14 days.

In addition, patients receive 400 mg sulfamethoxazole–80 mg trimethoprim one tablet daily for 6 months, *Pneumocystis pneu-*

*monia* prophylaxis and 900 mg/day valganciclovir for 14 weeks when there is cytomegalovirus status mismatch between donor and recipient, and in patients who have received lymphocyte-depleting induction agents.

### Immunosuppression

The immunosuppressive regimen of the original Edmonton protocol is still being used today, but with some modifications. Daclizumab was initially given at a dosage of 1 mg/kg every 2 weeks five times. After 2003, this was changed to 2 mg/kg at transplant and at 5 days post-transplant [99]. This was because the latter regimen was found to be efficacious and was more convenient for patients.

Recently, induction with antithymocyte globulin (6 mg/kg) and etanercept, with maintenance immunosuppression with tacrolimus (target trough level 8–10  $\mu$ g/L) and mycophenolate mofetil (1 g twice daily), has been used [100]. Also, a lymphocyte depletion protocol consisting of alemtuzumab (Campath-1H), tacrolimus and mycophenolate mofetil is being evaluated. Preliminary data suggest that the use of these potent induction agents have improved short to medium-term graft outcomes [101–103].

Many of the initial patients who were on sirolimus and tacrolimus for maintenance immunosuppression have had intolerable side effects which were attributed to sirolimus, necessitating a switch of immunosuppression to tacrolimus and mycophenolate mofetil. This latter combination appears to be as efficacious and better tolerated [104]. Furthermore, sirolimus impairs  $\beta$ -cell regeneration, and could contribute to the observed gradual loss of graft function seen following islet transplantation [105]. Thus, this combination is increasingly the first-line maintenance immunosuppression choice for islet transplantation.

---

## Islet transplantation outcomes

### Glycemic control

Insulin independence was achieved in 11 out of the first 12 patients, after a minimum of 9000 IE/kg were transplanted [66]. HbA<sub>1c</sub> levels improved in all patients, and this was achieved without hypoglycemia and was accompanied by an improved stability of glucose control [66]. Unfortunately, insulin independence was not sustainable in the long term for the majority of patients. From survival analysis, only approximately 10% of patients remained off insulin at 5 years, although most patients (approximately 80%) still had C-peptide present (Figure 61.6) [99].

In terms of overall blood glucose control, patients who remained off insulin did the best (median HbA<sub>1c</sub> of 6.2%, 44 mmol/mol), similar to the patients who were back on insulin but still had C peptide (median HbA<sub>1c</sub> of 6.7%, 50 mmol/mol). Patients who had lost all graft function had relatively poor glucose control (median HbA<sub>1c</sub> of 9.0%, 75 mmol/mol) and required more insulin than before the transplant (Figure 61.7) [99].

The HYPO score and lability index (LI) were developed to measure the severity of hypoglycemia and glycemic lability. The HYPO score is generated using a combination of 4 weeks of self glucose monitoring results and the patients' self-reported hypoglycemic episodes over the previous year. For every episode of hypoglycemia  $<3$  mmol/L during the 4 weeks, patients were instructed to record all symptoms felt and whether assistance was required for recognition or treatment of the hypoglycemia. Higher scores were given for more severe hypoglycemic episodes (i.e. lower glucose values, absence of symptoms or neuroglycopenic symptoms, needing outside help for recognition/treatment), while from the self-reported episodes during the past year higher points were awarded if an ambulance was called or glucagon given. The LI was also calculated from the 4 weeks of glucose records, using a formula that takes the number of glucose readings, the glucose values and the time interval between testing into account [106]. These scores are now routinely used in the assessment of suitability of a candidate for transplant, as well as for follow-up of patients after transplant. In addition, the Clarke score [107] is also frequently used, with a score of four or more indicating hypoglycemia unawareness.

Both the HYPO score and LI show marked improvement post-transplant. With resumption of insulin use, there was more lability and some episodes of hypoglycemia, but both scores were still better than pre-transplant [99].

A key indication for islet transplantation is hypoglycemia unawareness. Patients who have received a pancreas transplant have restoration of their counter-regulatory response to hypoglycemia [108,109]. The autonomic response and hence hypoglycemia awareness is also improved post-pancreas transplant [110]; however, the same restoration in counter-regulatory responses and symptom recognition was not seen following successful islet transplantation [111]. Conversely, others have found that counter-regulatory hormonal and symptom responses to hypoglycemia do improve after islet transplantation [112–114]. The reasons for these differences are unclear; however, there may be a subset of patients who have return of hypoglycemia awareness, and/or the timing of testing could be critical. Indeed, we have noted that 85% of our cohort of islet transplant recipients reported return of symptoms of hypoglycemia, although 62% of them subsequently lost hypoglycemia awareness.

**Figure 61.6** Current survival analysis for insulin independence and graft function as indicated by presence of C-peptide.

## Diabetes complications

### Retinopathy

Retinopathy has been reported to remain stable following islet transplantation [115,116]. The majority of our patients (approxi-

**Figure 61.7** Glycemic control is related to islet graft function.  $DCCT\ result\ (\%) = (0.0915 \times \text{New IFCC result in mmol/mol}) + 2.15$ .

mately 80%) showed either no change or an improvement in retinopathy grade compared with baseline 3 years following islet transplantation; however, in our cohort, 18 of 98 (18.4%) subjects had either vitreous hemorrhage or need for laser photocoagulation after islet transplantation, suggesting that close ophthalmologic follow-up remains necessary.

### Nephropathy

We have previously reported that the estimated glomerular filtration rate (eGFR) (by MDRD study equation) declined with time. The median rate of eGFR decline was  $-0.39 \text{ mL/min/1.73 m}^2$ /month, with wide inter-patient variability [117]. This decline in GFR is comparable to that seen in optimally treated albuminuric patients with T1DM [118]; however, for one-third of the patients, the decline in eGFR exceeded that in untreated diabetic nephropathy [119]. In addition, on follow-up, progression in albuminuria was seen in 24% of the patients, with regression only in 2.4% [117].

When tacrolimus and mycophenolate mofetil were used for maintenance immunosuppression, no difference in the rate of GFR decline was seen compared with either medically treated controls or the general population, nor was there any progression in albuminuria [120].

It is not clear at present whether the decline in renal function in islet alone transplants is brought about by progression of diabetic nephropathy or the effects of immunosuppression, in particular the combination of sirolimus and tacrolimus. Nevertheless, care has to be taken during the patient selection process with regard to the assessment of renal function.

### Neuropathy

There was no change in neuropathy status as assessed by vibration perception threshold or neuropathy disability score in our cohort [121], and others have shown stabilization of neuropathy [115].

### Cardiovascular disease

A substantial proportion (30%) of islet transplant recipients at our center have pre-existing coronary artery disease (CAD) prior to transplantation. In terms of CAD risk factors, triglyceride levels increased ( $0.82 \pm 0.04$  vs  $1.09 \pm 0.06 \text{ mmol/L}$ ;  $P < 0.001$ ), while there was a reduction in low density lipoprotein (LDL) cholesterol levels ( $2.53 \pm 0.06$  vs  $2.14 \pm 0.06 \text{ mmol/L}$ ;  $P < 0.001$ ), likely from an increase in statin use following transplantation. Blood pressure remained unchanged. Following islet transplantation, the rate of incident (new or worse) CAD was similar to the general population with T1DM at 8.9 events/1000 patient years [122].

### Procedure-related complications

Complete portal vein thrombosis has not occurred with the use of purified islet allograft preparations, although partial thrombosis (of right or left branch, or peripheral segmental vein) was seen in about 5% of patients, all of whom were treated with anticoagulation without any long-term clinical sequelae [66,99]. The risk

of portal vein thrombosis has been minimized by limiting the islet packed cell volume, careful monitoring of portal pressures during islet infusion and intraportal dosing with heparin followed by systemic anticoagulation. Other rare complications include gallbladder puncture and arteriovenous fistulae formation.

Liver enzymes (aspartate transaminase, alanine aminotransferase and alkaline phosphatase) were elevated in more than 50% of transplants and are generally subclinical. These enzymes peak at around 1 week and resolve spontaneously within a month [123].

Changes consistent with fatty liver have also been observed on imaging post-transplantation [124]. These steatotic changes were confirmed with biopsy in some cases, and may be related to the high insulin levels the hepatocytes are exposed to following intrahepatic transplant [124]. It is currently unclear whether these changes may result in any long-term sequelae.

### Side effects of immunosuppression

Most patients may have some side effects from immunosuppression, but it is highly variable among patients.

Mouth ulcers occur in >90% of the patients and is associated with sirolimus. These are usually small and self-limiting, but on occasion may be numerous and/or severe enough to require inpatient care. Most patients respond to topical therapy, dose reduction and switching to the tablet formulation of sirolimus [99].

Gastrointestinal disturbances, either constipation or diarrhea, are also common, occurring in 60% of the patients, while acne was noted in 52%. Peripheral edema was reported by 43% of the patients [100].

Ovarian cysts following transplants have been found to be common [99]. Another study found that among women, ovarian cysts occurred in 62% of the subjects, and menstrual irregularity developed in all six subjects who had regular menstrual cycles before transplant [125]. At our center, new ovarian cysts were found in 33 of 57 (57.9%) women after islet transplantation. Most cysts were asymptomatic but 14 women reported pelvic pain. Sirolimus withdrawal was associated with a reduction in cyst size and resolution of cysts in 80% of the subjects. Also, the use of combined oral contraception appeared to be protective against ovarian cyst development [126].

Other complications related to immunosuppressive therapy include anemia, leukopenia, hypertension, dyslipidemia, weight loss and fatigue [100].

Tacrolimus was associated in a dose-dependent manner with tremor and nephrotoxicity. The combination of sirolimus and tacrolimus could also worsen renal function. Indeed, two patients in whom tacrolimus was switched to mycophenolate mofetil had stabilization of renal impairment [127]. Also, three patients had resolution of proteinuria after sirolimus was withdrawn and replaced by a combination of mycophenolate mofetil and higher dose tacrolimus [128].

Mycophenolate mofetil is generally well tolerated, with the most commonly reported side effect being gastrointestinal in

**Figure 61.8** Complications following clinical islet transplantation – first 50 vs next 49 patients in Edmonton. \* Indicates significant difference ( $P < 0.05$ ) between first 50 and next 49 subjects. GB, gall bladder; GI, gastrointestinal; PRA, panel reactive antibody; PVT, portal vein thrombosis.

nature (bloating, diarrhea, abdominal cramps), which usually subside with dose reduction [129].

Pneumonia occurred in three patients, of whom one was considered fungal in etiology [98].

Cytomegaloviral disease has not occurred, although seroconversion from negative to positive has occurred in 4 of 67 (6%) patients. To date, no lymphoproliferative disease has been observed.

With experience, we have learned to tailor the immunosuppression regimen and target drug levels to minimize side effects without compromising graft function, such that fewer complications are seen in patients transplanted more recently than in earlier patients (Figure 61.8).

A total of 34 patients had undergone immunosuppression change from sirolimus + tacrolimus to tacrolimus + mycophenolate mofetil following islet transplantation. The three most frequent reasons for immunosuppression change were peripheral edema (18/34, 53%), gastrointestinal symptoms (11/34, 32%) and ovarian cysts in women (9/26, 35%). These all improved after the immunosuppression change. Also noteworthy, there were no changes in graft function or immune status following the change (Table 61.1) [104].

### Immune sensitization

The percentage of panel reactive antibodies (PRA) increased in 13% of the patients from levels  $<15\%$  to  $\geq 15\%$  after transplant [99]. Recently, it has become clear to us that positive PRA does impact islet transplant outcome negatively. Indeed, pre-transplant PRA of  $>15\%$  in either class I or II is an independent predictor of poor graft survival (in terms of C-peptide) after transplant [130].

For individuals with high PRA, it will be important to determine the specific antibodies causing the positive PRA and a flow cytometry-based cross-match performed against potential donors

**Table 61.1** Reasons for and outcomes after immunosuppression (IS) change.

	No. of patients with IS change (n = 34)	% with improvement / no change / worsening after IS change	P value
Peripheral edema	18	83 / 17 / 0	$<0.001$
Gastrointestinal symptoms	11	75 / 8 / 17	0.01
Fatigue	9	44 / 55 / 0	0.05
Proteinuria/renal function decline	6	100 / 0 / 0	0.01
Ulcers	4	100 / 0 / 0	0.05
Ovarian cysts/menstrual abnormalities in female patients (n = 26)	9	78 / 22 / 0	0.01

before transplant. Our current policy is to perform prospective cross-matches for all recipients with PRA above 5% and for those who have received previous transplants.

It has become apparent that high rates of broad PRA sensitization were observed in patients when immunosuppression was slowly and completely withdrawn following complete graft loss [131]. Our current approach is therefore not to withdraw all immunosuppression when a patient loses all islet function, but rather to wean down to single agent therapy with mycophenolate (Myfortic® therapy). We currently plan to continue this for at least 2 years after function is lost in order to reduce the risk of subsequent sensitization. The effectiveness of this strategy is still to be evaluated.

## Indications and contraindications for islet transplantation

At our center, islet transplantation is offered to patients with T1DM who have severe hypoglycemia and/or hypoglycemia unawareness, or glycemic lability, in spite of optimal medical therapy with frequent blood glucose monitoring and the use of multiple daily insulin injections or continuous subcutaneous insulin infusion. This is, by and large, still based on clinical judgment, although the use of the HYPO score and LI adds an objective component to the decision. Some patients have progressive complications despite optimization of medical therapy. Although we originally considered this group, they are now the exception, as we are concerned about the potential for immunosuppression to exacerbate renal impairment.

Diabetes-related complications are not absolute contraindications for islet transplantation. For patients with unstable retinopathy, we recommend waiting for 6 months from the last treatment for the disease to stabilize before islet transplantation because there is a risk of worsening following transplantation. The sirolimus and tacrolimus combination is avoided in patients with macroalbuminuria (>300 mg/day). We prefer not to transplant patients with mild to moderate reduction in GFR (<60 mL/min/1.73 m<sup>2</sup>). We also recommend waiting for at least 6 months following myocardial infarction, revascularization procedure or evidence of ischemia on functional cardiac testing. A severely reduced left ventricular ejection fraction <30% is a contraindication for islet transplantation.

The current accepted indications and contraindications for islet transplantation in most islet transplantation centers are listed in Table 61.2.

## Patient evaluation

At the assessment visit for islet transplantation the patient should have a realistic expectation of the outcome. If the patient has frequent hypoglycemia and glycemic lability problems, then both of these are readily correctable by islet transplantation. The ability to render the patient free of the progression risk of diabetes complications is unproven at this time, although given good glycemic control this may be expected in the longer term. Patients who have active infection, a history of cancer, severe vascular disease or active foot ulceration, who abuse alcohol or drugs, or who are younger than 18 or older than 65 years are not usually considered. Once the patient meets the entry criteria and is willing to accept the risks of the procedure and immunosuppression, a full evaluation is required. This includes a thorough history and physical examination, the latter concentrating on diabetes complications – retinopathy, neuropathy (autonomic and peripheral) and vascular disease. Our laboratory evaluation includes details of these complications with an ophthalmology report required, 24-hour urine for albuminuria, protein and creatinine clearance; together

**Table 61.2** Indications and contraindications for islet transplantation.

### Indications for islet transplantation

Clinical history compatible with type 1 diabetes, with stimulated C-peptide <0.3 µg/L on mixed meal tolerance test

Intensive diabetes management:

- Glucose testing ≥3 times/day
- ≥3 insulin injections/day or insulin pump as directed by endocrinologist, diabetologist or diabetes specialist with ≥3 clinical evaluations during the past year

≥1 severe hypoglycemic event, defined as an event with one of the following symptoms: memory loss; confusion; uncontrollable behavior; irrational behavior; unusual difficulty in awakening; suspected seizure; seizure; loss of consciousness; or visual symptoms, in which the subject was unable to treat him/herself and with blood glucose <54 mg/dL (3 mmol/L) or prompt recovery after oral carbohydrate, intravenous glucose or glucagon in the past 1 year

One of the following:

- Reduced hypoglycemia awareness (Clarke score ≥4 or HYPO score ≥90th percentile or ≥1047) within last 6 months
- Marked glycemic lability with wide swings in glucose levels despite optimal therapy, with glycemic lability index ≥90th percentile or 433 within last 6 months
- Composite Clarke score ≥4 + HYPO score ≥75th percentile (≥423) + lability index ≥75th percentile (≥279)

### Contraindications for islet transplantation

Glycated hemoglobin ≥10% (86 mmol/mol)

Untreated proliferative retinopathy

Blood pressure >160/100 mmHg

Glomerular filtration rate <80 mL/min/1.73 m<sup>2</sup>

Presence or history of macroalbuminuria >300 mg/day

Presence or history of panel reactive anti-HLA antibodies (by flow cytometry)

Active infections, including:

- Hepatitis B, hepatitis C or HIV
- Tuberculosis requiring treatment within the previous 3 years
- Invasive aspergillus, histoplasmosis or coccidiomycosis within 1 year

Severe cardiac disease:

- Myocardial infarction within 6 months
- Evidence of ischemia on functional cardiac testing within 1 year
- Left ventricular ejection fraction <30%

Any history of malignancy except for completely resected squamous or basal cell carcinoma of the skin

A history of factor V deficiency

Any coagulopathy or medical condition requiring long-term anticoagulant therapy after transplantation

Receiving treatment for a medical condition requiring chronic use of systemic steroids except for the use of ≤5 mg/day prednisolone or equivalent

Any medical condition that could interfere with safe participation in islet transplantation

Desired pregnancy (female recipient)

with a serum creatinine, ECG, stress methoxyisobutylisonitrile (MIBI) scan and a lipid panel. If there is any suggestion of an abnormality either clinically or on vascular testing, coronary angiogram is performed. In addition, the basic transplant screens are required, including blood group, complete blood count, coag-

ulation screen, liver function tests, electrolytes, calcium, magnesium, phosphorus, checks for HIV, hepatitis, Epstein–Barr virus, syphilis, cytomegalovirus and urine culture. An ultrasound of the abdomen and liver is required to ensure that no lesions are present in the liver. A hemangioma on the right side of the liver would place a patient at increased risk of bleeding during the procedure if a percutaneous approach was used. In subjects older than 40 years, mammograms are performed in women and prostate-specific antigen determinations in men. Considerable time is spent reviewing the potential complications with the patients so that each individual can make a personal assessment of the risk:benefit ratio for themselves and decide if they wish to proceed. In most other transplant settings (heart and liver), the issues are life and death but in islet transplantation this is not the case, as continuing to work with other insulin regimens is possible and thus risk:benefit issues are different.

---

## Challenges and future directions

### Islet shortage

The shortage of donor pancreases for islet transplantation remains a challenge. Most patients require more than one islet infusion to become insulin independent. Given the limited supply of organs, the ability to achieve insulin independence after infusion of islets from a single donor is an important goal which has been achieved by Hering *et al.* [101] in carefully selected recipients given excellent islet preparations, intensive peri-transplant management and alternative induction immunosuppression. Other alternative sources of islets include xenografts (e.g. porcine islets) or stem cells, but remain in the preclinical experimental phase at present [132–134].

### Islet engraftment

Defects in insulin secretion soon after transplantation of what should be an adequate islet mass indicates that many islets were lost at the time of engraftment. This could be because of hypoxia early post-transplant [135], the toxic effects of the immunosuppressive drugs [136] and the IBMIR, which results in immune destruction of islets [137]. It has been estimated that only one-third of islets engraft successfully [138].

Various strategies are being tested in attempts to improve engraftment, including the use of vascular growth factors to promote revascularization [139], inhibitors of IBMIR [140] and anti-apoptotic peptides (e.g. caspase inhibitors) [141]. The use of low molecular weight dextran sulfate was found to block IBMIR to a greater extent than heparin, possibly by its more potent inhibition of the complement system [142]. The use of islet surface heparinization was also shown to attenuate IBMIR significantly *in vitro* and *in vivo*, without systemic side effects [143].

### Monitoring the islet graft

A key barrier to understanding what happens to the islet graft after transplantation is the lack of access to the graft. Current

methods of monitoring graft function are based on the measurement of markers of glucose homeostasis, which may not be disrupted in early stages of rejection [144]. Immunologic monitoring is limited by the lack of standardized markers for autoimmunity and rejection [145]. Unlike other solid organ transplants, serial protocol liver biopsies may not yield sufficient islet tissue for examination. Several approaches for  $\beta$ -cell imaging have been proposed, but are still in various stages of development [146]. Clearly, it is of vital importance to develop one or more methods to detect graft dysfunction in its early stages or even before it happens, so as to allow intervention in an attempt to rescue the graft.

### Promoting graft survival

Islet graft function appears to decline over time, with most patients returning to insulin use. The glucagon-like peptide 1 (GLP-1) agonist, exenatide, when used in islet transplant recipients with failing islet graft function, resulted in reduction in insulin requirements, but this could not be sustained when the drug was discontinued, suggesting that there was no trophic effect on  $\beta$ -cell mass [147]. The lack of detectable changes in markers of allo-immunity or auto-immunity in the majority of islet transplant recipients, together with the absence of significant inflammatory infiltrate in histologic specimens of islet transplants, suggest that non-immunologic mechanisms have an important role in the gradual graft loss [99,148]. Possible culprits include increased metabolic demand and toxicity of immunosuppressants, and certainly warrants further investigation.

### Immunosuppression toxicity

While newer immunosuppressant drug combinations are associated with less toxicity, the ideal situation would be the ability to withdraw immunosuppressive drugs after an initial period of use post-transplant. To achieve this, tolerance to the graft must be induced. Co-stimulation blockade has shown promise for tolerance induction. There have been encouraging results with belatacept (LEA29Y), a potent new CTLA4-Ig in primate models of islet transplants [149], and clinical trials in human subjects are being undertaken. Indeed, the use of belatacept for ongoing maintenance immunosuppression, thus allowing the avoidance of calcineurin inhibitors, has been used successfully in the renal transplantation setting and may be the basis for future maintenance therapy [150].

Another strategy would be islet encapsulation, but this has been associated with limited success to date [151].

---

## Conclusions

Islet transplantation can correct problems with glycemic lability and recurrent hypoglycemia. Given its technical ease, it is particularly suitable for those with problems with glycemic control and no other major complications. The more technically difficult whole pancreas transplant provides stable glucose control and is

ideal in those undergoing simultaneous renal transplant. The islet transplant procedure has some risks, both acutely (particularly bleeding, and thrombosis in the portal vein circulation) and in the long-term, the unknown but real risk of sepsis and neoplasms. For some patients with major problems, with diabetes control these risks are acceptable. Whether the good glycemic control attained will prevent complications in the long term will take years to resolve. Using the indication of progressive diabetes complications is less suitable at this time, given the problems encountered. Islet transplantation can free a patient with very difficult diabetes from the risks of frequent hypoglycemia or glycemic lability. The decision whether to proceed can only be made by an informed patient who has to cope with difficult diabetes on a daily basis.

Major steps have been taken in islet transplantation but more needs to be done. Significant changes over the past 10 years have resulted in improved outcomes, but many challenges still remain. Islet transplantation has faced hurdles before and overcome them. These new challenges can be met and solved. To quote Sir Winston Churchill, "Now this is not the end. It is not even the beginning of the end. But it is, perhaps, the end of the beginning."

## Gene therapy

Andreea R. Barbu & Nils Welsh

### Keypoints

- Gene therapy for diabetes can be defined as transfer of DNA to somatic cells in order to understand, treat or prevent the disease or its complications.
- Because the etiology of diabetes is multifactorial in most cases, gene therapy aimed at correcting a single missing or multifunctioning gene will probably not be meaningful. Instead, gene therapy will need to interfere with more distal steps in the pathogenesis of diabetes, correct insulin deficiency or treat secondary complications.
- It is possible to outline several different gene transfer strategies for diabetes; prevention of  $\beta$ -cell destruction could be achieved by manipulating  $\beta$ -cells to produce a protection or survival factor.
- $\beta$ -Cell destruction might also be prevented by immunomodulation.
- Stimulation of  $\beta$ -cell differentiation and regeneration might involve gene therapy with transcription factors that control  $\beta$ -cell development.
- Ectopic production of insulin by substitute cells has been achieved with fibroblasts, hepatocytes, myocytes, pituitary and exocrine cells.
- Although experimental results are promising, none of the proposed gene therapy models for treatment or prevention of diabetes have reached the stage of clinical testing.
- Clinical trials are in progress with a view to treat diabetic complications such as foot ulcer and limb ischemia.

## Gene transfer techniques for genetic modification of pancreatic islets

The ability to engineer pancreatic  $\beta$ -cells is a prerequisite for a successful application of most gene therapy approaches in diabetes. Because pancreatic islets are terminally differentiated cell clusters, gene transfer into islet cells poses significant technical hurdles. To date, several gene therapy vectors have demonstrated their utility in genetic modification of islet cells (Table 61.3). While viral vectors, such as adenovirus [1], lentivirus [2], retrovirus [3] and adeno-associated virus [4], show the most promising gene transfer efficiency into islet cells, it is likely that non-viral vector systems will more easily satisfy biosafety concerns in clinical trials.

## Prevention of $\beta$ -cell destruction in type 1 diabetes

### $\beta$ -Cell survival factors

Prevention of  $\beta$ -cell destruction could be achieved by genetic manipulation of  $\beta$ -cells so that they produce a  $\beta$ -cell protection and/or survival factor. Such an approach would, in general, leave the immune system unaffected as the transgene production is localized to the islets. Targeting of a survival factor to the  $\beta$ -cells could be applied to individuals in whom autoimmune destruction of  $\beta$ -cells has begun, but not reached the end stage. Candidate transgenes currently under investigation include those encoding antioxidant enzymes: glutathione peroxidase, mitochondrial manganese superoxide dismutase (MnSOD), catalase, cytosolic copper-zinc superoxide dismutase, anti-apoptotic proteins (members of the heat shock proteins and Bcl-2 families) and modulators of cytokine signaling pathways (modulation of nuclear factor  $\kappa$ B, NF $\kappa$ B), and suppressors of cytokine signaling. Alternative approaches for cytoprotection of  $\beta$ -cells have been envisaged, such as immune modulators; for example, an interleukin-1 (IL-1) receptor antagonist, hepatocyte growth factor, transforming growth factor  $\beta$  (TGF- $\beta$ ), adenoviral E3 and calcitonin gene-related peptide, inhibitors of Fas ligand signaling, and antistress factors such as thioredoxin. These factors have been addressed experimentally and could possibly, when expressed by  $\beta$ -cells in patients with diabetes, promote  $\beta$ -cell survival.

### Genetic modulation of the immune system

In individuals with a high risk of developing T1DM, as indicated by genetic and humoral markers, but who have not yet entered the phase of autoimmune  $\beta$ -cell destruction, it might be possible to prevent the progression of the disease by DNA vaccination. In mice, it has already been observed that DNA vaccination with a glutamic acid decarboxylase 65 (GAD65) gene construct generates a protective humoral immune response and significantly delays the onset of diabetes [5]. Other studies of DNA vaccination in non-obese diabetic (NOD) mice were performed with a

**Table 61.3** Properties of gene therapy vectors with demonstrated utility in islet transduction.

Delivery method	Advantages	Disadvantages	
Non-viral vectors	Naked DNA DNA complexes Peptide transduction domains	High clinical safety Easy and inexpensive to produce Non-immunogenic Unlimited capacity	Low transfection efficiency Transient gene expression
Adenovirus		High transduction efficiency High viral titer Infects non-dividing cells	Transient gene expression Immunogenic Clinical safety issues
Adeno-associated virus		Potential site-specific integration Infects non-dividing cells No immune response High clinical safety	Low capacity (5 kb) Very difficult to generate
Lentivirus		High transduction efficiency Long term expression Easy to generate Relatively high titer	Possibility of insertional mutagenesis with clinical effects
Herpes simplex virus		High transduction efficiency Up to 30 kb insertion	Inflammatory and toxic reactions in patients Complicated genome and propagation

preproinsulin/glutamic acid decarboxylase 65 (Ins-GAD) fusion construct as the target antigen to introduce a larger number of autoantigenic target epitopes. DNA co-vaccination with Ins-GAD and B7-1wa (a membrane-bound molecule that can engage cytotoxic T-lymphocyte associated antigen 4 [CTLA-4] and promote negative signaling) generated protective regulatory T-cells and ameliorated the disease [6]. Both insulin and GAD65 may be key autoantigens in T1DM, and if the DNA vaccination approach leads to tolerance,  $\beta$ -cell destruction might be avoided.

Furthermore, virus-based IL-10 genetic studies showed beneficial effects on the development of T1DM, both effectively blocking progression of insulinitis as well as suppressing autoimmunity in NOD mice transplanted with syngeneic islet grafts [7]. Despite these results, significant immunosuppression, resulting from systemic expression of high levels of IL-10, give rise to serious concerns regarding the applicability of such an approach in clinical settings; however, the development of viral vectors promoting a tightly regulated transgene expression could overcome this obstacle.

Targeted immunomodulation has also been achieved by transducing autoantigen-specific CD4<sup>+</sup> T-cells *ex vivo* with retrovi-

ruses that encode immune regulatory proteins [8]. Following intravenous injection of the transduced T-cells, it appears that the cells accumulate at the site of inflammation. Using this site-specific delivery, immune regulatory proteins have been observed to protect against autoimmune reactions, possibly by converting the immune reaction from a Th1 to a Th2 response.

An alternative approach may be targeting expression of disease-specific epitopes to activated B lymphocytes [9]. Antigen presentation by these cells seems to result in immunosuppression and therapeutic efficacy. It is not clear why this is the case, but it has been suggested that antigen presentation by B lymphocytes leads to immune downregulation, whereas presentation by macrophages or dendritic cells is immune stimulatory.

---

### Stimulation of $\beta$ -cell differentiation and regeneration

A better understanding of the cellular sources for the expansion and turnover of  $\beta$ -cells seen in postnatal life could make way for a possible gene therapy approach leading to *in situ* regeneration of  $\beta$ -cells in patients with diabetes. Indirect evidence has suggested that postnatal  $\beta$ -cells derive from adult stem cells, proposed to reside in the pancreatic ducts, bone marrow, spleen or within islets. Lineage tracing experiments, however, demonstrated that the vast majority of adult  $\beta$ -cells derive from pre-existing  $\beta$ -cells, suggesting that terminally differentiated  $\beta$ -cells retain a significant proliferative capacity and thus could represent an attractive target for expansion using gene therapy [10]. For example, mice over-expressing gastrin and TGF- $\alpha$  display a significantly increased islet cell mass. In addition, the cyclin-dependent kinase 4 (CDK4) and cyclins D1/D2 emerge as key determinants of  $\beta$ -cell proliferation and  $\beta$ -cell mass. Indeed, mice lacking CDK4 display a selective loss of  $\beta$ -cell function and over-expression of CDK4 results in preferential hyperplasia of the  $\beta$ -cells; however, it is likely that all approaches aiming at regenerating  $\beta$ -cells in patients with T1DM must be combined with a strategy to prevent autoimmune destruction of the newly formed  $\beta$ -cells.

---

### Ectopic production of insulin by substitute cells

With the cloning of the insulin gene in the late 1970s, it was proposed that using a suitable promoter and insulin gene construct, non-insulin-producing cells could be made into insulin-producing substitute cells, and that such cells could restore insulin production in T1DM and some patients with T2DM. The original experiments were carried out on cell lines and fibroblasts, but since then hepatocytes, myocytes, pituitary and exocrine cells have also been made into insulin-producing substitute cells. Proinsulin is only converted into insulin by the prohormone convertases PC2 and PC3, which are not expressed in most substitute cells. This limitation has been overcome by mutating the insulin gene so that a furin cleavable site is generated (INS-FUR).

The protease furin, unlike PC2 and PC3, is expressed in most cells. Although processing of proinsulin to insulin can be achieved in substitute cells, none of these cells would be able to respond to insulin secretagogues with a physiologic secretion of insulin. Recent studies showed that both lentivirus [11] and adeno-associated virus vectors [12] were able to deliver INS-FUR cDNA efficiently to hepatocytes *in vitro* and *in vivo*, resulting in long-term correction of diabetes in rats.

Given its role in  $\beta$ -cell maintenance, the transcription factor Pdx-1 was investigated for its ability to induce ectopic insulin production in non  $\beta$ -cells *in vivo*. Ferber and colleagues have used adenoviral-mediated Pdx-1 overexpression for *ex vivo* transduction of adult human hepatocytes for cell-based therapy. In addition to glucagons, insulin and somatostatin, exogenous expression of Pdx-1 induced transcription of several  $\beta$ -cell products, including glucose transporter 2 and glucokinase, endogenous Pdx-1 and multiple downstream pro-endocrine developmental factors [13].

In a recent study Zhou *et al.* describe a way to reprogram pancreatic exocrine cells into insulin producing  $\beta$ -cells [14]. By using adenoviruses, they introduced combinations of nine different genes, previously identified to be essential to the embryonic development of  $\beta$ -cells, into the pancreas of live mice. They found that the transfer of three transcription factors (Ngn3, Pdx1 and Mafa) induces trans-differentiation of up to 20% of the successfully manipulated exocrine cells into  $\beta$ -like cells. By lineage tracing experiments, the authors proved that the trans-differentiated cells were, indeed, exocrine cells. These reprogrammed  $\beta$ -cells had similar morphology, protein expression and the capacity to secrete insulin as their “natural” counterparts. Moreover, they were able to improve hyperglycemia in mice with induced diabetes. This study elegantly shows that adult cells can be directly converted into another type of adult cell, which opens the possibility of directly converting cells *in vivo* for repair and regeneration as a therapeutic tool for diabetes and beyond [14].

---

### Cell therapy using $\beta$ -cells derived from embryonic stem cells

This topic is discussed in detail in the first part of this chapter.

---

### *Ex vivo* gene transfer to islets destined for transplantation

Pancreatic islet transplantation has been validated as a realistic alternative to correct the insulin deficiency in T1DM; however, islets are exposed to a plethora of insults before, during, after isolation and at the site of implantation, all of which could result in cellular death and impaired function, therefore reducing the yield of viable islets that engraft after implant. As a result, much effort has been made to understand better the molecular mechanisms involved in all these processes as well as in developing new therapeutic strategies to increase durable functional islet mass. In

**Table 61.4** Examples of gene therapy-based strategies leading to improved outcome of islet transplantation in animal models.

Gene product	Delivery method	Animal model	Desired effect
HGF and IL-1Ra	Adenovirus	STZ-induced-diabetic NOD-SCID mice	$\beta$ -cell survival, $\beta$ -cell proliferation, increased revascularization
HGF	Adenovirus	Allogeneic transplantation rat model	$\beta$ -cell survival, $\beta$ -cell proliferation
IL-10	Adenovirus AAV	STZ-induced diabetic rats (allotransplant) Autoimmune recurrence	Immunotolerance
sCD40-Ig	Adenovirus	Allogeneic transplantation mouse model	Immunotolerance
XIAP	Adenovirus	Chemically diabetic immunodeficient mice STZ-induced diabetic mice (allotransplant)	$\beta$ -cell survival
Akt	Adenovirus	STZ-induced diabetic SCID mice	$\beta$ -cell survival
IRAP	Adenovirus	STZ-induced diabetic rats	$\beta$ -cell survival
TNFR-Ig	Adenovirus	Diabetic mice (allotransplant)	Immunotolerance
VEGF	Non-viral	Diabetic mice	Increased revascularization
MnSOD	Adenovirus	STZ-induced diabetic NODscid mice	$\beta$ -cell protection against oxidative damage
TGF- $\beta$ 1	Adenovirus	Autoimmune recurrence in NOD mice	$\beta$ -cell survival
Bcl2	Adenovirus Adenovirus	Xenotransplantation Diabetic SCID mice	$\beta$ -cell survival

HGF, hepatocyte growth factor; Ig, immunoglobulin; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; IRAP, interleukin-1 receptor antagonist protein; MnSOD, manganese superoxide dismutase; NOD, non-obese diabetic; SCID, severe combined immunodeficiency; STZ, streptozotocin; TGF, transforming growth factor; TNFR, tumor necrosis factor receptor; VEGF, vascular endothelial growth factor; XIAP, X-linked inhibitor of apoptosis.

this context, *ex vivo* gene transfer to pancreatic islets represents an attractive approach towards enhancing graft survival after transplantation. Most of the gene therapy strategies described above show promise for the cytoprotection of islets in transplant settings and may ultimately promote significantly enhanced function and survival of transplanted islets leading to an improved outcome of the transplantation procedures (Table 61.4); however, considering the complex pathways involved in  $\beta$ -cell destruction and loss of function following islet transplantation, it is likely that gene therapy strategies targeting multiple genes, using multicistronic vectors, will be more beneficial for the improvement of graft survival. For this purpose, a number of factors still remain to be investigated to find which combination of genes proves optimal, what threshold level of gene expression is required and what delivery strategy is the most efficient for targeting the mechanisms leading to graft failure.

### Gene therapy strategies for type 2 diabetes

T2DM is characterized by hyperglycemia combined with variable degrees of insulin resistance. A potential therapeutic approach for the treatment of T2DM is the use of GLP-1, a gut-derived incretin hormone which has important roles in glucose homeostasis. Using an adenoviral vector to express GLP-1 with the insulin leader sequence to ensure secretion, Lee *et al.* [15] have recently

demonstrated transient improvement in glucose tolerance using an overt T2DM animal model. Significant therapeutic effects, including improved glucose homeostasis, decreased weight gain, reduced hepatic fat and improved adipokine profile, were also obtained by constitutively expressing exendin-4, a GLP-1 receptor (GLP-1R) agonist in a high fat induced obesity mouse model [16]). These studies suggest that GLP-1/GLP-1R agonist gene therapy may be a promising treatment modality for T2DM.

Another interesting line of research exploits the potential of viral proteins as therapeutic tools for treating glycemic dysregulation in humans. Human adenovirus type 36 (Ad-36) was determined as a novel candidate for improving metabolic profile by expanding adipose tissue while enhancing insulin sensitivity in experimentally infected rats [17]. Recent studies have demonstrated the capacity of Ad-36 to increase glucose uptake by adipose tissue explants obtained from subjects with and without diabetes. Ad-36 upregulated expression of several pro-adipogenic genes, adiponectin and fatty acid synthetase, and reduced the expression of inflammatory cytokine macrophage chemoattractant protein-1 in a phosphatidylinositol 3-kinase dependent manner [18]. Moreover, Ad-36 was also able to enhance glucose uptake in primary skeletal muscle cells from healthy lean subjects and subjects with diabetes [19]. Therefore, the potential of viral proteins to enhance glucose disposal and improve adipose and skeletal muscle tissues metabolic profile could be used as therapeutic targets for humans.

## Gene therapy for the treatment of diabetic complications

The gene therapy models for treatment or prevention of T1DM and T2DM outlined above have not yet reached clinical stages. By contrast, the use of gene therapy in the treatment of diabetes complications shows great promise and some projects are in the early stages of clinical testing. Briefly, transduction of nerves by herpes virus expressing nerve growth factor has been investigated for treatment of cystopathy and for peripheral neuropathy. In addition, the effects of gene therapy with vascular endothelial growth factor (VEGF) on coronary artery disease have been studied in a clinical trial. It has been shown that VEGF is required to initiate immature vascular formation, whereas angiopoietin-1 (Ang-1) is essential for the maintenance of endothelial integrity and vascular formation. In this regard, a recent study demonstrated that Ang-1 gene therapy promotes vascular maturation and stabilization and rescues diabetes impaired myocardial angiogenesis and myocardial remodeling in *db/db* mice [20]. Another small clinical trial showed significant improvement in patients with diabetes and diffuse peripheral vascular disease after intramuscular administration of a VEGF gene-carrying plasmid. Furthermore, delivery of insulin-like growth factor I by non-viral gene therapy in combination with autologous cell transplantation improved diabetic wound healing significantly in a preclinical large-animal model [21].

## Problems and future directions

Although significant progress is currently being made in the field of gene therapy of diabetes, it should be emphasized that gene therapy is neither a low cost:benefit nor a low risk:benefit approach. For example, there is the obvious risk that the gene therapy could induce severe hypoglycemia if the number of gene modified insulin-producing cells and their insulin release is not under perfect control. In addition, we need to await ongoing developments in gene transfer techniques to achieve therapeutic long-term expression, *in vivo* regulation of transgene expression and lack of immune triggering, in order to conduct gene therapy on  $\beta$ -cells *in vivo*. Because T1DM is usually more severe than T2DM, it is natural to assume that the first gene therapy efforts will be dedicated to the treatment of T1DM, and that the experiences from these trials will be used for later strategies for the treatment of T2DM. Finally, it must be clear that the benefits of gene therapy of diabetes outweigh the risks and offer advantages compared to those of conventional treatment before this approach could become accepted in general practice.

## Future Models of Diabetes Care

Robert A. Gabbay<sup>1</sup> & Alan M. Adelman<sup>2</sup>

<sup>1</sup>Penn State Institute for Diabetes and Department of Medicine and Molecular Medicine, Penn State Milton S. Hershey Medical Center, Hershey, PA, USA

<sup>2</sup>Department of Family & Community Medicine, Penn State Milton S. Hershey Medical Center and Penn State College of Medicine, Hershey, PA, USA

### Keypoints

- Future diabetes care will continue to be delivered mainly in the primary care setting.
- Efforts must continue to bridge the gap between evidence-based recommendations and the current outcomes of patients with diabetes.
- The Chronic Care Model (CCM) provides the best evidence-based framework for organizing and improving chronic care delivery to ensure productive interactions between an informed activated patient and a proactive prepared practice team.
- The CCM defines six domains that require attention to optimize outcomes: delivery system design, self-management support, clinical information systems, decision support, community and health system-related issues.
- The most robust results are obtained when multiple elements of the CCM are incorporated together.
- Team-based care is a particularly effective strategy to improve diabetes outcomes.
- Future models for diabetes care need to continue to involve patients in designing the experience of the visit and various aspects of care improvement.

### Introduction

The future of diabetes care will be shaped by the projections of increased incidence, producing more devastating complications and higher costs of care. Projections suggest that the worldwide prevalence of 6.6% in 2010 will increase to 7.8% in 2030. This translates into an increase in the number of individuals with diabetes from 285 million in 2010 to 435 million in 2030 [1]. Increased efforts to prevent the development of diabetes will be necessitated by current predictions that one out of three babies born in the USA will develop diabetes in their lifetime [2]. There is expected to be a dramatic increase in incidence of diabetes in low and middle income countries. Current health care costs associated with diabetes and its complications total more than \$174 billion in the USA, and worldwide estimates are considerably higher. Despite the necessary efforts towards diabetes prevention, it is clear that with spiraling health care costs the millions of patients with diabetes will require better care models.

Many drivers for new care models are already in place, foremost of which appears to be financial. This is true whether the payer is a government authority, private insurer or purchaser of health care. Nearly a decade after the Institute of Medicine's report describing *Crossing the Quality Chasm* [3], momentum

continues to build for an implementation of better models of chronic illness care and diabetes is at the forefront of these efforts. In many ways, diabetes is the hallmark disease for studying quality improvement because of the prevalence, cost and strong evidence-base for specific quality goals. The challenge remains that despite strong agreement about minimum goals for HbA<sub>1c</sub> < 7% (53 mmol/mol), low density lipoprotein (LDL) cholesterol <100 mg/dL (26 mmol/L) and blood pressure (BP) < 130/80 mmHg, fewer than 7% of Americans with diabetes are currently achieving these goals [4]. Key barriers to achieving these evidence-based patient goals are insufficient patient self-management support to facilitate adherence and clinical inertia. It has become increasingly clear that the systems of care are more responsible for these poorer outcomes than are either providers or patients.

Diabetes is one of the most psychologically and behaviorally challenging chronic illnesses to manage because as much as 95% of the management relies on the patients' self-care efforts [5]. Despite this, the current health care system often does not have in place appropriate resources to foster patient self-management. Limitations in the availability of self-management education and the lack of ongoing self-management support impair patient adherence to self-care. Clinical inertia is defined as the clinician's "recognition of the problem but failure to act" [6]. This refers to the situation where physicians fail to intensify therapy when faced with patients who are not meeting target goals for clinical variables. This inertia certainly has many components including

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

decreased provider visit time, lack of timely appropriate data, inadequate provider attention to patient adherence and financial barriers. More information is ultimately needed on the basic epidemiology of clinical inertia including a careful analysis of associated patient, physician and clinic characteristics.

Compounding these challenges of self-management and clinical inertia is the plethora of new diabetes management data that is becoming available to the provider. The expanding use of continuous glucose monitoring, personal health records and shared web-based patient portals presents the risk of overwhelming diabetes care providers. Better management systems with appropriate filters and alerts are needed to analyze all these data and to present them in a usable format for providers.

Primary care is an important foundation of care in any health system. Starfield *et al.* [7,8] have shown that residents of countries with strong primary care foundations have improved health outcomes and lower mortality, with lower costs and with fewer health disparities. Despite the highest cost expenditure (\$7000 per capita versus less than \$3500 for Australia, Canada France, Germany, The Netherlands, New Zealand, and the UK), the USA has a weak primary care base and approximately 50 million uninsured citizens. It comes as no surprise that in a comparison of these eight developed Western nations, the USA had the most negative ratings for access, coordination and safety experiences [9]. What characterized all countries was the need for improved care systems.

For patients with type 2 diabetes mellitus (T2DM) and those at risk for developing the disease, primary care physicians are a critical foundation of the health care delivery system. In the USA, patients with T2DM consulting a primary care physician outnumber those consulting an endocrinologist by almost 10 to 1 [10]. In general, patients at risk for T2DM are seen by primary care physicians and not by endocrinologists. Therefore, any reorganization of care will need to focus on the primary care settings.

Overall, the solutions to these issues will require reorganizing and reinventing diabetes care from a systems approach. In the cross-national Diabetes Attitudes Wishes and Needs (DAWN) study, attitudes towards diabetes care were assessed across 13 countries from Asia, Australia, Europe and North America [11,12]. Although variation existed among countries in terms of both provider and patient perspectives of diabetes care, all respondents (primary care physicians, nurses and specialists) noted lack of care coordination and implementation of chronic disease strategies as an area in need of improvement worldwide. The payment system was also identified as a barrier in most of the countries surveyed, with the USA, Germany and Japan leading the way. Patients reported high ease of access to providers, but patients' ratings of team collaboration among their providers were relatively low. By the same token, primary care physicians noted a lack of multidisciplinary care and a need for more coordination of care. This chapter focuses on the most promising models for diabetes care, provides current examples and attempts to project into the future how these systems will evolve.

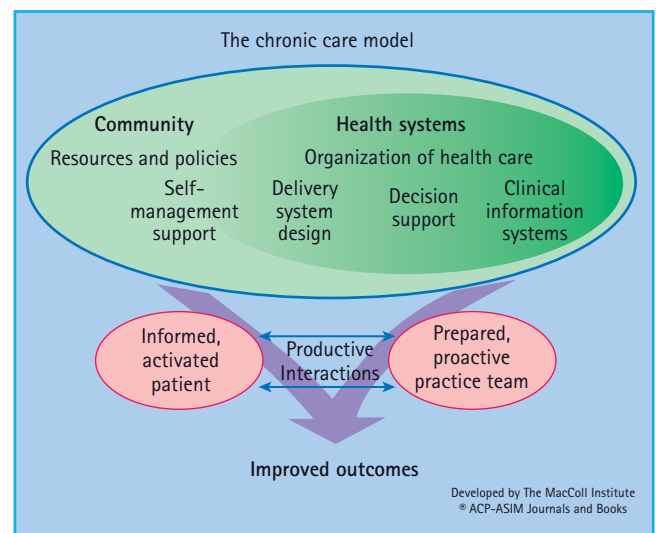

## The Chronic Care Model

Although several approaches have been utilized to translate evidence-based recommendations into clinical practice, the Chronic Care Model (CCM) has been the most effective model that has been implemented in a variety of clinical settings in the USA and internationally, often with diabetes as the focus disease [13]. The CCM proposes that the productive interactions of a prepared proactive practice team and an informed empowered patient and family will lead to improved outcomes (Figure 62.1). This provides a conceptual framework and roadmap for redesigning care from the typical acute reactive system to one transformed to population-based proactively planned care of individuals with chronic diseases such as diabetes. Mounting evidence from comparison of high and lower performing practices, evaluation of large-scale quality improvement efforts and randomized intervention trials have demonstrated that the implementation of the CCM is feasible by busy practices with resultant improved disease outcomes [14].

The CCM has been employed for diabetes in a number of health care settings and has demonstrated improvement in cardiovascular risk factors [15,16] and reductions in HbA<sub>1c</sub> [16], along with improvements in complication screening. Although simpler interventions would be attractive, the evidence suggests that high performing practices do best when they incorporate multiple elements of the CCM [17–21].

The CCM focuses on six elements:

**1 Delivery system design.** One of the most critical elements of transforming care relates to the systems for delivery of care. Planned visits are focused to meet the needs of the patient in terms of disease complexity, cognition, social needs, learning style and degree of support needed from providers and staff. Team-based care distributes tasks among the members of the health care

**Figure 62.1** The Chronic Care Model. Reproduced from [www.improvingchroniccare.org](http://www.improvingchroniccare.org) with permission from Group Health Research Institute.

team to optimize care. Reorienting care towards team-based care delivery includes elements such as clinical case management for complex patients, defining and distributing roles amongst team members (nurses, physician assistants, diabetes educators, dietitians, pharmacists and non-medically trained office staff), ensuring follow-up care and identifying patients who “fall between the cracks.”

**2 Self-management support.** Self-management support is focused on providing the knowledge needed by the patient to manage their own disease successfully. It also acknowledges patients’ central role in their care. This helps to foster the incorporation of effective strategies for living with diabetes and emphasizes the individuals’ responsibility for their own health. Although diabetes education has long been recognized as a crucial part of diabetes management, there is increased recognition for the need for ongoing support.

**3 Clinical information systems.** These systems leverage information technology to provide timely reminders to both providers and patients and to identify high-risk subpopulations for proactive care. Diabetes registries that provide searchable information on diabetes populations have proliferated in many health care settings [22].

**4 Decision support.** Embedding evidence-based guidelines into daily clinical practice and sharing those guidelines and information with patients to encourage their participation are the keys to decision support. Guidelines are best integrated through reminder systems that can be embedded into daily care; periodic feedback and standing orders can be used to empower other practice staff to ensure that evidence-based guidelines are implemented. Although much attention has been given to provider education, better models are needed to integrate specialist expertise and primary care. Innovative approaches that incorporate real-time specialist-based decision support are needed.

**5 Community.** Patients should be encouraged to participate in effective community programs, and this highlights the need of providers to partner with those within the community to fill gaps of care. Partnering becomes even more critical in limited resource environments where extending care beyond the confines of the clinic is essential.

**6 Health systems.** The diabetes care culture must promote effective improvement strategies and support optimal diabetes care. This can include better reimbursement models to encourage optimal care and leadership that stresses the importance of such care.

### Delivery system design

Although the best results are obtained when multiple facets of the CCM are implemented together, probably the single most effective quality improvement intervention in diabetes care involves delivery system design to incorporate a team-based approach [23]. Other key elements of delivery system design are case management and shared care.

Realistically, primary care providers have reached their limit in terms of additional tasks that they can undertake, and therefore

it is inevitable that the care team needs to be expanded. In many ways, team management has been considered a central feature of superior diabetes care. Diabetes educators and dietitians have long been part of standard diabetes care and the expansion of the roles of these and other individuals within the health care system will likely continue.

Team-based care allows task distribution which includes indentifying team members to:

- 1 Track longitudinal information through flowsheets or registry data;
- 2 Perform BP and foot exams; and
- 3 Ask patients about self-care goals and care barriers prior to the primary health care provider entering the room.

Standing orders can be used to empower office staff to order overdue laboratory screening and eye exam referral, and can even extend to algorithms for medication intensification. Appropriate communication between team members is the key, and the incorporation of clinic “huddles” at the beginning of the day can ensure that appropriately planned care is delivered to all individuals with diabetes.

Diabetes has been a fertile testing ground for case management approaches in which usually either a nurse or pharmacist meets regularly with high-risk patients to provide intensified care [23,24]. Care populations are segmented based on needs to ensure that appropriate care intensity is provided. Key elements of care management include:

- 1 Defining and identifying high-risk patients;
- 2 Case assessment;
- 3 Individualized care plans; and
- 4 Development, implementation and monitoring of outcomes.

Diabetes registries are an ideal source for identifying high-risk patients either based on clinical measurements (e.g. HbA<sub>1c</sub> levels), low self-management skills or overdue visits. Intensification of therapy can be facilitated by empowering other health care providers through standing orders to implement changes, and by clearly assessing health management needs and support. Care management is most effective when incorporated within the primary care clinic as opposed to “carve out” models where an outside entity provides telephonic care management for patients and which subsequently leads to ineffective communication with the primary health care provider. Integration of care management with the primary care practice is needed to ensure appropriate information exchange, shared goals and coordination of care.

Diabetes nurses are eager to increase their involvement and take on more responsibility for diabetes care, as recently surveyed internationally through the DAWN study [11]. Pharmacists have also been utilized to work in conjunction with primary care physicians in a case management role. Recent reimbursement changes within the US Medicare system have facilitated billing for these services based on non-randomized trials in which this care has been found to be cost-effective [25].

Care management approaches have been effective at improving glucose control, BP and lipid control in many different settings

in the USA and elsewhere [23,24]. One controversy has been the extent to which case management permits medication titration. Two models have been used: one in which the case manager advises the primary care physician who then makes the medication change versus the second in which a standing order algorithm enables a case manager to intensify treatment without routinely checking with the primary care provider. Although studies suggest that standing order algorithms are more effective in lowering HbA<sub>1c</sub> levels [23,24], some physicians have concerns about nurses or pharmacists making these changes without routine provider input. As more studies and appropriate training programs are developed to allow other health professionals to assist in medication titration, this approach will continue to show promise in improving clinical outcomes while not overburdening the already overtaxed primary care system.

Shared care is defined as “the joint participation of primary care physicians and specialty care physicians in the planned delivery of care, informed by an enhanced information exchange over and above routine discharge and referral notices as the co-management of patients by primary care and subspecialty specialists” [26]. Currently, when most patients are referred to endocrinologists, care is subsumed by the specialists and true co-management is rare. In a recent Cochrane review which examined shared care across multiple chronic illnesses, limited data were available on effective models [27].

### Self-management support

A distinction needs to be made between self-management support and self-management education. Self-management education is quite familiar in the diabetes community and encompasses the traditional role of the diabetes educator providing knowledge and skills to patients with diabetes. Self-management support, however, needs not be performed by a diabetes educator and, in fact, peer coaches have been utilized to foster self-management support. Self-management support involves the ongoing collaborative approach between coach and patients to define problems, set priorities, establish goals and create treatment plans. Resources offered to problem solve can include community-based organizations, peer support programs and other groups. Individualized approaches that address the major concerns defined by the patient typically involve a strong element of coaching with the goal of educating and empowering the patient. The challenge for the future is to make self-management support more widely available. Innovative approaches that leverage information technology to provide patient coaching are possible solutions [28].

Self-management has long been recognized as a key determinant of disease outcome. Traditional diabetes education programs have focused on knowledge and specific skills training. It has become increasingly clear, however, that knowledge is necessary but not sufficient to influence behavior. This has led to increased attention to determinants of patient behavior change. In this regard, importance and confidence for a behavior change are key determinants [29].

### Importance and confidence

The overall importance of a behavior change is judged by the patients based on their values. Knowledge and education can clearly influence importance by providing the rationale for health improvement. Confidence, also referred to as self-efficacy, is the inherent confidence that a patient can be successful in making the behavior change. This can be augmented through problem-solving and discussion of alternative strategies. Adherence to diet, exercise, monitoring and medication are required for optimal diabetes outcomes. Although many social and societal factors influence patient adherence, clinician counseling style has a profound impact on potential behavior change. Providers can either increase resistance to change or help to facilitate readiness to change on the part of the patient. Patient empowerment and increased self-efficacy are key factors in enabling patients to feel confident in making necessary changes. Recent years have brought to the forefront behavior change approaches from the psychological literature to be applied to diabetes. One of the most promising approaches is motivational interviewing [29,30].

Motivational interviewing is a directive patient-centered counseling style for eliciting behavior change by helping patients to explore and resolve ambivalence. It is a collaborative patient-provider model that stresses that motivation must come from the patient, not the provider, and honours and respects the patient's autonomy. Initially utilized in the addiction field, it is now being applied to a number of chronic diseases including diabetes [31]. It is a teachable evidence-based approach that holds significant promise to improve patient adherence. Part of the attractiveness of motivational interviewing has been the well-defined set of skills that can be taught to different individuals. Certified trainers are available worldwide [32]. Brief motivational interviewing has adapted many of the skills of traditional motivational interviewing, as used by psychologists, for use in the busy time-pressured health care environment. Meta-analyses have shown this to be a powerful approach which can be learned by people with varying backgrounds and applied to multiple chronic illnesses [31]. Early studies in diabetes are promising [33,34] and larger scale trials are currently underway [35].

Several other behavior change models/theories, which can either explain or help practitioners conceptualize behavior change, have been identified. They include the health belief model, theory of reasoned action or theory of planned behavior, stages of change or transtheoretical model, social cognitive or social learning theory, community organization/building, and social marketing [36].

### Clinical information systems

Clinical information systems help to organize patient and population data to facilitate effective and efficient care delivery. Diabetes registries are being adopted in a variety of health care settings involving municipalities, academic health centers, third-party payers, the US Veterans Affairs Health System and international registries in Europe, Canada and elsewhere [37]. A registry is a searchable list of all patients with a particular chronic disease.

The well-designed registry lists all members of the patients' health team and provides key information for patients and providers. The critical impact of the registry is that it can allow timely identification of high-risk subpopulations, permitting the health care team to intensify treatment. A registry can also provide snapshots of care that can collate the many data elements needed for optimal care (e.g. last eye exam, foot exam, nephropathy screen, HbA<sub>1c</sub>, cholesterol, BP) and can include prompts for care (decision support) as seen in Figure 62.2.

The primary challenges to further adoption of diabetes registries are cost and interoperability issues between different electronic health record systems. Information technology-related issues often receive the most attention by practices in the USA [19]; however, even non-technologic approaches such as incorporation of paper flowsheets can be an effective start. Furthermore, caution is needed to avoid wasting time and resources on implementing information technology solutions to diabetes care without attending to some of the more fundamental practice redesign issues. More robust results are often seen when team-based care and care management are in place.

A new challenge of information overload is entering into diabetes care. The widespread availability of the Internet makes it an attractive communication tool among patients and providers. It has been useful in multiple areas ranging from videoconferencing for diabetes education to tele-ophthalmology to patient support and education websites. Patients desire an effective tool to communicate with their providers in order to receive responsive feedback and advice in a timely manner. Web-based management of diabetes through patient-initiated glucometer uploads can facilitate provider treatment intensification and has demonstrated mixed results in different patient populations [38]. Glucometer uploading is undoubtedly more accurate than patient recorded values. A potential advantage of between visit care offered by this type of telemedicine approach is an improvement in the "velocity to goal" (i.e. how fast the patient reaches good diabetes control). This is particularly important because studies suggest that the average time between treatment intensification in some cases may be as long as 27–35 months [39]. Telemedicine provides a significant opportunity to give providers updated clinical data for more appropriate medication adjustments; however, enthusiasm is tempered by the data burden presented by the frequent communication between patients and providers related to blood glucose values. Reimbursement could facilitate greater adoption of this approach, and future advances could provide clinicians with treatment algorithms that can assist clinical decisions by interpreting data from these glucometer downloads.

The use of computerized glucose predicting engines shows promise in optimizing insulin management [40]. Albisser *et al.* [41] have demonstrated that utilizing a shared central database allowing for patient input of glucose self-monitoring values as well as medication, diet and exercise data, analyzed with a glucose predicting algorithm, enabled providers to reduce iatrogenic hypoglycemic events ninefold compared to that of baseline. The reduction in hypoglycemic events was accomplished without

change in HbA<sub>1c</sub>. Thus, the ability to predict future blood glucose levels improves glycemic stability and may also prove useful in patient self-management. Current research on closed-loop artificial pancreas systems are expected to provide more robust algorithms that will become available to guide patient self-titration of insulin and/or streamline provider titration decisions.

### Decision support

The approach frequently used as decision support involves embedding evidence-based guidelines into daily practice to obtain clinical improvement. A number of organizations provide evidence-based clinical guidelines. Although there can be some discrepancies among them, most are generally disagreements on how low goals should be brought down. While these debates are important, overriding evidence suggests that the vast majority of patients are not at minimum clinical care goals. Establishing clinical goals is a first step; however, the best practices to achieve those goals are critically important to ensure positive clinical outcomes. The American Diabetes Association (ADA) and national bodies such as the National Institute for Clinical Excellence (NICE) provide detailed guidelines [42]. This is a necessary first step, but decision support goes beyond the acceptance of consensus guidelines and focuses on the implementation of those guidelines in everyday practice. Although provider education regarding guidelines is important, these interventions typically have had limited impact beyond processes of care (i.e. ensuring that more patients are screened for complications). Effective multifaceted interventions most often include academic detailing, physician reminders, and audit and feedback to improve diabetes outcomes. Patient tracking systems (patient registries) and nurse-led interventions are also effective [43].

Examples of guideline implementation can include incorporating decision support into electronic health records or reviewing the chart prior to a planned visit to identify gaps in care and strategies to intensify treatment plan. Although provider knowledge of guidelines is critical, these guidelines need to be shared with patients to encourage their participation. Empowering patients to "know their numbers" provides the basis for a negotiated treatment plan to achieve those goals.

Given the evidence that BP control can reduce both microvascular and macrovascular complications, future efforts will clearly focus on identifying better approaches for monitoring this outcome. Self or automated BP monitoring offers many of the same advantages as glucose monitoring. An increased number of BP recordings increases the accuracy of the measurement. It may also empower patients to discuss their BP with their physician [44]. Home monitoring, in conjunction with other interventions such as patient education, Internet communication, nurse or pharmacist follow-up, does lead to improved BP control [45,46]. Telemonitoring of BP may lead to reductions in both systolic and diastolic BP [47].

The initial disadvantage of self or automated blood glucose or BP monitorings is that clinicians continue to be bombarded by

more and more data. The increasing availability of continuous glucose monitoring data, routine self glucose monitoring results that can be shared through web portals, ambulatory BP monitoring and personal health records are all at the expense of potentially overburdening the already busy clinician with too much information. There will clearly be a need to develop more robust data filtering methodologies to analyze and package this information in clear concise summaries that can lead to appropriate clinician and patient action. Some evidence of this is already apparent in software for many of the self glucose monitoring devices that provide ready access to glucose averages, standard deviations and other simple data analytical features. Merging this information with evidence-based decision support tools for providers is likely to increase their overall value to improve quality of care.

### Health systems

The overall health care system is an important factor. In suggesting solutions to improving the US health care system, Berwick *et al.* [48] provide insight into important aspects of the health care delivery system that translate into improved outcomes. They propose that an effective health care system that produces outstanding health outcomes pursues three primary goals:

- 1 Improving the patient's experience of health;
- 2 Improving the health of a defined population; and
- 3 Reducing the costs of care for populations.

They refer to this as the Triple Aim. In order to accomplish these goals, Berwick *et al.* define three preconditions. First, the health care system must be focused and responsible for the health of a defined population. Second, monetary and related constraints are placed on the system. The system does not have unlimited resources. The USA has experienced unrestrained health care costs and spends far more than any other developed country's health system, yet its health outcomes lag behind other countries [49]. Third, there is an over-arching entity that is responsible for the health of the population and pursues the goals of the Triple Aim. Health systems such as those in Canada and the UK already embody these principles. There are also several examples in the USA such as Kaiser Permanente and Health Partners in Minneapolis, both closed-panel health maintenance organizations.

Several approaches have been utilized from perspectives to improve clinical outcomes for patients with diabetes. Disease management programs have proliferated in the USA, and worldwide there has been enthusiasm for pay-for-performance (P4P) models that alter reimbursement based on achievement of quality goals.

"Disease management" has been defined by the Disease Management Association of America as "a system of coordinated health care interventions and communications for populations with conditions in which patient self-care efforts are significant" [50]. In the USA, this is a one billion dollar industry that usually is managed by a private company working with a health insurance plan or state health program. Mattke *et al.* [51] question the

effectiveness of these programs. They did find that these programs can lower hospitalization rates for patients with congestive heart failure and increase outpatient care and prescriptions for patients with depression and these programs have also lead to improvements in process of care, but it is uncertain if they lead to reduced costs [50]. Linden and Adams [52] found a slight cost savings but cautioned that study design had an influence on the findings. Randomized clinical trials showed a net loss while pre-/post-comparisons and case-control studies demonstrated cost savings. Typically, the severity of illness and intervention intensity varied greatly, and these disease management programs were not fully integrated into the patient's care.

Reimbursement of providers of care may be a mechanism for improving health outcomes of individuals with diabetes. Recently, P4P has been touted as a way of incentivizing clinicians to improve the quality of care that they deliver. Two recent reviews point out that P4P programs may have both benefits and adverse effects [53,54]. Adverse effects include a focusing on only those elements measured and avoiding severely ill patients who may adversely affect performance measures [53]. In a study of the effects of P4P on intermediate outcomes for patients with diabetes in the UK, Millett *et al.* [55] found that while improvements were made, the magnitude of improvements differed according to ethnic group. Comparing P4P between primary care practices in the USA and UK, McDonald and Roland [56] reported that there were unintended consequences resulting from the implementation of P4P. Physicians in the USA were more likely to report that P4P had little impact on their office and voiced feelings of resentment, lack of understanding of the program, loss of autonomy and less satisfaction than their UK counterparts. Design elements such as who is incentivized (individual clinicians, medical groups or hospitals) and what is incentivized (documentation of process of care measures or outcome measures) may be important.

Others suggested models of payment to improve quality of care including non-payment for avoidable complications, case-management fees, primary care capitation, episode-based payment and shared savings [57]. Non-payment models and episode-based payment models usually focus on care provided to inpatients. For example, non-payment models do not pay the provider and/or hospital for removing the wrong body part or preventable inpatient complications (urinary tract infections). Episode-based payment models define a global rate for a specific condition such as diabetes or myocardial infarction and the meeting of pre-defined process standards such as achieving best practice standards. Case management fees and primary care capitation to primary care physicians have been proposed to coordinate ambulatory care better, particularly in patients with chronic diseases such as diabetes. Lastly, shared savings payment models involve sharing savings from providing improved quality of care with large groups or individual practitioners. Many of these payment models may be specific in the attempt to "fix" the fragmented US health system. Elements of these payment models may already be incorporated into the more integrated single-payor systems of other developed countries.

Another reimbursement model being explored is providing patients with monetary incentives to engage in appropriate self-care and/or removing financial barriers to care. A municipality in the USA (Asheville, North Carolina) eliminated pharmaceutical costs for patients with diabetes in return for mandated regular pharmacist visits and noted significant savings in health care costs [58–60]. Large corporations in the USA have been examining other models whereby patients are incentivized to engage in various programs or activities. To date, there are limited data regarding the efficacy of these initiatives despite their potential promise.

### Community

Community resources are often overlooked and not integrated into care for patients with diabetes. Providers can become more familiar with these resources and work collaboratively to make patients aware of opportunities. These can include safe exercise opportunities, healthy food availability, social programs and support services that are available through non-governmental organizations. Communities can partner with health care organizations and governments to improve public awareness about diabetes. For example, recent efforts in the USA between the ADA and the American Heart Association (AHA) publicizing the link between diabetes and heart disease have raised better awareness. Overall, as prevention of diabetes and its complications becomes an increasing public focus, public awareness efforts to empower patients to engage in appropriate diet and exercise will be needed. Social marketing provides a rationale for how this approach can be effective, and an excellent example of success is the change in tobacco use in the USA over the last three decades. Similar public health initiatives are needed to stem the epidemic of obesity that is fueling the rise in diabetes.

Overwhelming evidence now suggests that the simultaneous incorporation of multiple components of the CCM is synergistic and more effective than traditional single intervention approaches [19,23]. Too much past research focused on only a single intervention and therefore missed the potential value of the concurrent implementation of multiple interventions for true “transformation of care.”

Transformation of care, according to the CCM, has often been accomplished through “learning collaboratives” either through the Breakthrough Series Collaborative [61,62] or through other similar experiences. Widespread implementation in the USA has generally occurred in large organizations, in part based on supportive reimbursement systems. Nevertheless, external support for practice transformation is being explored in several regional improvement programs [62,63]. Recent position statements from many professional societies have come in strong support for the CCM [64]. Alternatives to the time-consuming learning collaborative model such as practice coaching and web-based learning networks are being developed and tested [65–67].

Another initiative to improve chronic disease management in the USA has focused on the patient-centered medical home. The patient-centered medical home is a concept being developed by

the major primary care societies in the USA. It combines the principles of primary care (continuity of care, whole person orientation, quality/safety, prevention, timely access to care) with many of the elements of the CCM (coordinated/integrated care, teams, population health). One of the driving forces behind this concept is to revitalize primary care in the USA.

Although the concept of patient medical home has been attractive and a certification program has been established in the USA, there are concerns that this model may have limited application outside the country. In particular, many of the elements described for the National Center for Quality Assurance certification process require advanced information technology capabilities that generally necessitate an electronic health record. Despite the value of electronic health records, the mere availability of these tools is often insufficient to transform care. Often, practices and health systems can get sidetracked with the formidable information technology and interoperability challenges, losing sight of the overall goal of transforming health care. In comparison, the CCM elements are more easily translatable in low technology environments within the developing world.

In the USA, several states have explored integrated approaches to adopt the CCM. The foremost of these has been initial experience in Pennsylvania where insurers have agreed to provide significant reimbursement and incentives for primary care adoption of the CCM to improve diabetes care. Learning collaboratives are conducted across the state to teach clinicians and office staff the implementation aspects of the CCM. These efforts are supported by practice coaches who meet with practices individually to problem-solve implementation efforts. Clinics are required to report on clinical outcomes and care changes on a monthly basis, and payers have agreed to provide funding for needed practice changes such as case management in the hopes of containing spiraling health care costs [62]. A national initiative is currently underway in Australia to implement the CCM through the Australian National Primary Care Collaboratives [68], and similar initiatives are being explored in Canada, Denmark, Netherlands, New Zealand and elsewhere.

### Ideal appointment of the future

One informative exercise is to solicit from patients and providers what the ideal appointment of the future will look like. Certainly, many challenges face health care, but returning the focus to be more patient-centered is a universally adopted goal for patient care. The classic clinical visit can be modified in a variety of ways.

As care moves to be more patient-centered, a key need is to involve patients in designing the type of care and how it could be implemented. This can be rather enlightening to those in the medical community by stretching the medical model in ways not previously considered. The patient’s perspective is needed because: “without the inclusion of the affected individual’s perspective, it is possible that the information, from the provider’s perspective, is incomplete or misleading” [69].

Significant opportunities exist to improve the pre-arrival visit so that patients could spend quality time speaking with their provider, as opposed to providing data. To accomplish this, patients could utilize kiosks in waiting rooms to search for specific disease conditions and receive tailored messages about their health that prompt questions they may want to ask their provider during the visit. Creating such opportunities for “patient activation,” which enables patients to become collaborative partners in managing their healths, have had some promising results [40,70,71]. Where kiosks are not feasible, even low-tech (paper) methods to capture current medical histories, patient concerns and symptom screening (e.g. depression) would give patients more time with the provider to focus on the issues they want to address. During the appointment, less time would be spent talking about factual information that could be captured electronically (medications, insurance information, address changes, phone numbers) and more time talking about what matters most to the patient.

A warm inviting environment can have a positive impact on the “ideal” patient appointment [72]. The use of art, particularly art that holds meaning for the patient, is one method to enhance the office environment. Studies have also looked at the creation of art by patients to express their thoughts about having a chronic illness [73,74], which could then be shown to others. The use of art in waiting rooms is an effective way to create an environment that allows for reflection and discussion [75,76]. In fact, the overall patient experience could be improved through providing a service that resembles check-in at a hotel or restaurant. [The word “hospital” comes from Latin *hospes* (host), which is also the root for the English words “hotel,” “hostel” and “hospitality.”] Imagine being greeted by a concierge, who offers to take the “guest’s” coat and find a seat. The guest has the option of reviewing medical information and providing corrected data (phone/address) through either the concierge or a computer station at the concierge’s desk. The concierge asks what the main concern of the appointment is today, and makes a note that is forwarded to the provider electronically. Instead of thinking about the patient experience in a clinical way, the model of hospital hospitality opens up the doors for true customer service delivery.

Some may argue that at the core of the issue is how the patient appointment itself should be changed so that patients are treated more like people and less like walking diseases. Contrary to many preconceptions, the clinician may actually gain time by altering current practices, rather than lose time at each appointment [77]. Time is always limited and clinicians can find ways to use interventions or strategies to make most efficient use of the time. Thus, identifying one focused question that connects to the heart of the issue, rather than a dozen that do not, can save time and introduce important matters that otherwise would take years to disclose [78]. The question should be open-ended, not closed, to generate a discussion. If a patient does not have ideal self-management, the clinician could ask a question such as: “Tell me about your struggles (difficulties) with having diabetes?” and then make notes of the patient’s response. In turn, the clinician would

repeat back the response, and ask, “Did I get it right?” This is a narrative enquiry technique used in medical settings to assist clinicians in understanding the patient’s situations, thus being able to offer better suggestions or assist the patient in problem solving on what could be done to overcome those struggles [79]. Other examples of questions used in narrative inquiries include: “How does diabetes impact your life, both negatively and positively?” “What is important to you in your life, besides diabetes?” and “What could I do differently as a provider to help you?” Asking questions such as these often encourages dialogue and deepens the sense of mutual commitment and investment in the learning experience.

In the ideal future appointment, we want to examine critically those things which inhibit our practice from being successful. By asking patients what they want and need from us will improve upon the productive interaction between patients and providers, which is the ultimate goal of the CCM. We want to ask ourselves and our patients “What are the barriers that prevent us from achieving success?” and take action based upon those recommendations. Then we go back to our patients and ask “Did we get it right?” This process will help us redesign our practice to meet needs and provide self-management improvement for patients.

Overall, the future models of diabetes care are in many ways available today. The CCM has been implemented in a number of practice settings with improvements in diabetes quality of care. The model provides a conceptual framework to attend to the many aspects of care required to ensure that productive interactions are achieved between a proactive prepared practice team and an informed activated patient. The assignments of this model to different practice settings and further dissemination of the model are the near-term challenges. Care will inevitably become more patient-centered. Collaboration between patients and practice teams will be required to improve clinical outcomes and subsequently costs. Understanding the needs of patients, creating the ideal environment for their care and using system-based approaches to optimize their care will converge to improve the lives of those with diabetes in the future. Supporting self-management will be critical to achieving these outcomes.

In many ways, the future lies in developing integrated systems of care that are responsible for the outcomes and in getting individuals to take more responsibility to manage their own disease. Diabetes has led the way in many CCM studies and included elements, in part because it represents a costly disease reaching epidemic proportions. Nevertheless, this disease is also blessed with many evidence-based goals of care that can prevent long-term complications, which are the source of most of the overall costs of diabetes.

---

## Acknowledgments

The authors would like to thank Drs. Heather Stuckey and Rena Dearment for their contributions to this chapter and support provided by the National Institute of Diabetes and Digestive and Kidney Diseases (R18-DK067495).
