# Textbook of Diabetes

EDITED BY

**RICHARD I.G. HOLT** MA, MB BChir, PhD, FRCP, FHEA

Professor in Diabetes & Endocrinology  
Developmental Origins of Health and Disease Division  
University of Southampton School of Medicine  
Southampton, UK

**CLIVE S. COCKRAM** MBBS, BSc, MD (Lond), FRCP, FRACP, FHKAM (Med)

Emeritus Professor of Medicine  
Chinese University of Hong Kong  
Hong Kong SAR  
People's Republic of China

**ALLAN FLYVBJERG** MD, DMSc

Professor of Clinical Endocrinology and  
Chair, Department of Endocrinology and Internal Medicine  
The Medical Research Laboratories  
Aarhus University Hospital – Aarhus University  
Aarhus, Denmark

**BARRY J. GOLDSTEIN** MD, PhD, FACP, FACE

Therapeutic Area Head, Diabetes and Obesity  
Vice President, Clinical Research, Metabolism  
Merck Research Laboratories  
Rahway, NJ, USA

**FOURTH EDITION**

 **WILEY-BLACKWELL**

## COMPANION WEBSITE

Purchasing this book entitles you to access to the companion website:

[textbookofdiabetes.com](http://textbookofdiabetes.com)

### The website includes:

- Interactive Multiple-Choice Questions for each chapter
- Reference lists with external links
- Figures from the book for downloading
- All chapters online

### How to access the site:

- Scratch off the label below to see your unique PIN number
- Go to the website [textbookofdiabetes.com](http://textbookofdiabetes.com) and follow the registration instructions

SCRATCH CODE HERE

Please note that the book cannot be returned once the label is scratched off, and the unique (personal) PIN cannot be shared. The site is for individual use by purchasers only and cannot be networked.

We dedicate this book to all people living with diabetes and the healthcare professionals who look after them. We would also like to dedicate this book to our families without whose support and encouragement the book would never have been finished.

# Contents

List of Contributors, ix

Preface to the Fourth Edition, xiii

Foreword, xv

List of Abbreviations, xvi

## Part 1 Diabetes in its Historical and Social Context

- 1 The History of Diabetes Mellitus, 3  
*Robert B. Tattersall*
- 2 The Classification and Diagnosis of Diabetes, 24  
*K. George M.M. Alberti*
- 3 Epidemiology of Type 1 Diabetes, 31  
*Lars C. Stene, Valma Harjutsalo, Elena Moltchanova  
& Jaakko Tuomilehto*
- 4 Epidemiology of Type 2 Diabetes, 45  
*Ronald C.W. Ma & Peter C.Y. Tong*
- 5 The Global Burden of Diabetes, 69  
*Mohammed K. Ali, Mary Beth Weber & K.M. Venkat  
Narayan*

## Part 2 Normal Physiology

- 6 Islet Function and Insulin Secretion, 87  
*Peter M. Jones & Shanta J. Persaud*
- 7 Insulin Action, 104  
*Xuxia Wu & W. Timothy Garvey*
- 8 Control of Weight: How Do We Get Fat? 126  
*George A. Bray*

## Part 3 Pathogenesis of Diabetes

- 9 Type 1 Diabetes, 141  
Autoimmune Type 1 Diabetes, 141  
*Ahmed J. Delli, Helena Elding Larsson, Sten-A. Ivarsson  
& Åke Lernmark*  
Other Disorders with Type 1 Phenotype, 152  
*Alice P.S. Kong & Juliana C.N. Chan*
- 10 Abnormalities of Insulin Secretion and  $\beta$ -Cell Defects in Type 2 Diabetes, 160  
*Mazen Alsahli & John E. Gerich*
- 11 Insulin Resistance in Type 2 Diabetes, 174  
*Hannele Yki-Järvinen*
- 12 The Genetics of Type 2 Diabetes: From Candidate Gene Biology to Genome-Wide Studies, 191  
*Martine Vaxillaire & Philippe Froguel*
- 13 Metabolic Disturbances in Diabetes, 215  
*Adrian Vella & Robert A. Rizza*
- 14 Obesity and Diabetes, 227  
*Hans Hauner*

## Part 4 Other Types of Diabetes

- 15 Monogenic Causes of Diabetes, 245  
*Angus Jones & Andrew T. Hattersley*
- 16 Drug-Induced Diabetes, 265  
*Neil J.L. Gittoes, John Ayuk & Robin E. Ferner*
- 17 Endocrine Disorders that Cause Diabetes, 279  
*Neil A. Hanley*
- 18 Pancreatic Diseases and Diabetes, 298  
*Ranjit Unnikrishnan & Viswanathan Mohan*

## Part 5 Managing the Patient with Diabetes

- 19 Clinical Presentations of Diabetes, 313  
*Ee Lin Lim & Roy Taylor*
- 20 The Aims of Diabetes Care, 323  
*Richard I.G. Holt & Barry J. Goldstein*
- 21 Educating the Patient with Diabetes, 334  
*Carolé Mensing & Barbara Eichorst*
- 22 Lifestyle Issues: Diet, 346  
*Monika Toeller*
- 23 Lifestyle Issues: Exercise, 358  
*Jane E. Yardley, Angela Alberga, Glen P. Kenny  
& Ronald J. Sigal*
- 24 Social Aspects of Diabetes, 380  
*Brian M. Frier & Mark W.J. Strachan*
- 25 Monitoring Diabetes, 399  
*Andrew J. Farmer*
- 26 Drug Therapy: Special Considerations  
in Diabetes, 410  
*Bernard M.Y. Cheung & Robin E. Ferner*

## Part 6 Treatment of Diabetes

- 27 Insulin and Insulin Treatment, 427  
*Stephen Gough & Parth Narendran*
- 28 New Technologies for Insulin Administration and Glucose  
Monitoring, 440  
*Howard Wolpert & Judy Shih*
- 29 Oral Antidiabetic Agents, 452  
*Clifford J. Bailey & Andrew J. Krentz*
- 30 Non-Insulin Parenteral Therapies, 478  
*Jens Juul Holst, Sten Madsbad & Ole Schmitz*
- 31 How to Use Type 2 Diabetes Treatments in Clinical  
Practice: Combination Therapies, 494  
*Joseph A. Aloï & Anthony L. McCall*
- 32 In-Hospital Treatment and Surgery in Patients with  
Diabetes, 514  
*Maggie Sinclair Hammersley & June James*
- 33 Hypoglycemia in Diabetes, 528  
*Philip E. Cryer*
- 34 Acute Metabolic Complications of Diabetes: Diabetic  
Ketoacidosis and Hyperosmolar Hyperglycemia, 546  
*Troels Krarup Hansen & Niels Møller*

## Part 7 Microvascular Complications in Diabetes

- 35 Pathogenesis of Microvascular Complications, 555  
*Ferdinando Giacco & Michael Brownlee*
- 36 Diabetic Retinopathy, 575  
*Peter H. Scanlon*
- 37 Diabetic Nephropathy, 599  
*Sally M. Marshall & Allan Flyvbjerg*
- 38 Diabetic Peripheral Neuropathy, 615  
*Dan Ziegler*

## Part 8 Macrovascular Complications in Diabetes

- 39 The Pathogenesis of Macrovascular Complications  
Including Atherosclerosis in Diabetes, 637  
*Riccardo Candido, Mark E. Cooper & Karin A.M.  
Jandeleit-Dahm*
- 40 Cardiovascular Risk Factors, 657  
Hypertension, 657  
*Peter M. Nilsson*  
  
Dyslipidemia: Diabetes Lipid Therapies, 672  
*Adie Viljoen & Anthony S. Wierzbicki*
- 41 Congestive Heart Failure, 684  
*Inga S. Thrainsdottir & Lars Rydén*
- 42 Cerebrovascular Disease, 698  
*Colum F. Amory & Jesse Weinberger*
- 43 Peripheral Vascular Disease, 710  
*Henrik H. Sillesen*

## Part 9 Other Complications of Diabetes

- 44 Foot Problems in Patients with Diabetes, 727  
*Andrew J.M. Boulton*
- 45 Sexual Function in Men and Woman with Diabetes, 743  
*David Price*
- 46 Gastrointestinal Manifestations of Diabetes, 760  
*Adil E. Bharucha & Michael Camilleri*
- 47 The Skin in Diabetes, 774  
*Graham R. Sharpe & Paul D. Yesudian*
- 48 Bone and Rheumatic Disorders in Diabetes, 789  
*Andrew Grey & Nicola Dalbeth*

49 Psychologic Factors and Diabetes, 807  
*Christopher M. Ryan*

50 Diabetes and Infections, 835  
*Clive S. Cockram & Nelson Lee*

## Part 10 Diabetes in Special Groups

51 Diabetes in Childhood, 859  
*Christine Chan & Marian Rewers*

52 Diabetes in Adolescence and Transitional Care, 875  
*Debbie Kralik & Maria Kambourakis*

53 Diabetes in Pregnancy, 888  
*Anne Dornhorst & Anita Banerjee*

54 Diabetes in Old Age, 922  
*Alan J. Sinclair*

55 Psychiatric Disorders and Diabetes, 940  
*Robert C. Peveler & Richard I.G. Holt*

## Part 11 Delivery and Organization of Diabetes Care

56 The Role of Community and Specialist Services, 959  
*Jane Overland, Margaret McGill & Dennis K. Yue*

57 The Role of the Multidisciplinary Team, 969  
*Wing-Yee So & Juliana C.N. Chan*

58 Models of Diabetes Care Across Different Resource Settings, 984  
*Naomi S. Levitt, Bob Mash, Nigel Unwin, Jean Claude Mbanya, Jae-Hyoung Cho & Kun-Ho Yoon*

## Part 12 Future Directions

59 Future Drug Treatment for Type 1 Diabetes, 1001  
*Helena Elding Larsson, Ahmed J. Delli, Sten-A. Ivarsson & Åke Lernmark*

60 Future Drug Treatments for Type 2 Diabetes, 1017  
*Clifford J. Bailey*

61 Other Future Directions, 1045  
Stem Cell Therapy in Diabetes, 1045  
*Shuibing Chen, Jayaraj Rajagopal, Qiao Zhou & Douglas A. Melton*

Islet Transplantation, 1050  
*Angela Koh, Peter Senior & A.M. James Shapiro*

Gene Therapy, 1064  
*Andreea R. Barbu & Nils Welsh*

62 Future Models of Diabetes Care, 1070  
*Robert A. Gabbay & Alan M. Adelman*

Index, 1081

# List of Contributors

**Alan M. Adelman MS, MD**

Professor of Family and Community Medicine, Vice Chair for Academic Affairs and Research, Penn State Milton S. Hershey Medical Center, Penn State College of Medicine, Hershey, PA, USA

**Angela Alberga MSc**

Faculty of Health Sciences, University of Ottawa and Ottawa Hospital Research Institute, Ottawa, Ontario, Canada

**K. George M.M. Alberti DPhil, FRCP**

Senior Research Fellow, Imperial College, London; Emeritus Professor of Medicine, University of Newcastle, Newcastle, UK

**Mohammed K. Ali MBChB, MSc**

Assistant Professor, Hubert Department of Global Health, Rollins School of Public Health, Global Diabetes Research Center, Emory University, Atlanta, GA, USA

**Joseph A. Aloï MD**

Associate Professor of Internal Medicine, The Strelitz Diabetes Center for Endocrine and Metabolic Disorders, Eastern Virginia Medical School, Norfolk, VA, USA

**Mazen Alsahli MD**

Professor of Medicine, University of Rochester School of Medicine, Rochester, NY, USA

**Colum F. Amory MD, MPH**

Mount Sinai School of Medicine, New York, NY, USA

**John Ayuk MD**

Centre for Endocrinology, Diabetes and Metabolism, University of Birmingham and Queen Elizabeth Hospital Birmingham, Birmingham, UK

**Clifford J. Bailey PhD, FRCP(Edin),****FRCPath**

Professor in Clinical Science and Head of Diabetes Research, School of Life and Health Sciences, Aston University, Birmingham, UK

**Anita Banerjee BSc, MBBS, MRCP**

Obstetric Physician, Diabetes and Endocrinology, Princess Royal University Hospital, London, England UK

**Andreea R. Barbu PhD**

Department of Medical Cell Biology and Department of Medical Sciences, Uppsala University, Uppsala, Sweden

**Adil E. Bharucha MD**

Professor of Medicine, Division of Gastroenterology and Hepatology, Clinical Enteric Neuroscience Translational and Epidemiological Research Program, Mayo Clinic, Rochester, MN, USA

**Andrew J.M. Boulton MD, DSc (Hon),****FRCP**

Professor of Medicine, University of Manchester and Manchester Royal Infirmary, Manchester, UK; Miller School of Medicine, University of Miami, Miami, FL, USA

**George A. Bray MD, MACP**

Boyd Professor, Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA, USA

**Michael Brownlee MD**

Anita and Jack Saltz Professor of Diabetes Research, Albert Einstein College of Medicine, New York, NY, USA

**Michael Camilleri MD**

Atherton and Winifred W. Bean Professor, Professor of Medicine and Physiology, College of Medicine, Mayo Clinic and Clinical Enteric Neuroscience Translational and Epidemiological Research Program, Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, MN, USA

**Riccardo Candido MD, PhD**

Diabetic Centre, Trieste, Italy

**Christine M. Chan MD**

Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, School of Medicine, Aurora, CO, USA

**Juliana C.N. Chan MBChB MD FRCP**

Professor of Medicine and Therapeutics, Director, Hong Kong Institute of Diabetes and Obesity, The Chinese University of Hong Kong, The Prince of Wales Hospital, Hong Kong SAR, China

**Shuibing Chen PhD**

Postdoctoral Fellow, Department of Stem Cell and Regenerative Biology, Harvard University, Cambridge, MA, USA

**Bernard M.Y. Cheung MD, PhD**

Chair of Clinical Pharmacology and Therapeutics, Department of Clinical Pharmacology, University of Birmingham, Birmingham, UK

**Jae-Hyoung Cho MD**

Assistant Professor, Department of Endocrinology, Seoul St. Mary's Hospital, College of Medicine, The Catholic University of Korea, Seoul, Korea

**Mark E. Cooper MD, PhD**

Director, Danielle Alberti JDRF Centre for Diabetes Complications, Head, Vascular Division – Baker IDI Heart Research Institute, Melbourne, Australia

## List of Contributors

### **Philip E. Cryer MD**

Irene E. and Michael M. Karl Professor of Endocrinology and Metabolism in Medicine, Washington University School of Medicine, St. Louis, MO, USA

### **Nicola Dalbeth MD, FRACP**

Department of Medicine, University of Auckland, Auckland, New Zealand

### **Ahmed J. Delli MD, MPH**

Clinical Research Center (CRC), Lund University, Department of Clinical Sciences/Diabetes and Celiac Disease, University Hospital MAS, Malmö, Sweden

### **Anne Dornhorst BSc, DM, FRCP, FRCPath**

Consultant Physician, Honorary Senior Lecturer, Department of Medicine, Imperial College Healthcare NHS Trust, Hammersmith Hospital, London, UK

### **Barbara Eichorst MS, RD, CDE**

Healthy Interactions Global Conversation Map™ Facilitator, Chicago, IL, USA

### **Andrew J. Farmer DM, FRCGP**

University Lecturer, Department of Primary Health Care, University of Oxford, Oxford, UK

### **Robin E. Ferner MSc, MD, FRCP**

Professor, West Midlands Centre for Adverse Drug Reactions, City Hospital, Birmingham, UK

### **Brian M. Frier BSc(Hons), MD, FRCPE, FRCPG**

Professor, Department of Diabetes, Royal Infirmary of Edinburgh, Edinburgh, UK

### **Philippe Froguel MD, PhD**

Institut de Biologie de Lille, Institut Pasteur de Lille, Lille, France; Section of Genomic Medicine, Imperial College London, London, UK

### **Robert A. Gabbay MD, PhD**

Director, Penn State Institute for Diabetes and Obesity; Professor of Medicine and Molecular Medicine, Penn State College of Medicine; Director, Diabetes Program, Penn State Milton S. Hershey Medical Center, Hershey, PA, USA

### **W. Timothy Garvey MD**

Butterworth Professor and Chair, Department of Nutrition Sciences; Director, UAB Diabetes Research and Training Center, University of Alabama at Birmingham; Birmingham Veterans Affairs Medical Center, Birmingham, AL, USA

### **John E. Gerich MD**

Professor of Medicine, University of Rochester School of Medicine, Rochester, NY, USA

### **Ferdinando Giacco PhD**

Postdoctoral Fellow, Diabetes Research and Training Center, Departments of Medicine and Endocrinology, Albert Einstein College of Medicine, New York, NY, USA

### **Neil J.L. Gittos MD**

Senior Lecturer in Medicine, Centre for Endocrinology, Diabetes and Metabolism, University of Birmingham and Queen Elizabeth Hospital Birmingham, Birmingham, UK

### **Steve Gough**

Professor of Diabetes, Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford; Consultant Physician, Churchill Hospital, Oxford, UK

### **Andrew Grey MD**

Department of Medicine, University of Auckland, Auckland, New Zealand

### **Maggie Sinclair Hammersley MB, FRCP**

Consultant Physician and Senior Lecturer, Nuffield Department of Medicine, University of Oxford, Oxford, UK

### **Neil A. Hanley MBChB, PhD**

Professor of Medicine, Endocrinology and Diabetes Group, University of Manchester, Manchester, UK

### **Troels Krarup Hansen MD, PhD**

Associate Professor, Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark

### **Valma Harjutsalo PhD**

Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki; Diabetes Prevention Unit, National Institute of Health and Welfare, Helsinki, Finland; Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland

### **Andrew T. Hattersley MD**

Diabetes and Vascular Medicine, Peninsula Medical School, Exeter, UK

### **Hans Hauner MD**

Director, Else Kröner-Fresenius-Center for Nutritional Medicine, Klinikum rechts der Isar, Technical University of Munich, Munich, Germany

### **Jens Juul Holst MD, DMSc**

Professor of Medical Physiology, Department of Biomedical Sciences, The Panum Institute, University of Copenhagen, Denmark

### **Sten-A. Ivarsson MD, PhD**

Clinical Research Center (CRC), Lund University and Department of Clinical Sciences/Paediatric Endocrinology, University Hospital MAS, Malmö, Sweden

### **June James MSc, BA (Hons) Dip Nursing, NP RGN**

Consultant Nurse in Diabetes, University Hospitals of Leicester, Leicester, UK

### **Karin A.M. Jandeleit-Dahm MD, PhD, FRACP**

Baker IDI Heart and Diabetes Institute, Co-head, Diabetes Division; Professor of Medicine (Adjunct), Monash University, Melbourne, Australia

### **Peter Jones PhD**

Professor of Endocrine Biology, King's College London, London, UK

### **Angus Jones MBBS, MRCP**

Diabetes and Vascular Medicine, Peninsula Medical School, Exeter, UK

### **Maria Kambourakis BSc(Hons)**

Research Officer/Type 1 Diabetes Program Officer, Type 1 Diabetes Program, Diabetes Australia, Victoria, Australia

### **Glen P. Kenny MD**

Ottawa Hospital Research Institute and Laboratory of Human Bioenergetics and Environmental Physiology, School of Human Kinetics, Faculty of Health Sciences, University of Ottawa, Ottawa, Ontario, Canada

### **Angela Koh MBBS (Singapore), MRCP (UK)**

Assistant Professor, Department of Medicine (Endocrinology), Attending Physician, Clinical Islet Transplant Program, University of Alberta, Edmonton, Canada

### **Alice P.S. Kong MBChB, MRCP (UK), FRCP (Glasg)**

Associate Professor, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong SAR, China

### **Debbie Kralik PhD, RN**

General Manager, Research and Strategy, Royal District Nursing Service, South Australia; Associate Professor, University of South Australia and University of Adelaide, Glenside, Australia

### **Andrew J. Krentz MD, FRCP**

Formerly Southampton University Hospitals NHS Trust, Southampton, UK

**Helena Elding Larsson MD, PhD**

Clinical Research Center (CRC), Lund University; Department of Clinical Sciences/Paediatric Endocrinology, University Hospital MAS, Malmö, Sweden

**Nelson Lee MD, FRCP(Edin)**

Associate Professor, Head, Division of Infectious Diseases, Department of Medicine and Therapeutics, Faculty of Medicine, The Chinese University of Hong Kong, Hong Kong SAR, China

**Åke Lernmark PhD**

Professor of Experimental Diabetes, Lund University/CRC, Department of Clinical Sciences, University Hospital MAS, Malmö, Sweden

**Naomi S. Levitt MBChB, MD, FCP(SA)**

Professor and Head of Division of Diabetic Medicine and Endocrinology, Department of Medicine, University of Cape Town and Groote Schuur Hospital, Cape Town, South Africa

**Ee Lin Lim MRCP**

Diabetes Research Group, Institute of Cellular Medicine, University of Newcastle, Newcastle upon Tyne, UK

**Ronald C.W. Ma MB BChir, MRCP**

Associate Professor, Division of Endocrinology and Diabetes, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Prince Of Wales Hospital, Hong Kong SAR, China

**Sten Madsbad MD, DMSc**

Professor of Diabetology, Department of Endocrinology, Hvidovre Hospital, Hvidovre, Denmark

**Sally M. Marshall MD**

Professor of Diabetes, Diabetes Research Group, Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK

**Bob Mash MBChB, MRCP, PhD**

Professor, Division of Family Medicine and Primary Care, Stellenbosch University, Tygerberg, South Africa

**Jean-Claude Mbanya MD, PhD, FRCP**

Professor of Medicine and Endocrinology, Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon

**Anthony L. McCall MD, PhD**

James M. Moss Professor of Diabetes in Internal Medicine, Diabetes and Hormone Center of Excellence, University of Virginia School of Medicine, Charlottesville, VA, USA

**Margaret McGill RN, MSc(med)**

Diabetes Centre, Royal Prince Alfred Hospital, Camperdown, Sydney, New South Wales, Australia

**Douglas A. Melton**

Thomas Dudley Cabot Professor in the Natural Sciences, Department of Stem Cell and Regenerative Biology; Harvard Stem Cell Institute; Investigator, Howard Hughes Medical Institute, Harvard University, Cambridge, MA, USA

**Carolé R. Mensing RN, MA, CDE**

Joslin Diabetes Center, Boston, MA, USA

**Viswanathan Mohan MD, FRCP(UK),****FRCP(Glasg), PhD, DSc, FNAsc**

Chairman and Chief Diabetologist, Dr. Mohan's Diabetes Specialities Centre, WHO Collaborating Centre for Non Communicable Diseases Prevention and Control, IDF Centre of Education; President and Chief of Diabetes Research, Madras Diabetes Research Foundation, ICMR Advanced Centre for Genomics of Diabetes, Gopalapuram, Chennai, India

**Niels Møller MD, DMSc**

Professor, Department of Endocrinology and Internal Medicine, The Medical Research Laboratories, Aarhus University Hospital, Aarhus, Denmark

**Elena Moltchanova PhD**

Diabetes Unit, Department of Health Promotion and Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland

**K. M. Venkat Narayan MD, MSc, MBA, FRCP**

Ruth and O.C. Hubert Professor of Global Health, Professor of Epidemiology and Medicine, Rollins School of Public Health, Emory University, Atlanta, GA, USA

**Parth Narendran**

Institute of Biomedical Research, The Medical School, University of Birmingham, Birmingham, UK

**Peter M. Nilsson MD**

Professor of Clinical Cardiovascular Research, Department of Clinical Sciences, Lund University, University Hospital, Malmö, Sweden

**Jane Overland MPH, PhD**

Nurse Practitioner, Diabetes Centre, Royal Prince Alfred Hospital, Camperdown, New South Wales, Australia; Clinical Associate Professor, The Faculty of Nursing and Midwifery, The University of Sydney, Sydney, Australia

**Shanta J. Persaud PhD**

Professor of Diabetes and Endocrinology, King's College London, London, UK

**Robert C. Peveler MA, DPhil, BM, BCh, FRCPsych**

Clinical Neurosciences Division, School of Medicine, University of Southampton and Royal South Hants Hospital, Southampton, UK

**David Price MD, FRCP**

Department of Diabetes and Endocrinology, Morriston Hospital, Swansea, UK

**Jayaraj Rajagopal**

Center for Regenerative Medicine, Massachusetts General Hospital; Principal Investigator, Harvard Stem Cell Institute, Boston, MA, USA

**Marian Rewers MD, PhD**

Professor, Pediatrics and Preventive Medicine; Clinical Director, Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, School of Medicine, Aurora, CO, USA

**Robert A. Rizza MD**

Professor of Medicine, Division of Endocrinology, Diabetes, Metabolism and Nutrition, Mayo Clinic, Rochester, MN, USA

**Christopher M. Ryan PhD**

Professor of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania, USA

**Lars Rydén MD, FRCP, FESC, FACC, FAHA**

Professor Emeritus, Cardiology Unit, Department of Medicine, Karolinska Institute, Stockholm, Sweden

**Peter H. Scanlon MD, MRCPophth, DCH, FRCP**

Consultant Ophthalmologist, Gloucestershire and Oxford Eye Units; Lecturer, Harris Manchester College, University of Oxford, Oxford, UK

**Ole Schmitz MD, DMSc**

Professor of Clinical Pharmacology, Department of Clinical Pharmacology, Aarhus University Hospital, Denmark

**Peter A. Senior BMedSci, MBBS, PhD, MRCP(UK)**

Clinical Islet Transplant Program, University of Alberta, Edmonton, Alberta, Canada

**A.M. James Shapiro MD PhD DSc (Hon) FRCS(Eng) FRCS(MSM)**

Professor of Surgery, Director, Clinical Islet Transplant Program, AHFMR Scholar, University of Alberta, Edmonton, Canada

## List of Contributors

**Graham R. Sharpe MBChB, BA, PhD, FRCP**  
Consultant Dermatologist, Department of  
Dermatology, Broadgreen Hospital, Liverpool, UK

**Judy Shih MD, PhD**  
Joslin Diabetes Center, Boston, MA, USA

**Ronald J. Sigal MD, MPH, FRCPC**  
Professor of Medicine, Cardiac Sciences, and  
Community Health Sciences, Faculties of Medicine  
and Kinesiology, The University of Calgary, Canada

**Henrik H. Sillesen MD, DMSc**  
Head, Department of Vascular Surgery,  
Rigshospitalet, University of Copenhagen,  
Copenhagen, Denmark

**Alan J. Sinclair MSc, MD, FRCP**  
Deputy Dean and Professor of Medicine,  
Bedfordshire and Hertfordshire Postgraduate  
Medical School; Geriatric and Diabetes Research  
Centre, University of Bedfordshire, Luton, UK

**Wing-Yee So MBChB, MD, FRCP**  
Associate Consultant, Prince of Wales Hospital,  
Hong Kong SAR, China

**Lars C. Stene PhD**  
Division of Epidemiology, Norwegian Institute of  
Public Health, Oslo, Norway; Oslo Diabetes  
Research Centre, Oslo University Hospital, Oslo,  
Norway

**Mark W. J. Strachan MD, FRCP (Edin)**  
Consultant in Diabetes and Endocrinology,  
Metabolic Unit, Western General Hospital,  
Edinburgh, UK

**Robert B. Tattersall MB, ChB, MD, FRCP**  
Emeritus Professor of Clinical Diabetes, University  
of Nottingham, Nottinghamshire, UK

**Roy Taylor MD, FRCP**  
Professor of Medicine and Metabolism, and  
Director, Newcastle Magnetic Resonance Centre,

Diseases, University Hospital, Düsseldorf, Germany

---

# Preface to the Fourth Edition

The management of diabetes is a major health challenge, and its prevalence is increasing at an alarming rate, especially in the developing world. According to the International Diabetes Federation, diabetes currently affects more than 285 million people worldwide, a figure that is expected to rise to 435 million by 2030. During the writing of this book over the last 18 months, approximately 15 million people will have developed diabetes. Although treatments continue to improve, many people die as a result of their diabetes. Between 6–16% of all deaths are attributable to diabetes and around 900 will have died in the 2 hours taken to write this preface. Diabetes accounts for about 6% of total global mortality, on a par with that seen in HIV/AIDS. Many of these deaths will result from cardiovascular disease which occurs at least twice as often in diabetes as in people without diabetes. Diabetes continues to cause suffering through its complications. It is the commonest cause of kidney failure in developed countries where it is also the leading cause of blindness in adults of working age. Diabetes is also a major cause of non-traumatic lower limb amputation. As well as the personal cost, diabetes places a huge burden on health economies. In 2010, it is estimated that worldwide, at least US\$ 376 billion will be used to treat and prevent diabetes and its complications. Never have the challenges in providing diabetes healthcare been larger.

During the eight years since the publication of the previous edition of this textbook, there have been great strides in the management and understanding of diabetes. International collaborations using large and varied cohorts with increasingly sophisticated technologies have allowed a greater appreciation of the genetic factors that predispose to diabetes. Our molecular understanding of insulin resistance and the regulation of insulin secretion has increased as has our appreciation of the mechanisms underlying complications.

The diagnostic criteria look set to be changed again and may incorporate hemoglobin A1c ( $\text{HbA}_{1c}$ ) while the units of the latter have also recently changed to reflect the development of more reliable and traceable assays. As  $\text{HbA}_{1c}$  remains the currency of everyday diabetes practice, these changes will provide major educational challenges for patients and professionals alike.

Alongside the developments in the pathophysiology of diabetes have come major advances in the treatment of diabetes. Some of these therapeutic innovations have been withdrawn, such as inhaled insulin, but many have been adopted in clinical practice. The development of new oral agents to treat type 2 diabetes has diversified choices for clinicians and people with diabetes. Drugs affecting glucagon-like peptide 1 (GLP-1) and the incretin axis that were mentioned briefly as future treatments in the last edition are now firmly established as effective treatments of type 2 diabetes. Many studies have highlighted the advantages and disadvantages of the newer agents making the choice of treatment more complicated than ever. Beyond the gluco-centric view of diabetes, major cardiovascular trials continue to show the benefits of statin therapy in people with diabetes.

The publication of this new edition is timely given the rapid advances in knowledge. This edition has a new editorial team drawn from the UK, Europe, USA and Asia to reflect the global nature of the diabetes epidemic. The new team has experienced a big learning curve and we are profoundly grateful that we could stand on the shoulders of John Pickup and Gareth Williams, the editors of the previous three editions. The new book has retained many of the excellent author team brought together by John and Gareth and the structure is similar to the previous editions. Nevertheless like any new teams we have tried to improve the book while keeping the sound ideas from the previous book. The book has been shortened into one volume to make it easier to use. We have emphasized the clinical aspects of diabetes to a greater extent than previous editions and reflecting the diverse locations of the editors, the chapter authors are also dispersed throughout the globe making this a truly international textbook which crosses continents and highlights both developed and developing health systems.

As editors we are only too aware of the work that many people have contributed to the book, without which our endeavors would have been much harder, if not impossible. The chapter authors are at the top of our list for our gratitude. Their willingness to devote their time and effort into compiling scholarly and

relevant chapters, while tolerating nagging e-mails from us, has been humbling. In an age where book writing often comes fourth behind grant and paper writing and clinical work, we are grateful for the way that the authors met the deadlines set by us. We are also grateful for the immense help we have received from our publisher, Wiley-Blackwell. Our Commissioning Editor Oliver Walter, who took over from Alison Brown shortly into the book's development, has provided encouragement, support and guidance as has Jennifer Seward, the Development Editor. Often just at the time when things appeared to be insurmountable, Oliver or Jennifer took steps to get the project moving again.

Our thanks also go to Rob Blundell (Production Editor) and Helen Harvey (Project Manager) in the production team.

We hope you enjoy reading the book and find it useful whether this is helping people with diabetes or teaching physicians and other health professionals how best to manage this disease and its complications.

# Foreword

The face of diabetes is forever changing. Scientific knowledge increases exponentially and our understanding slowly improves although there are still massive gaps in many fundamental aspects of the diabetes story, such as the mechanisms underlying the development of type 2 diabetes. Trying to keep up with all the advances is an ever increasing burden, but with a large array of means to achieve this. Many people use the web, both specific websites and more general search engines, but there are still a large number of people who prefer the printed word and the collection together of an accessible compendium where you can expect to obtain answers to your questions. This volume provides exactly that; namely a series of up-to-date, well referenced, learned articles covering the manifold manifestations of diabetes together with the basic underlying science. It is truly comprehensive and I would challenge any reader to find missing aspects of the pathophysiology, treatment and care of people with diabetes.

The book begins with a fascinating historical essay which should be read by anybody who picks up the book. It reminds us that much valuable information is forgotten and many lessons can be learned by going back to pre-internet days! The possibility of using HbA<sub>1c</sub> for the diagnosis of diabetes is discussed reflecting a potentially seismic shift in our diagnostic armamentarium that has relied on the measurement of glucose since that became avail-

able routinely a century ago. The world pandemic of diabetes is described with few populations spared and then each type of diabetes is described together with what is known of their pathophysiology. Particularly valuable are the essays on non-classical type 1 and type 2 diabetes.

The management and treatment of diabetes from education through lifestyle modification and the use of oral agents and insulin is dealt with exhaustively with useful chapters on the oft ignored psychological and social aspects of the disorder. Different models of care are also well discussed. Complications are dealt with comprehensively and again the book is of particular value in going beyond the classical complications and dealing with a range of less well defined problems found in people with diabetes. The book finishes with crystal ball gazing: a look at future drugs for both type 1 and type 2 diabetes, as well as the potential for stem cell therapy, islet cell transplantation and gene therapy, all of which are thought provoking and informative.

Overall I feel that this volume fulfils a major need for anyone with an interest in diabetes; it should be available in every setting where people with diabetes receive their care and will serve as an excellent *vade mecum*.

K. George M.M. Alberti  
*Imperial College London*

# List of Abbreviations

AA	arachidonic acid	BUN	blood urea nitrogen
AAA	abdominal aortic aneurysm	CABG	coronary artery bypass grafting
AACE	American Association of Clinical Endocrinologists	CAD	coronary artery disease
AADE	American Association of Diabetes Educators	CaMK	calcium/calmodulin-dependent kinase
ABI	ankle brachial index	cAMP	cyclic adenosine monophosphate
ACA	acetyl co-enzyme A	CA-MRSA	community-associated methicillin-resistant <i>Staphylococcus aureus</i>
ACC	acetyl-CoA carboxylase	CAP	Cbl associated protein
ACCORD	Action to Control Cardiovascular Risk in Diabetes	CAPD	continuous ambulatory peritoneal dialysis
ACE	American College of Endocrinology	CART	cocaine and amphetamine-related transcript
ACE	angiotensin-converting enzyme	CBF	cerebral blood flow
ACEi	angiotensin-converting enzyme inhibitor	CBT	cognitive-behavioral therapy
ACR	albumin:creatinine ratio	CCA	calcium-channel antagonist
ACS	acute coronary syndromes	CCK	cholecystokinin
ACTH	adrenocorticotrophic hormone	CCM	Chronic Care Model
ADA	American Diabetes Association	CD	celiac disease
ADASP	autoimmune diabetes in adults with slowly progressive $\beta$ -cell failure	CDC	Centers for Disease Control and Prevention
ADI	acceptable daily intake	CDFC	comprehensive diabetic foot examination
AGE	advanced glycation end-product	CDK	cyclin-dependent kinase
AGRP	agouti-related peptide	CEL	carboxyl ester lipase
ALT	alanine aminotransferase	CETP	cholesterol ester transfer protein
AMI	acute myocardial infarction	CFTR	cystic fibrosis transmembrane conductance regulator
AMPK	adenosine 5'-monophosphate-activated protein kinase	CGM	continuous glucose monitoring
APC	antigen-presenting cell	cGMP	cyclic guanosine monophosphate
ARB	angiotensin receptor blocker	CGMS	continuous glucose monitoring systems
AST	aspartate aminotransferase	CGRP	calcitonin gene-related peptide
AT	angiotensin	CHD	coronary heart disease
ATG	antithymocyte globulin	CHF	congestive heart failure
BB	bio-breeding	CHO	Chinese hamster ovary
BCG	bacille Calmette-Guérin	CI	confidence interval
BIPSS	bilateral inferior petrosal sinus sampling	cIMT	carotid intima-media thickness
BMD	bone mineral density	CKD	chronic kidney disease
BMI	body mass index	CML	carboxymethyl lysine
BNP	B-type natriuretic peptide	CN	Charcot neuroarthropathy
BP	blood pressure	CNV	copy number variant
		CoA	coenzyme A
		COX	cyclo-oxygenase

cPLA <sub>2</sub>	cytosolic PLA <sub>2</sub>	eNOS	endothelial nitric oxide synthase
CPT	carnitine palmitoyltransferase	EPA	eicosapentaenoic acid
CRH	corticotropin releasing hormone	EPAC	exchange protein activated by cyclic AMP
CRP	C-reactive protein	EPC	endothelial progenitor cell
CRS	congenital rubella syndrome	ER	endoplasmic reticulum
CSII	continuous subcutaneous insulin infusion	ERCP	endoscopic retrograde cholangiopancreatography
CsA	cyclosporine A	ERK	extracellular signal-regulated kinase
CT	computed tomography	ERM	ezrin-radixin-moesin
CTGF	connective tissue growth factor	ESCS	electrical spinal cord stimulation
CVD	cardiovascular disease	ESRD	end-stage renal disease
DAG	diacylglycerol	ESRF	end-stage renal failure
DASP	Diabetes Antibody Standardization Program	ET	endothelin
DAWN	Diabetes Attitudes, Wishes, and Needs study	ETDRS	Early Treatment Diabetic Retinopathy Study
DCCT	Diabetes Control and Complications Trial	EVAR	endovascular aneurysm repair
DD	disc diameter	FADH <sub>2</sub>	flavine adenine dinucleotide
DEND	developmental delay, epilepsy and neonatal diabetes	FAS	fatty acid synthase
DEXA	dual-energy X-ray absorptiometry	FCPD	fibrocalculous pancreatic diabetes
DHA	docosahexanoic acid	FDA	Food and Drug Administration
DHEA	dehydroepiandrosterone	FDG	[ <sup>18</sup> F]-2-deoxy-2-fluoro-D-glucose
DIDMOAD	diabetes insipidus, diabetes mellitus, optic atrophy and deafness	FDGF	fibroblast-derived growth factor
DIGAMI	Diabetes mellitus, Insulin Glucose infusion in Acute Myocardial Infarction	FDR	first-degree relative
DISH	diffuse idiopathic skeletal hyperostosis	FFA	free fatty acid
DKA	diabetic ketoacidosis	FHWA	Federal Highways Administration
DM	diabetic maculopathy	FPD	fibrous proliferation at the disc
DNSG EASD	Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes	FPE	fibrous proliferation elsewhere
DPN	distal symmetrical sensory or sensorimotor polyneuropathy	FPG	fasting plasma glucose
DPP	Diabetes Prevention Program	FPIR	first-phase insulin release
DPP-4	dipeptidyl peptidase 4	FSGS	focal segmental glomerular sclerosis
DQOL	Diabetes Quality of Life	FSH	follicle stimulating hormone
DR	diabetic retinopathy	GABA	γ-aminobutyric acid
DRS	Diabetic Retinopathy Study	GAD	glutamine acid decarboxylase
DSA	digital subtraction angiography	GAG	glycosaminoglycan
DSME	diabetes self-management education	GAPDH	glyceraldehyde-3 phosphate dehydrogenase
DVLA	Driver and Vehicle Licensing Agency	GAS	group A streptococcus
DVT	deep venous thrombosis	GDM	gestational diabetes mellitus
DZ	dizygotic	GFA	glutamine:fructose-6-amidotransferase
eAG	estimated average glucose measurement	GFR	glomerular filtration rate
EASD	European Association for the Study of Diabetes	GH	growth hormone
ECG	electrocardiography/electrocardiogram	GHb	glycated hemoglobin
ED	erectile dysfunction	GHBP	growth hormone-binding protein
EDHF	endothelium-derived hyperpolarizing factor	GHD	growth hormone deficiency
EDIC	Epidemiology of Diabetes Interventions and Complications	GHRH	growth hormone-releasing hormone
EDNOS	eating disorder not otherwise specified	GI	glycemic index
EEG	electroencephalography/electroencephalogram	GIP	glucose-dependent insulinotropic peptide
eGFR	estimated glomerular filtration rate	GK	glucokinase
ELISA	enzyme-linked immunosorbent assay	GLP	glucagon-like peptide
ELISPOT	enzyme-linked immunospot assay	GLUT	glucose transporter
EMEA	European Medicines Agency	GMP	good manufacturing practice
		GNSO	S-nitrosoglutathione
		GP	general practitioner
		GRP	gastrin-releasing polypeptide
		G <sub>s</sub>	stimulatory G-protein
		GSH	glutathione

List of Abbreviations

GSK	glycogen synthesis kinase	IKK $\beta$	inhibitor $\kappa$ -B kinase- $\beta$
GSSG	glutathione disulfide	IL	interleukin
GWA	genome-wide association	INR	International Normalized Ratio
GWL	genome-wide familial linkage	IOB	insulin-on-board
HAAF	hypoglycemia-associated autonomic failure	IP <sub>3</sub>	inositol 1,4,5-trisphosphate
HAART	highly active antiretroviral therapy	IPAN	intrinsic primary afferent neuron
HBO	hyperbaric oxygen	IPF	insulin promoter factor
HBV	hepatitis B virus	iPS	induced pluripotent cell
HCV	hepatitis C virus	IR	insulin resistance
HDL	high density lipoprotein	IRE	inositol-requiring kinase
HETES	hydroxyeicosatetrenoic acids	IRE	insulin response element
HFCS	high-fructose corn syrup	IRMA	intraretinal microvascular abnormality
HGF	hepatocyte growth factor	IRS	insulin receptor substrate
hGH	human recombinant growth hormone	ISH	International Society of Hypertension
HH	hyperosmolar non-ketotic hyperglycemia	IUD	intrauterine contraceptive device
HIC	high income country	IVGTT	intravenous glucose tolerance test
HIF	hypoxia-inducible factor	JaK	Janus kinase
HLA	human leukocyte antigen	JDRF	Juvenile Diabetes Research Foundation
HMa	small hemorrhage or microaneurysm	JNK	c-Jun N-terminal kinase
HMG	high mobility group	Km	Michaelis constant
HNF	hepatic nuclear factor	KO	knockout
HOMA	homeostasis model assessment	LADA	latent autoimmune diabetes of adults
HONK	hyperosmolar non-ketotic coma	LADC	latent autoimmune diabetes in children
HPA	hypothalamic-pituitary-adrenal	LADY	latent autoimmune diabetes in the young
HPETES	hydroperoxyeicosatetrenoic acids	LAR	leukocyte antigen-related phosphatase
HR	hazard ratio	LD	linkage disequilibrium
hrIFN	human recombinant interferon	LDL	low density lipoprotein
HRT	hormone replacement therapy	LEAD	Liraglutide Effect and Action in Diabetes
HSL	hormone sensitive lipase	LGV	large goods vehicle
HSS	hyperosmolar hyperglycemic syndrome	LH	lactic hydrogenase
IA-2	insulinoma-associated antigen 2	LI	lability index
IAA	insulin autoantibody	LMIC	low and middle income countries
IAPP	islet amyloid polypeptide	LOX	lipoxigenase
IBGMS	Internet-based glucose monitoring system	LPL	lipoprotein lipase
IBMIR	immediate blood mediated inflammatory reaction	LVH	left ventricular hypertrophy
ICA	islet cell antibody	MACE	major adverse cardiovascular event
ICAM	intercellular adhesion molecule	MAPK	mitogen activated protein kinase
ICC	interstitial cells of Cajal	MBL	mannose-binding lectin
ICCC	Innovative Care for Chronic Conditions	MCH	melanin-concentrating hormone
ICSA	islet surface antibody	MCP	metacarpophalangeal
IDDM	insulin-dependent diabetes mellitus	MCP	monocyte chemotactic protein
IDF	International Diabetes Federation	MDI	multiple daily injection
IDMPS	International Diabetes Management Practice Study	MELAS	mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes
IENF	intra-epidermal nerve fiber	MEN	multiple endocrine neoplasia
IFCC	International Federation of Clinical Chemistry	MHC	major histocompatibility complex
IFG	impaired fasting glucose	MI	myocardial infarction
Ig	immunoglobulin	MIBI	methoxybutylisonitrile
IGF	insulin-like growth factor	MIDD	maternal inherited diabetes and deafness
IGFBP	insulin-like growth factor binding protein	MMP	matrix metalloproteinase
IGF1R	insulin-like growth factor 1 receptor	MnSOD	manganese superoxide dismutase
IGT	impaired glucose tolerance	MODY	maturity-onset diabetes of the young
IHD	ischemic heart disease	MR	modified release
		MRA	magnetic resonance angiography

MRDM	malnutrition-related diabetes mellitus	OPG	osteoprotegerin
MRI	magnetic resonance imaging	OR	odds ratio
MRSA	methacillin-resistant <i>Staphylococcus aureus</i>	ORP	oxygen-regulated protein
MSH	melanocyte stimulating hormone	PACAP	pituitary adenylate cyclase-activating polypeptide
MSU	monosodium urate	PAD	peripheral arterial disease
mTOR	mammalian target of rapamycin	PAI	plasminogen activator inhibitor
MTP	microsomal triglyceride transfer protein	PARP	poly(ADP-ribose) polymerase
MUFA	monounsaturated fatty acid	PCOS	polycystic ovary syndrome
MZ	monozygotic	PCV	passenger-carrying vehicle
NAA	N-acetyl aspartate	PDE	phosphodiesterase
NAC	N-acetylcysteine	PDGF	platelet-derived growth factor
NADPH	nicotinic acid adenine dinucleotide phosphate	PDK	3-phosphoinositide-dependent protein kinase
NAFLD	non-alcoholic fatty liver disease	PDR	proliferative diabetic retinopathy
NAION	non-arteritic anterior ischemic optic neuropathy	PDX	pancreatic duodenal homeobox
NASH	non-alcoholic steatohepatitis	PEG	percutaneous endoscopic gastrostomy
NCD	non-communicable disease	PEPCK	phosphoenolpyruvate carboxykinase
NDDG	National Diabetes Data Group	PET	positron emission tomography
NEFA	non-esterified fatty acid	PFC	perfluorodecalin
NFG	normal fasting glucose	PFC	prefrontal cortex
NFκB	nuclear factor κB	PGE	prostaglandin
NGF	nerve growth factor	PH	pleckstrin homology
NGT	nasogastric tube	PHHI	persistent hyperinsulinemic hypoglycemia of infancy
NGT	normal glucose tolerance	PI	protease inhibitor
NHANES	National Health and Nutrition Examination Survey	PI <sub>3</sub>	phosphoinositide 3'
NICE	National Institute for Health and Clinical Excellence	PID	pelvic inflammatory disease
NIDDM	non-insulin-dependent diabetes mellitus	PIP	proximal interphalangeal
NIH	National Institutes of Health	PIP <sub>2</sub>	phosphoinositol 4,5-bisphosphate
NIMGU	non-insulin-mediated glucose uptake	PIP <sub>3</sub>	phosphatidylinositol 3,4,5-trisphosphate
NINDS	National Institute of Neurologic Disorders	PK	protein kinase
NK	natural killer	PLC	phospholipase C
NLD	necrobiosis lipoidica diabetorum	PLP	periodate-lysine-paraformaldehyde
NNH	number needed to harm	PNDM	permanent neonatal diabetes mellitus
NNRTI	non-nucleoside reverse-transcriptase inhibitor	PNMT	phenylethanolamine-N-methyltransferase
NNT	number needed to treat	POMC	pro-opiomelanocortin
NO	nitric oxide	POP	progesterone-only pill
NOD	non-obese diabetic	PP	pancreatic polypeptide
NOS	nitric oxide synthase	PPAR	peroxisome proliferator-activated receptor
NPDR	non-proliferative diabetic retinopathy	PPG	post-prandial plasma glucose
NPH	neutral protamine Hagedorn	PPRE	peroxisome proliferator response element
NPWT	negative pressure wound therapy	PRA	panel reactive antibody
NPY	neuropeptide Y	PRH	preretinal hemorrhage
NRTI	nucleoside reverse-transcriptase inhibitor	PTA	percutaneous transluminal angioplasty
NSAID	non-steroidal anti-inflammatory drug	PTB	phosphotyrosine binding
NTD	neural tube defect	PTDM	post-transplantation diabetes mellitus
NVD	new vessels on and/or within 1 disc diameter of the disc	PTEN	phosphatase and tensin homolog
NVE	new vessels elsewhere	PTSD	post-traumatic stress disorder
NYHA	New York Heart Association	PTH	parathyroid hormone
OCP	oral contraceptive pill	PTP	protein tyrosine phosphatase
OCT	optical coherence topography	PVD	peripheral vascular disease
OGT	O-linked N-acetylglucosamine transferase	PVN	paraventricular nucleus
OGTT	oral glucose tolerance test(ing)	QALY	quality-adjusted life year
		QST	quantitative sensory testing

## List of Abbreviations

RAGE	receptor for advanced glycation end-product	T1DM	type 1 diabetes mellitus
RAI	rapid acting analog	T2DM	type 2 diabetes mellitus
RANKL	receptor activator of nuclear factor $\kappa$ B ligand	TCA	tricarboxylic acid
RAS	renin angiotensin system	TCA	tricyclic antidepressant
RBP	retinol-binding protein	TCC	total contact cast
RCAD	renal cysts and diabetes syndrome	TCC	transition case coordinator
RCW	removable cast walker	TCF	transcription factor
rhIGF	recombinant human insulin-like growth factor	TCR	T-cell receptor
RMR	resting metabolic rate	TDI	tissue Doppler imaging
ROC	receiver operator characteristic	TENS	transcutaneous electrical nerve stimulation
ROS	reactive oxygen species	TG	triglyceride
RRT	renal replacement therapy	TGF	transforming growth factor
RT-CGM	real-time continuous glucose monitoring	TIA	transient ischemic attack
SADS	seasonal affective depressive syndrome	TKA	tyrosine kinase activity
SARS	severe acute respiratory syndrome	TLR	toll-like receptor
SCID	severe combined immunodeficiency	TNDM	transient neonatal diabetes mellitus
SD	standard deviation	TNF	tumor necrosis factor
SDF	stromal cell-derived factor	t-PA	tissue plasminogen activator
SDH	sorbitol dehydrogenase	TRAIL	tumor necrosis factor related apoptosis inducing ligand
SGLT	sodium-glucose co-transporter		
SH2	Src homology 2	TSC	tuberous sclerosis complex
SHBG	sex hormone-binding globulin	TSH	thyroid stimulating hormone
SHIP	SH2-containing inositol phosphatase	TZD	thiazolidinedione
SHORT	short stature, hyperextensibility of joints, ocular depression, Reiger anomaly, teething delay (syndrome)	UAE	urinary albumin excretion
		UCP	uncoupling protein
SHP2	SH2-domain-containing tyrosine phosphatase 2	UDP	uridine diphosphate
SMBG	self-monitoring of blood glucose	UKPDS	UK Prospective Diabetes Study
SMI	serious mental illness	USDA	US Department of Agriculture
SMR	standardized mortality ratio	UT	urotensin
SNARE	soluble N-ethylmaleimide-sensitive factor attachment protein receptor	UTI	urinary tract infection
		UW	University of Wisconsin solution
SNP	single nucleotide polymorphism	VADT	Veterans Affairs Diabetes Trial
SNRI	serotonin noradrenaline reuptake inhibitor	VB	venous beading
SOCS	suppressor of cytokine signaling	VCAM	vascular cell adhesion molecule
SoHo	sorbin homology	VEGF	vascular endothelial growth factor
SPECT	single photon emission computed tomography	VH	vitreous hemorrhage
sRAGE	soluble receptor for advanced glycation end-product	VIP	vasoactive intestinal polypeptide
		VLCD	very low calorie diet
SREBP	sterol regulatory element-binding protein	VLDL	very low density lipoprotein
SSRI	selective serotonin reuptake inhibitor	VNTR	variable number tandem repeat
SST	somatostatin	$\dot{V}O_{2max}$	maximal oxygen consumption
SSTR	somatostatin receptor	VPT	vibration perception threshold
STAT	signal transducer and activator of transcription	VSMC	vascular smooth muscle cell
SUR	sulfonylurea receptor	WHI	Women's Health Initiative
$t_{1/2}$	half-life	WHO	World Health Organization

# 1 Diabetes in its Historical and Social Context

# 1

## The History of Diabetes Mellitus

**Robert B. Tattersall**

University of Nottingham, Nottingham, UK

### Keypoints

- Polyuric diseases have been described for over 3500 years. The name “diabetes” comes from the Greek word for a syphon; the sweet taste of diabetic urine was recognized at the beginning of the first millennium, but the adjective “mellitus” (honeyed) was only added by Rollo in the late 18th century.
- The sugar in diabetic urine was identified as glucose by Chevreul in 1815. In the 1840s, Bernard showed that glucose was normally present in blood, and showed that it was stored in the liver (as glycogen) for secretion into the bloodstream during fasting.
- In 1889, Minkowski and von Mering reported that pancreatectomy caused severe diabetes in the dog. In 1893, Laguesse suggested that the pancreatic “islets” described by Langerhans in 1869 produced an internal secretion that regulated glucose metabolism.
- Insulin was discovered in 1921 by Banting, Best, Macleod and Collip in acid-ethanol extracts of pancreas. It was first used for treatment in January 1922.
- Diabetes was subdivided on clinical grounds into *diabète maigre* (lean subjects) and *diabète gras* (obese) by Lancereaux in 1880, and during the 1930s by Falta and Himsworth into insulin-sensitive and insulin-insensitive types. These classifications were the forerunners of the etiological classification into type 1 (insulin-dependent) and type 2 (non-insulin-dependent) diabetes.
- Insulin resistance and  $\beta$ -cell failure, the fundamental defects of type 2 diabetes, have been investigated by many researchers. The “insulin clamp” method devised by Andres and DeFronzo was the first accurate technique for measuring insulin action. Maturity-onset diabetes of the young was described as a distinct variant of type 2 diabetes by Tattersall in 1974.
- Lymphocytic infiltration of the islets (insulinitis) was described as early as 1901 and highlighted in 1965 by Gepts who suggested that it might be a marker of autoimmunity. Islet cell antibodies were discovered by Doniach and Bottazzo in 1979.
- The primary sequence of insulin was reported in 1955 by Sanger and the three-dimensional structure by Hodgkin in 1969. Proinsulin was discovered by Steiner in 1967, and the sequence of the human insulin gene by Bell in 1980. Yalow and Berson invented the radioimmunoassay for insulin in 1956. The presence of insulin receptors was deduced in 1971 by Freychet, and the receptor protein was isolated in 1972 by Cuatrecasas.
- The various types of diabetic retinopathy were described in the second half of the 19th century as were the symptoms of neuropathy. Albuminuria was noted as a common abnormality in patients with diabetes in the 19th century and a unique type of kidney disease was described in 1936 by Kimmelstiel and Wilson. The concept of a specific diabetic angiopathy was developed by Lundbaek in the early 1950s.
- Milestones in insulin pharmacology have included the invention of delayed-action preparations in the 1930s and 1940s; synthetic human insulin in 1979; and in the 1990s novel insulin analogs by recombinant DNA technology.
- The first sulfonylurea carbutamide was introduced in 1955, followed by tolbutamide in 1957 and chlorpropamide in 1960. The biguanide phenformin became available in 1959 and metformin in 1960.
- That improved glucose control in both type 1 and type 2 diabetes was beneficial was proved by the Diabetes Control and Complications Trial (1993) and the UK Prospective Diabetes Study (1998).
- Landmarks in the treatment of complications include photocoagulation for retinopathy first described by Meyer-Schwickerath; the importance of blood pressure to slow the progression of nephropathy (demonstrated by Mogensen and Parving); the introduction of low-dose insulin in the treatment of diabetic ketoacidosis in the 1970s; and improvements in the care of pregnant women with diabetes pioneered by White and Pedersen.

### Ancient times

Diseases with the cardinal features of diabetes mellitus were recognized in antiquity (Table 1.1). A polyuric state was described

in an Egyptian papyrus dating from *c.* 1550 BC, discovered by Georg Ebers (Figure 1.1), and a clearly recognizable description of what would now be called type 1 diabetes was given by Aretaeus of Cappadocia in the 2nd century AD (Figure 1.2a). Aretaeus was the first to use the term “diabetes,” from the Greek word for a syphon, “because the fluid does not remain in the body, but uses the man’s body as a channel whereby to leave it.” His graphic account of the disease highlighted the incessant flow of urine,

(a)

Diabetes is a dreadful affliction, not very frequent among men, being a melting down of the flesh and limbs into urine. The patients never stop making water and the flow is incessant, like the opening of aqueducts. Life is short, unpleasant and painful, thirst unquenchable, drinking excessive, and disproportionate to the large quantity of urine, for yet more urine is passed. One cannot stop them either from drinking or making water. If for a while they abstain from drinking, their mouths become parched and their bodies dry; the viscera seem scorched up, the patients are affected by nausea, restlessness and a burning thirst, and within a short time, they expire.

(b)

**Figure 1.2** (a) Clinical description of diabetes by Aretaeus of Cappadocia (2nd century AD). Adapted from Papanstoyanos NS (1952) *The History of Diabetes Mellitus*. (b) Sushrut (Susrata), an Indian physician who wrote medical texts with Charak (Charuka) between 500 BC and 400 BC.

unquenchable thirst, the “melting down of the flesh and limbs into urine” and short survival.

The Hindu physicians, Charak and Sushrut, who wrote between 400 and 500 BC, were probably the first to recognize the sweetness of diabetic urine (Figure 1.2b). Indeed, the diagnosis was made by tasting the urine or noting that ants congregated round it. Charak and Sushrut noted that the disease was most prevalent in those who were indolent, overweight and gluttonous, and who indulged in sweet and fatty foods. Physical exercise and liberal quantities of vegetables were the mainstays of treatment in the obese, while lean people, in whom the disease was regarded as more serious, were given a nourishing diet. The crucial fact that diabetic urine tasted sweet was also emphasized by Arabic medical texts from the 9–11th centuries AD, notably in the medical encyclopedia written by Avicenna (980–1037).

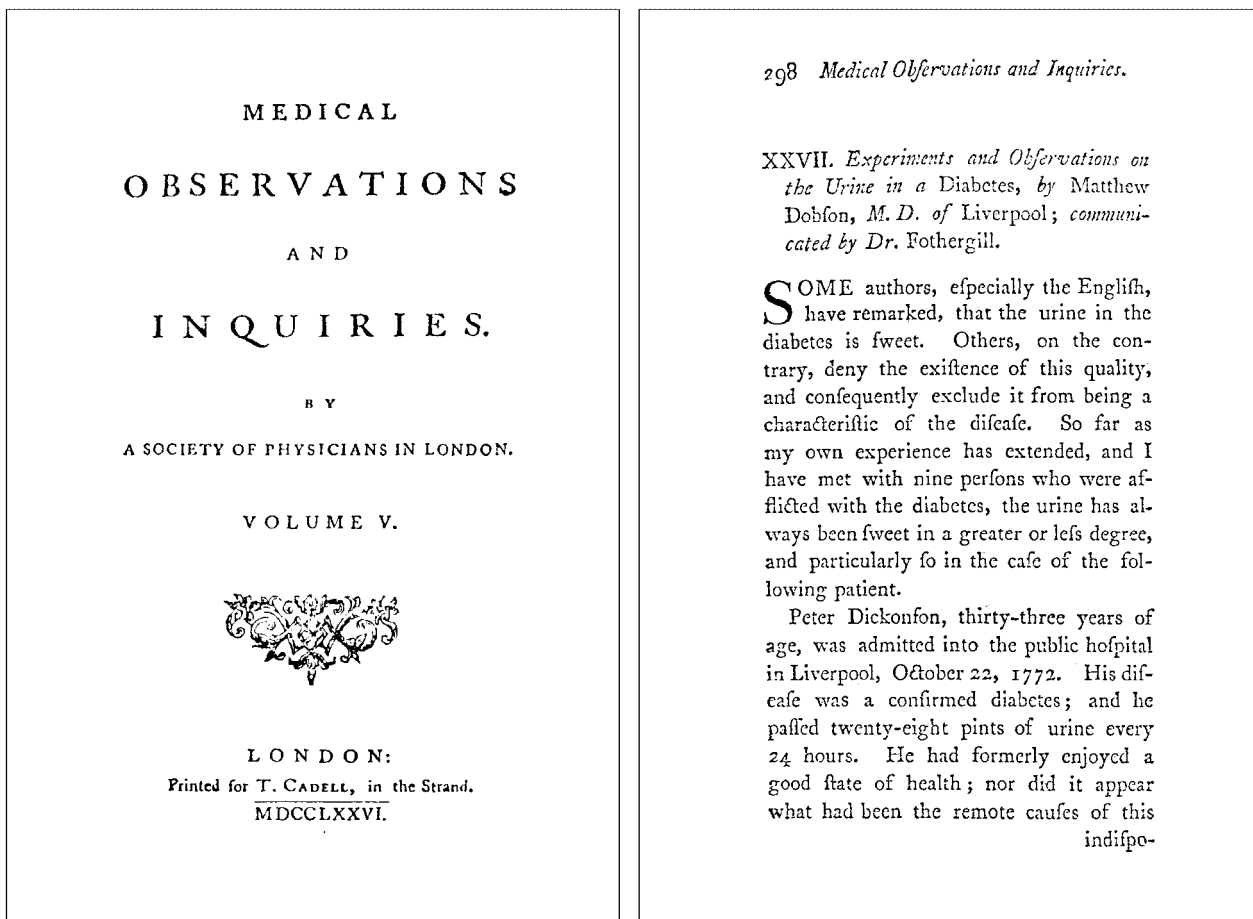

### The 17th and 18th centuries

In Europe, diabetes was neglected until Thomas Willis (1621–1675) wrote *Diabetes, or the Pissing Evil* [1]. According to him,

“diabetes was a disease so rare among the ancients that many famous physicians made no mention of it ... but in our age, given to good fellowship and guzzling down of unallayed wine, we meet with examples and instances enough, I may say daily, of this disease.” He described the urine as being “wonderfully sweet like sugar or honey” but did not consider that this might be because it contained sugar.

The first description of hyperglycemia was in a paper published in 1776 by Matthew Dobson (1735–1784) of Liverpool (Figure 1.3) [2]. He found that the serum as well as the urine of his patient Peter Dickonson (who passed 28 pints of urine a day) tasted sweet. Moreover, he evaporated the urine to “a white cake [which] smelled sweet like brown sugar, neither could it by the taste be distinguished from sugar.” Dobson concluded that the kidneys excreted sugar and that it was not “formed in the secretory organ but previously existed in the serum of the blood.”

The Edinburgh-trained surgeon, John Rollo (*d.* 1809) was the first to apply the adjective “mellitus” (from the Latin word meaning “honey”). He also achieved fame with his “animal diet,” which became the standard treatment for most of the 19th century. Rollo thought that sugar was formed in the stomach

**Figure 1.3** Frontispiece and opening page of the paper by Matthew Dobson (1776), in which he described the sweet taste of both urine and serum from a patient with diabetes [2].

42

5<sup>th</sup>.

\* My urine as yesterday. Eat animal food only; took an emetic of ipecacuan in the evening, which made me very sick, and I brought up all I had eaten in the course of the day; and in the last puke the matter was very four.

6<sup>th</sup>.

\* Urine since last night not exceeding a pint and a quarter, high coloured, very urinous in smell, and depositing a reddish sand. Continued my bitter, alkali in milk, and the hepatifed ammonia.

*Remarks.*

The patient was strongly remonstrated with, and told the consequence of repeated deviations, in probably fixing the disposition to the disease so firmly as not only to increase the difficulty, but to establish the impracticability of removing it. Fair promises were therefore renewed, and absolute confinement to the house, entire animal food, and the hepatifed ammonia as before, with the quassia infusion, were prescribed and agreed upon. The urine continued pale, though salt, and of an urinous smell; but on Sunday the 4th December, the urine had a doubtful smell, and some of it being evaporated, yielded a residuum evidently saccharine, though much less so than in the first experiment, the urinous salts being now more predominant.

**Figure 1.4** Extract from John Rollo’s account of two cases of diabetes (1797). Rollo was well aware of the problem of non-compliance. Note that “the patient was strongly remonstrated with, and told of the consequences of repeated deviations.” Courtesy of the Wellcome Library, London.

from vegetables, and concluded that the obvious solution was a diet of animal food. Thus, the regimen described in his 1797 book, *An Account of Two Cases of the Diabetes Mellitus* [3], allowed his patient Captain Meredith to have for dinner “Game or old meats which have been long kept; and as far as the stomach may bear, fat and rancid old meats, as pork.” Rollo was probably the first to note the difficulty that some patients find in adhering to treatment – a difficulty he blamed for the death of his second patient (Figure 1.4).

## The 19th century

In 1815, the French chemist Michel Chevreul (1786–1889) proved that the sugar in diabetic urine was glucose [4]. In the middle of the century, tasting the urine to make the diagnosis was superseded by chemical tests for reducing agents such as glucose as

**Figure 1.5** Claude Bernard (1813–1878). Courtesy of the Wellcome Institute Library, London.

introduced by Trommer in 1841, Moore in 1844 and – the best known – Fehling in 1848. Measurement of blood glucose could only be done by skilled chemists but needed so much blood that it was rarely used in either clinical care or research. It only became practicable with the introduction in 1913 of a micromethod by the Norwegian-born physician Ivar Christian Bang (1869–1918) and it was the ability to measure glucose repeatedly which led to development of the glucose tolerance test between 1913 and 1915.

Glucose metabolism was clarified by the work of Claude Bernard (1813–1878) [5], the Frenchman whose numerous discoveries have given him a special place in the history of physiology (Figure 1.5). When Bernard began work in 1843, the prevailing theory was that sugar could only be synthesized by plants, and that animal metabolism broke down substances originally made in plants. It was also thought that the blood only contained sugar after meals, or in pathologic states such as diabetes. Between 1846 and 1848, Bernard reported that glucose was present in the blood of normal animals, even when starved. He also found higher concentrations of glucose in the hepatic than in the portal vein, and “enormous quantities” of a starch-like substance in the liver which could be readily converted into sugar. He called this “gly-

**Figure 1.6** Oskar Minkowski (1858–1931).

cogen” (i.e. sugar-forming) and regarded it as analogous to starch in plants. His hypothesis – the “glycogenic” theory – was that sugar absorbed from the intestine was converted in the liver into glycogen and then constantly released into the blood during fasting.

Another discovery by Bernard made a great impression in an era when the nervous control of bodily functions was a scientifically fashionable concept. He found that a lesion in the floor of the fourth ventricle produced temporary hyperglycemia (*piqûre* diabetes) [6]. This finding spawned a long period in which nervous influences were thought to be important causes of diabetes; indeed, one piece of “evidence” – cited by J.J.R. Macleod as late as 1914 – was that diabetes was more common among engine drivers than other railway workers because of the mental strain involved [7].

In the first part of the 19th century the cause of diabetes was a mystery, because autopsy usually did not show any specific lesions. A breakthrough came in 1889 when Oskar Minkowski (Figure 1.6) and Josef von Mering (1849–1908) reported that pancreatectomy in the dog caused severe diabetes [8]. This was serendipitous, because they were investigating fat metabolism; it is said that the laboratory technician mentioned to Minkowski

**Figure 1.7** Paul Langerhans (1847–1888). Courtesy of the Wellcome Institute Library, London.

that the dog, previously house-trained, was now incontinent of urine. Minkowski realized the significance of the polyuria, and tested the dog’s urine.

Possible explanations for the role of the pancreas were that it removed a diabetogenic toxin, or produced an internal secretion that controlled carbohydrate metabolism. The concept of “internal secretions” had been publicized in June 1889, by the well-known physiologist Charles-Édouard Brown-Séquard (1817–1894), who claimed to have rejuvenated himself by injections of testicular extract [9]. It was given further credence in 1891, when Murray reported that myxoedema could be cured by sheep thyroid extract by injection or orally.

In 1893, Gustave Laguesse suggested that the putative internal secretion of the pancreas was produced by the “islands” of cells scattered through the gland’s parenchyma [10], which had been discovered in 1869 by the 22-year-old Paul Langerhans (1847–1888) (Figure 1.7). Langerhans had described these clusters of cells, having teased them out from the general pancreatic tissue, but had not speculated about their possible function [11]; it was Laguesse who named them the “islets of Langerhans.” At this time, the glucose-lowering internal secretion of the islets was still hypothetical, but in 1909 the Belgian Jean de Meyer named it *insuline* (from the Latin for “island”) [12].

It would be wrong to give the impression that Minkowski’s experiments immediately established the pancreatic origin of diabetes. In fact, during the next two decades, it was widely agreed that diabetes was a heterogeneous disorder with various subtypes, and that its pathogenesis involved at least three organs: the brain, pancreas and liver [13]. The discovery by Blum in 1901 that injec-

tion of an adrenal extract caused glycosuria implicated other glands, and led to the “polyglandular theory” of Carl von Noorden (Vienna), who proposed that the thyroid, pancreas, adrenals and parathyroids controlled carbohydrate metabolism.

### Clinical diabetes in the 19th century

Doctors in the 19th century were therapeutically impotent; their main role was as taxonomists who described symptom complexes and the natural history of disease. As a result, most of the major complications of diabetes were well described before 1900.

Eduard von Jaeger (1818–1884) is credited with the first description of diabetic retinopathy, in his beautiful *Atlas of Diseases of the Ocular Fundus*, published in 1869 [14]. In fact, the features illustrated (Figure 1.8), from a 22-year-old patient, look

more like hypertensive retinopathy. In 1879, Stephen Mackenzie (1844–1909) and Sir Edward Nettleship (1845–1913) found microaneurysms in flat preparations of the retina and, in 1888, Nettleship described new vessels and the beaded appearance of retinal veins [15]. The full picture of diabetic retinopathy was described in 1890 by Julius Hirschberg (1843–1925) who was the first to claim that it was specific to diabetes [16].

Neuropathic symptoms in patients with diabetes had been mentioned by Rollo at the end of the 18th century, and in 1864 Charles Marchal de Calvi (1815–1873) concluded that nerve damage was a specific complication of diabetes. In 1885, the Guy's Hospital physician, Frederick Pavy (1829–1911), gave a description of neuropathic symptoms which would grace any modern textbook [17]:

*“The usual account given by these patients of their condition is that they cannot feel properly in their legs, that their feet are numb, that their legs seem too heavy – as one patient expressed it, “as if he had 20lb weights on his legs and a feeling as if his boots were great deal too large for his feet.” Darting or “lightning” pains are often complained of. Or there may be hyperaesthesia, so that a mere pinching of the skin gives rise to great pain; or it may be the patient is unable to bear the contact of the seam of the dress against the skin on account of the suffering it causes. Not infrequently there is deep-seated pain located, as the patient describes it, in the marrow of the bones which are tender on being grasped, and I have noticed that these pains are generally worse at night.”*

Pavy also recorded unusual presentations, including a 67-year-old who complained of “lightning pains on the right side of the waist” and cases in which the third nerve was affected with “dropped lid and external squint” [18].

Kidney disease was known to be relatively common in diabetes. In 1859, Wilhelm Griesinger (1817–1868) reported 64 autopsies in adults, half of whom had renal changes which he attributed to hypertension and atherosclerosis [19]; however, the histologic

features of diabetic kidney disease and the importance of renal complications were not reported until the 1930s.

In the latter part of the 19th century it was becoming apparent that there were at least two clinically distinct forms of diabetes. In 1880, the French physician Etienne Lancereaux (1829–1910) identified lean and obese patients as having *diabète maigre* and *diabète gras* [20], and this observation laid the foundations for subsequent etiologic classifications of the disease.

## The 20th century

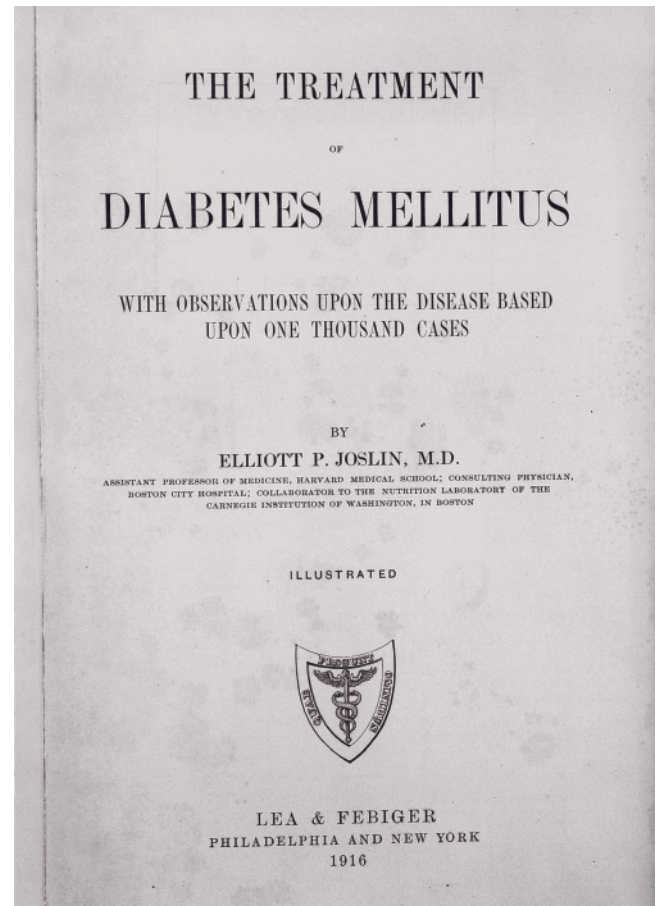

Murray’s cure of myxoedema in 1891 led to a belief that pancreatic extract would soon result in a cure for diabetes, but, in the face of repeated failures over the next 30 years, even believers in an antidiabetic internal secretion were depressed about the likelihood of isolating it, and diverted their attention to diet as a treatment for the disease.

Best known was the starvation regimen of Frederick Madison Allen (1876–1964), which Joslin (Figure 1.9) described in 1915 as the greatest advance since Rollo’s time [21]. This approach was

(a)

(b)

**Figure 1.9** Elliott P. Joslin (1869–1962), arguably the most famous diabetes specialist of the 20th century and the frontispiece to his 1916 textbook [22]. Courtesy of the Wellcome Library, London.

an extreme application of one that had been proposed as early as 1875 by Apollinaire Bouchardat (1806–1886), who advocated intensive exercise and “*manger le moins possible*.” Starvation treatment did work in a limited sense, in that some patients could survive for many months or even years, instead of a few weeks or months with untreated type 1 diabetes. The quality of life, however, was very poor, and some patients died of malnutrition rather than diabetes. In 1921, Carl von Noorden (1858–1944) – proponent of the “oatmeal cure” – turned away in disapproval when he saw Joslin’s prize patient, 17-year-old Ruth A, who at just over 1.52 m in height weighed only 24.5 kg (a body mass index of 10.6 kg/m<sup>2</sup>).

### Discovery of insulin

Many attempts were made between 1889 and 1921 to isolate the elusive internal secretion of the pancreas. These largely failed because the extracts were inactive or had unacceptable side effects; some preparations may have had limited biologic activity, but this was not recognized, either because hypoglycemia was misinterpreted as a toxic reaction or because blood glucose was not measured. Those who came closest were the Berlin physician, Georg Zuelzer (1840–1949) in 1907 [23], Ernest Scott (1877–1966) in Chicago in 1911 [24] and Nicolas Paulesco (1869–1931) in Romania in 1920–1921 [25] (Figure 1.10).

The story of how insulin was discovered in Toronto in 1921 is well known, at least superficially (Figure 1.11). A young orthopedic surgeon, Frederick Banting, inspired after reading an article by the pathologist Moses Barron (1884–1975), wondered whether the antidiabetic pancreatic principle was digested by trypsin during extraction, and decided to prevent this loss by ligating the pancreatic duct, thus causing the exocrine tissue to degenerate. He approached the Professor of Physiology in Toronto, J.J.R. Macleod, an authority on carbohydrate metabolism, who poured scorn on the idea and suggested that the only likely outcome would be “a negative result of great physiological importance.”

Eventually, Macleod relented and installed Banting in a rundown laboratory, later leaving for Scotland and a fishing holiday. A student, Charles Best, was chosen by the toss of a coin to help Banting. Within 6 months of this unpromising start, Banting and Best (referred to in Toronto academic circles as B<sup>2</sup>) had discovered the most important new therapy since the antisyphilitic agent Salvarsan. These events are described in detail in the excellent book by Michael Bliss [26].

Their approach began with the injection of extracts of atrophied pancreas (prepared according to Macleod’s suggestions) into dogs rendered diabetic by pancreatectomy). Subsequently, they discovered that active extracts could be obtained from beef pancreas which Best obtained from the abattoir. The extraction procedure (using ice-cold acid-ethanol) was greatly refined by James B. (Bert) Collip, a biochemist who was visiting Toronto on sabbatical leave.

The first clinical trial of insulin (using an extract made by Best) took place on January 11, 1922, on 14-year-old Leonard

Thompson, who had been on the Allen starvation regimen since 1919 and weighed only 30 kg (Figure 1.12). After the first injection, his blood glucose level fell slightly, but his symptoms were unchanged and he developed a sterile abscess. On January 23, he was given another extract prepared by Collip, and this normalized his blood glucose by the next morning; further injections over the next 10 days led to marked clinical improvement and complete elimination of glycosuria and ketonuria. Initial clinical results in seven cases were published in the March 1922 issue of the *Canadian Medical Association Journal* [27], which concluded dramatically that:

- 1 Blood sugar can be markedly reduced, even to normal values;
- 2 Glycosuria can be abolished;
- 3 The acetone bodies can be made to disappear from the urine;
- 4 The respiratory quotient shows evidence of increased utilization of carbohydrates;
- 5 A definite improvement is observed in the general condition of these patients and, in addition, the patients themselves report a subjective sense of well-being and increased vigor for a period following the administration of these preparations.

The term “insulin” was coined by Macleod, who was unaware of de Meyer’s earlier suggestion of *insuline*. News of its miraculous effects spread astonishingly rapidly [28]. In 1922, there were only 19 references in the world literature to “insulin” or equivalent terms such as “pancreatic extract”; by the end of 1923, there were 320 new reports, and a further 317 were published during the first 6 months of 1924.

By October 1923, insulin was available widely throughout North America and Europe. International recognition followed rapidly for its discoverers, and the 1923 Nobel Prize for Physiology or Medicine was awarded jointly to Banting and Macleod. Banting was angered by the decision, and announced publicly that he would share his prize with Best, whereupon Macleod decided to do the same with Collip.

### The postinsulin era

It was confidently anticipated that insulin would do for diabetes in the young what thyroid extract had done for myxoedema, but it soon became obvious that insulin was a very different type of treatment. Thyroid was given once a day by mouth and at a fixed dosage. Insulin had to be injected in measured amounts which varied from day to day, and carried the ever-present danger of hypoglycemia. One often reads that insulin “revolutionized” the treatment of diabetes; it did so in the sense that it saved the lives of many who would otherwise have died, but its unforeseen effect was to transform an acute, rapidly fatal illness into a chronic disease with serious long-term complications. For example, only 2% of deaths among Joslin’s young patients with diabetes before 1937 were caused by kidney disease, while over 50% dying between 1944 and 1950 had advanced renal failure. Strategies to avoid and prevent the chronic complications of diabetes remain important scientific and clinical priorities today.

## Experimentelle Untersuchungen über den Diabetes.<sup>1)</sup>

Kurze Mitteilung.<sup>2)</sup>

Von

G. Zuelzer.

F. Blum hat vor einigen Jahren gezeigt, dass subkutane oder intravenöse Injektion von Nebennierensaft bei den verschiedensten Tieren Glykosurie hervorruft, die 48 bis 74 Stunden anhalten kann. Ich, und kurze Zeit darauf Metzger wiesen nach, dass gleichzeitig eine Hyperglykämie besteht, dass es sich beim Nebennierendiabetes also nicht etwa um ein Analogon des Phloridzindiabetes, um einen sogenannten Nierendiabetes handeln könne. Während ich mich dahin aussprach, dass dieser Diabetes seiner ganzen Natur nach dem richtigen Diabetes ähnele, nur durch die Dauer seines Bestehens von ihm unterschieden sei und naturgemäss auch keine Tendenz zum Fortschreiten zeigen, i. e. niemals das Endstadium des gewöhnlichen schweren menschlichen Diabetes darbieten könne, wurde die in Frage stehende Glykosurie von den meisten anderen Autoren als eine ziemlich belanglose toxische Glykosurie aufgefasst.

Es schien mir nicht sehr wahrscheinlich, dass ein Körper, der anscheinend unverändert, wie er normalerweise produziert und dauernd<sup>3)</sup> dem Säftestrom des Organismus zugeführt wird, dass ein solcher, quasi physiologischer Körper eine vollkommen unphysiologische Wirkung sollte hervorbringen können. Ich habe also versucht, den Ort des Angriffs des Nebennierensaftes<sup>4)</sup>, sowie die Ursachen seiner toxischen Wirkung näher zu erforschen. Ich folgte dabei, wie gesagt, stets dem Gedanken, in dem Nebennierendiabetes ein, wenn auch nur flüchtiges Bild gewisser menschlicher Diabetesformen zu finden.

So untersuchte ich zuerst, welchen Einfluss hat der Nebennierensaft auf die Leber als dasjenige Organ, welches, allgemein angedrückt, mit der Zuckerregulierung im Körper in erster

1) Die Untersuchungen wurden zum Teil mit Unterstützung der Gräfin Bose-Stiftung im physiologischen Institut der Berliner Universität, und zwar noch unter Mithilfe der verstorbenen Prof. I. Munk und Paul Schultz ausgeführt.

2) Diese kurze Mitteilung wurde der Redaktion bereits vor ca. 3 Jahren eingereicht. Die Drucklegung unterblieb auf Wunsch des Verf. in der bisher nicht erfüllten Erwartung, dass es gelingen würde, aus den theoretischen Untersuchungen praktisch-therapeutische Resultate zu erzielen.

3) Durch Versuche von Ehrmann, Archiv f. experim. Pathol. u. Pharmakol., Bd. 55, ist inzwischen der Nachweis erbracht worden, dass die Adrenalinsekretion konstant vor sich geht.

4) In meinen ersten Versuchen bediente ich mich des von mir selbst hergestellten Nebennierensaftes. In den zahlreichen späteren Versuchen habe ich inzwischen genau die gleichen Wirkungen mit den verschiedenartig hergestellten käuflichen Adrenalinpräparaten feststellen können.

**Figure 1.10** (a) Georg Zuelzer (1840–1949) and (b) the title page from his paper (1907) reporting that a pancreatic extract reduced glycosuria in pancreatectomized dogs [23] (top). (c) Nicolas Paulesco (1869–1931).

The rest of this chapter highlights some developments that can be regarded as landmarks in the understanding and management of the disease: to some extent, this is a personal choice, and it is obvious from the other chapters in this book that the “history” of diabetes is being rewritten all the time.

### Causes and natural history of diabetes

The recognition that diabetes was not a single disease was important in initiating research that has helped to unravel the causes of hyperglycemia.

The broad etiologic subdivision into type 1 (juvenile-onset, or insulin-dependent) and type 2 diabetes (maturity-onset, or

**Figure 1.11** The discoverers of insulin. Clockwise from top left: Frederick G. Banting (1891–1941); James B. Collip (1892–1965); J.J.R. Macleod (1876–1935); and Charles H. Best (1899–1978). Courtesy of the Fisher Rare Book Library, University of Toronto.

**Figure 1.12** Leonard Thompson, the first patient to receive insulin, in January 1922. Courtesy of the Fisher Rare Book Library, University of Toronto.

non-insulin-dependent) stemmed ultimately from Lancereaux’s *diabète maigre* and *diabète gras* distinction, as well as observations soon after the discovery of insulin that some patients did not react “normally” to insulin. In the 1930s, Wilhelm Falta (1875–1950) in Vienna [29] and Harold Himsworth (1905–93) in London [30] proposed that some individuals with diabetes were more sensitive to the glucose-lowering effects of insulin, whereas others were insulin-insensitive, or insulin-resistant. The former were usually thin and required insulin to prevent ketoacidosis, while the latter were older, obese and ketosis-resistant.

The “insulin clamp” technique developed in the 1970s by Ralph DeFronzo *et al.* [31] in the USA was the first to measure rigorously the hypoglycemic action of insulin, and has led to countless studies of insulin resistance and its relationship to type 2 diabetes and vascular disease. Various groups, including DeFronzo’s, have helped to clarify the role of  $\beta$ -cell failure in type 2 diabetes, and how it relates to insulin resistance. Maturity-onset diabetes of the young (MODY) was recognized in 1974 by Robert Tattersall (*b.* 1943) as a distinct, dominantly inherited subset of type 2 diabetes [32]; since 1993, five different molecular defects have been identified in this condition.

The causes of the profound  $\beta$ -cell loss that led to the severe insulin deficiency of type 1 diabetes remained a mystery for a long time. “Insulinitis”, predominantly lymphocytic infiltration of the islets, was noted as early as 1901 by Eugene L. Opie (1873–1971) and colleagues [33], but because it was apparently very rare, found in only six of 189 cases studied by Anton Weichselbaum (1845–1920) in 1910, its importance was not appreciated. The possible role of insulinitis in  $\beta$ -cell destruction was not suggested until 1965, by the Belgian Willy Gepts (1922–1991) [34]. The theory that type 1 diabetes results from autoimmune destruction of the  $\beta$  cells was first made in 1979 by Deborah Doniach (1912–2004) and GianFranco Bottazzo (*b.* 1946) [35]. Unlike other autoimmune endocrine diseases where the autoantibody persists, islet cell antibodies (ICA) turned out to be transient and disappeared within a year of the onset of diabetes. An unexpected finding from the Barts–Windsor prospective study of the epidemiology of diabetes in childhood started by Andrew Cudworth (1939–1982) was that ICA could be detected in siblings of young people with diabetes up to 10 years before they developed apparently acute-onset diabetes. This long lead-in period raised the possibility of an intervention to prevent continuing  $\beta$ -cell destruction. Cyclosporine in people with newly diagnosed type 1 diabetes prolongs the honeymoon period but without permanent benefit once the drug is stopped [36]. Nicotinamide and small doses of insulin (together with many other interventions) prevent diabetes in the non-obese diabetic (NOD) mouse but were without effect in relatives of people with type 1 diabetes with high titers of ICA [37,38].

From 1967, when Paul Lacy (1924–2005) showed that it was possible to “cure” diabetes in inbred rats with an islet cell transplant, it always seemed that the problem of islet cell transplantation in humans was about to be solved. Hope was rekindled in 2000 by a team in Edmonton, Canada. After 5 years 80% of their transplanted patients were producing some endogenous insulin but only 10% could manage without any injected insulin [39].

### Chronic diabetic complications

It had been assumed that arteriosclerosis caused chronic diabetic complications, but this notion was challenged by two papers published in the mid-1930s, which pointed to specific associations of diabetes with retinal and renal disease (Table 1.2). In 1934, Henry Wagener (1890–1961) and Russell Wilder (1885–1959) from the Mayo Clinic reported patients who had retinal hemorrhages but no other clinical evidence of vascular disease [40], and concluded that “The very existence of retinitis in cases in which patients have no other signs of vascular disease must mean that diabetes alone does something to injure the finer arterioles or venules of the retina, probably the latter.”

In 1936, Paul Kimmelstiel (1900–1970) and Clifford Wilson (1906–1997) described the striking histologic finding of “intercapillary glomerulosclerosis” – large hyaline nodules in the glomeruli – in the kidneys of eight subjects at autopsy (Figure 1.13) [41]. Seven of the eight patients had a known history of diabetes, and Kimmelstiel and Wilson noted the common fea-

Graham Bell (USA, 1980)	Reported sequence of human insulin gene

tures of hypertension, heavy albuminuria with “oedema of the nephrotic type,” and renal failure. In fact, this paper led to considerable confusion during the next 15 years: according to one writer, the “Kimmelstiel–Wilson syndrome” came to mean all things to all men [42]. Nonetheless, it was significant because it drew attention to a specific diabetic renal disease.

Acceptance of the concept that diabetic angiopathy was specific to the disease owed much to the work of Knud Lundbæk of Aarhus in Denmark (Figure 1.14), who published his findings in a book in 1953–1954 and a paper in the *Lancet* in 1954 [43,44]. His key arguments were that long-standing diabetic vascular disease differed fundamentally from atherosclerosis, in that both sexes were equally affected and that microaneurysms, ocular phlebopathy and Kimmelstiel–Wilson nodules were unique to diabetes and usually occurred together.

The molecular and cellular mechanisms underlying diabetic tissue damage remain controversial after decades of intensive research. One of the early landmarks in this field was the work of J.H. Kinoshita (*b.* 1922) during the early 1970s, which pointed to the involvement of the polyol pathway in the formation of diabetic cataracts [45].

**Physiology**

In 1907, M.A. Lane, a student of Robert Bensley (1867–1956), Professor of Anatomy in Chicago, used conventional histologic techniques to distinguish two different cell types in the islet of Langerhans, which he termed A and B [46]. The hormones secreted by these respective cell types were not identified until much later (Table 1.2). Frank Young (1908–1988) and colleagues reported in 1938 that injections of anterior pituitary extract could induce permanent diabetes in the dog, and that this was accompanied by selective degranulation and loss of the  $\beta$ -cells [47]; it was surmised that these cells produced insulin, and this was finally confirmed using immuno-histochemistry by Paul Lacy in 1959 [48]. Glucagon was similarly localized to the  $\alpha$ -cells in 1962 by John Baum and colleagues [49].

The amino acid sequence of insulin was reported in 1955 by Frederick Sanger in Cambridge, UK [50], and the three-dimensional structure of the molecule in 1969 by Dorothy Hodgkin, in Oxford [51]; both discoveries were recognized by the award of Nobel Prizes (Figure 1.15). The complete insulin molecule was synthesized from amino acids by Wang Ying-lai (1908–2001) and colleagues in Shanghai in 1965 [52]. The insulin precursor, proinsulin, was described in 1967 by Donald Steiner (*b.* 1930) in Chicago [53]. The first bioassay for insulin, based on the hormone's ability to lower blood glucose in the alloxan-diabetic rat, was reported in 1950 by the Australian Joseph Bornstein (1918–1994), working in London with Robin D. Lawrence (see Fig. 1.20) [54]. This method was superseded in 1956 by Rosalyn Yalow and Solomon Berson in the USA, who discovered that insulin was antigenic; they exploited the binding of the hormone to anti-insulin antibodies to develop the first radio-immunoassay [55]. This assay method revolutionized endocrinology – and indeed, many areas of physiology and medicine – and was also rewarded with a Nobel Prize (Figure 1.16).

The sequence of rat insulin genes was described in 1977 by Axel Ullrich (*b.* 1945) and colleagues [56], and the human sequence by Graham Bell (*b.* 1948) and his group in 1980 [57]. The existence of insulin receptors was inferred from the insulin-binding characteristics of liver-cell membranes by Pierre Freychet (*b.* 1935) and colleagues in 1971 [58], and the receptor protein was isolated by Pedro Cuatrecasas (*b.* 1936) in the following year [59]. The gene encoding the insulin receptor was cloned and sequenced in 1985 by two groups [60,61]. In recent years, numerous advances have helped to clarify how insulin exerts its biologic actions. Among these was the discovery in 1985 of the first of the

**Figure 1.16** Solomon Berson and Rosalyn Yalow.

glucose transporter (GLUT) proteins by Mueckler and colleagues in the USA [62].

### Management of diabetes

An objective observer surveying clinical diabetes during the half-century after the discovery of insulin and the “resurrection” (a word used by Joslin) of young people with diabetes would have been dismayed by what he saw (Table 1.4). In particular, young people were dying of complications that had previously been assumed to be the preserve of the elderly. Two particularly depressing papers were published in 1947 and 1950. First, Henry Dolger (1909–1997) in New York described 20 patients who fulfilled the then-accepted criteria for excellent diabetic control, but

**Table 1.4** Selected milestones in the management of diabetes.

**Lifestyle modification**

Li Hsuan (China, 7th century)	Avoid wine, sex and salty cereals
Thomas Willis (England, 17th century)	Food restriction
John Rollo (England, 1797)	Animal diet
Apollinaire Bouchardat (France, 1875)	Food restriction and increased exercise
Carl von Noorden (Germany, 1903)	“Oatmeal” cure
Frederick Allen (USA, 1913)	Starvation diet for early-onset diabetes
Karl Petrén (Sweden, 1915)	High-fat, low-carbohydrate diet

**Insulin treatment**

Georg Zuelzer (Germany, 1907) and Nicolas Paulesco (Romania, 1921)	Isolated pancreatic extracts with hypoglycemic activity
Frederick Banting, Charles Best, J.J.R. Macleod, and James Collip (Canada, 1922–1923)	Isolation and first clinical use of insulin
Hans Christian Hagedorn (Denmark, 1936)	Protamine insulin, the first long-acting insulin
David Goeddel (USA, 1979)	Synthetic human-sequence insulin produced by recombinant DNA technology
John Pickup (London, 1978)	Described continuous subcutaneous insulin infusion
John Ireland (Scotland, 1981)	Invented pen injection device

**Oral hypoglycemic agents**

Avicenna (Arabia, 10th century)	Recommended lupin, fenugreek and zedoary seeds
Willhelm Ebstein (Germany, 1876)	Recommended sodium salicylate
E. Frank (Germany, 1926)	Biguanide derivative (Synthalin) introduced, but withdrawn because of toxicity
Celestino Ruiz (Argentina, 1930)	Noted hypoglycemic action of some sulfonamides
Auguste Loubatières (France, 1942)	Discovered hypoglycemic action of prototype sulfonylurea
H. Franke and J. Fuchs (Germany, 1955)	Carbutamide introduced
G. Ungar (USA, 1957)	Phenformin introduced

**Diabetic monitoring and treatment targets**

University Group Diabetes Program (USA, 1969)	First randomized trial in diabetes
Peter Sönksen and Robert Tattersall (1978)	Introduction of home blood glucose monitoring
R. Flückiger and K.H. Winterhalter (Germany, 1975)	Showed that HbA <sub>1c</sub> was glycated hemoglobin
World Health Organization (1991)	St Vincent Declaration identified targets for diabetes care
Diabetes Control and Complications Trial (USA, 1993)	Proved that improved glycemic control prevents and slows progression of microvascular complication in type 1 diabetes
UK Prospective Diabetes Study (UK, 1998)	Proved that improved glycemic and blood-pressure control improve microvascular and macrovascular outcomes in type 2 diabetes

**Management of complications**

Gerd Meyer-Schwickerath (Germany, 1964)	Use of xenon arc lamp to treat diabetic retinopathy
University of Minnesota Team (USA, 1966)	First combined kidney–pancreas transplants
Carl-Erik Mogensen and Hans-Henrik Parving (Denmark, 1980s)	Strict blood pressure controls slows progression of diabetic neuropathy

who all developed severe retinopathy after 6–22 years [63]; among these was the first patient ever to receive insulin at Mount Sinai Hospital, New York, who also had heavy albuminuria and hypertension by the age of 32. Second, Ruth Reuting reported a cohort of 50 young patients originally identified in 1929 [64]. By 1949, one-third had died (mostly from cardiovascular and renal disease) at an average age of 25 years, after only 18 years of diabetes, and the survivors showed “ominous signs of hypertension, azotemia and proteinuria in significant numbers.” This had occurred despite the introduction of more versatile insulin preparations (see below); the situation was so hopeless that it inaugurated 20 years of treatment with “heroic” measures such as adrenalectomy and hypophysectomy.

These and other studies raised questions about whether lowering blood glucose levels to normal could prevent diabetic complications or reverse them once they had appeared. The hypothesis remained untestable for four more decades, until the means to achieve tight glycemic control and measure it had been devised.

**Insulin**

For the first decade after its discovery, insulin was available only in its soluble (regular) formulation, whose short-action profile required multiple daily injections. The first delayed-action preparation, protamine insulinate, was introduced in 1936 by Hans Christian Hagedorn in Denmark (Figure 1.17) [65]. This was followed by protamine zinc insulin later the same year, then

**Figure 1.17** Hans Christian Hagedorn (1888–1971) from the Hagedorn Medal. Courtesy of C. Binder, Steno Institute, Hvidovre, Denmark.

globin insulin in 1939, NPH (neutral protamine Hagedorn, or isophane) in 1946, and the lente series in 1952. Long-acting insulins were welcomed by diabetes specialists and patients, but their use as a single daily injection probably produced worse glycemic control than three or four injections of soluble insulin. Indeed, delayed-action preparations were initially condemned by some diabetes specialists, such as Russell Wilder of the Mayo Clinic, because the patient could slip without apparent warning into hypoglycemia.

The number and variety of insulin preparations proliferated, but the main advances were in methods to produce highly purified preparations from porcine or bovine pancreas, which remained the source for therapeutic insulin until the early 1980s. Insulin was the first therapeutic protein to be produced by recombinant DNA technology, initially by David Goeddel (*b.* 1951), who expressed synthetic genes encoding the A- and B-chains separately in *Escherichia coli* and then combined these chemically to produce human-sequence insulin [66]. From there, genetic engineering has been used to produce “designer” insulins such as the fast-acting insulin analogs lispro and aspart and the “peakless” basal insulins such as glargine and detemir. How much these will improve glycemic control in the generality of people with diabetes is debatable; weekend golfers do not become champions when given expensive clubs!

Most people with diabetes still inject insulin subcutaneously. From the patient’s viewpoint, major milestones were the replacement of glass and steel syringes by disposable plastic syringes with fine-gauge needles, and then by “pen” injection devices invented by John Ireland (1933–1988) in Glasgow, Scotland, in 1981 [67]. Portable insulin infusion pumps were developed by John Pickup (*b.* 1947) and colleagues in London during the late 1970s [68], and have become progressively smaller and more sophisticated. Patients and manufacturers hope that there will eventually be an

insulin that can be given without injection. The first inhaled insulin was marketed in 2006 but withdrawn a year later because of lack of demand and concerns about safety [69].

### Oral hypoglycemic agents

The first orally active glucose-lowering drug, synthalin, a guanidine derivative, was developed by Frank and colleagues in Breslau in 1926 [70], but had to be withdrawn because of toxicity (a recurrent problem for oral hypoglycemic drugs). The sulfonylureas originated from the work of Auguste Loubatières (1912–1977) in France during the early 1940s on the glucose-lowering action of a sulfonamide derivative, 2254RP. Loubatières made the crucial observations that proved that these drugs act as insulin secretagogues and that they were effective in intact, but not in pancreatectomized, animals [71]. In 1955 carbutamide was the first sulfonylurea to enter clinical practice and tolbutamide followed in 1957. Phenformin, the first biguanide, was introduced in 1959 following research into the metabolic effects of guanidine derivatives which had built on Frank’s initial studies [72]. Metformin appeared on the European market in 1960 but was not marketed in the USA until 1994. Troglitazone, the first of a new class of antidiabetic drugs, the glitazones, was also marketed in 1994 but withdrawn because of liver damage. It was followed by rosiglitazone and pioglitazone. Another new class of drugs, acting on the incretin system, were introduced in 2005. These are either glucagon-like peptide 1 (GLP-1) agonists (such as exenatide) or inhibitors of the enzyme dipeptidylpeptidase-4 (DPP-4) which breaks down GLP-1 (gliptins).

Tolbutamide, phenformin and insulin were compared in the treatment of maturity-onset diabetes in the first randomized controlled trial, the University Group Diabetes Program [73–75]. This much-criticized study concluded that the death rate was higher for both oral agents than for placebo, and that insulin (whether given in a fixed or variable dose) was no better than placebo [75]. These findings were interpreted by some as suggesting that treatment of maturity-onset diabetes was a waste of time – a myth that was only laid finally to rest by the UK Prospective Diabetes Study.

### Glucose control and treatment targets

During the 1920s, opinion leaders advocated normalizing blood glucose in young patients with diabetes, the rationale being to “rest” the pancreas, in the hope that it might regenerate. The only way of monitoring diabetic control was by testing the urine for glucose, and attempts to keep the urine free from sugar inevitably resulted in severe hypoglycemia and often psychological damage. This led to the so-called “free diet” movement – linked particularly with Adolf Lichtenstein (Stockholm) and Edward Tolstoi (New York) – which encouraged patients to eat whatever they liked and not to worry about glycosuria, however heavy. Tolstoi’s view [76] was that a life saved by insulin should be worth living, and that patients should be able to forget that they had diabetes after each morning’s injection; it seems likely that many physicians followed this policy for the next 40 years.

Adult physicians were similarly ambivalent about the importance of good glycemic control. Only one-third of diabetes physicians questioned in England in 1953 thought that normoglycemia would prevent diabetic complications, and only one-half advised urine testing at home [77].

Practical monitoring of diabetic control became feasible in the late 1970s with the introduction into clinical practice of test strips for measuring blood glucose in a fingerprick sample and the demonstration that ordinary patients could use them at home [78,79]. The discovery of hemoglobin A<sub>1c</sub> by Samuel Rahbar (*b.* 1929) paved the way for glycated hemoglobin (HbA<sub>1c</sub>) assays which gave an objective measure of overall glucose control [80]. These methods in turn made possible the North American Diabetes Control and Complications Trial, which in 1993 finally established that good control prevents and delays the progression of microvascular complications in type 1 diabetes [81]. For type 2 diabetes, the importance of good glycemic control was definitively proved by another landmark study, the UK Prospective Diabetes Study (UKPDS), masterminded in Oxford, UK, by Robert Turner (Figure 1.18). The UKPDS reported in 1998, and not only showed a beneficial effect of improved glycemic control on microvascular complications [82], but also established the importance of treating hypertension [83]. By the late 1990s it was clear that reducing glucose levels, high blood pressure or cholesterol separately would reduce the frequency of heart disease and death and it was natural to wonder whether tackling them simultaneously (multiple risk factor intervention) would be even better. The Steno 2 study, which began in Denmark in 1992, enrolled patients with type 2 diabetes with microalbuminuria and after 13 years of follow-up showed that multiple risk factor intervention reduced the risk of death by 20% and the risk of developing nephropathy, retinopathy and neuropathy by 50% [84].

### Diabetic complications

Apart from the general benefits of controlling blood glucose, some specific treatments have emerged for certain chronic complications. Well-conducted clinical trials during the late 1970s showed the effectiveness of laser photocoagulation in preventing visual loss from both maculopathy and proliferative retinopathy [85]. This technique was derived from the xenon arc lamp originally described in the late 1950s by Gerd Meyer-Schwickerath (1921–92) of Essen, Germany [86].

The importance of blood pressure control in preventing the progression of nephropathy is now fully recognized, and angiotensin-converting enzyme inhibitors may be particularly beneficial; that blood pressure control slowed the progression of nephropathy was shown in studies by Carl-Erik Mogensen (*b.* 1938) and Hans-Henrik Parving (*b.* 1943) published in the early 1980s [87]. The measurement of low albumin concentrations in urine (microalbuminuria), now used throughout the world to screen for and monitor the course of diabetic nephropathy, is derived from a radioimmunoassay developed in 1969 by Harry Keen and Costas Chlouverakis, at Guy's Hospital in London [88].

**Figure 1.18** Robert Turner (1939–1999), instigator of the UKPDS, the first study to show that good control of blood glucose and blood pressure was beneficial in type 2 diabetes. Courtesy of the British Diabetic Association.

### Diabetic ketoacidosis

The introduction of insulin was only one aspect of the management of this acute and previously fatal complication of diabetes. Of the first 33 cases treated by Joslin and his colleagues between January 1, 1923 and April 1, 1925, 31 survived – an excellent outcome, even by modern standards, which Joslin [89] attributed to: “Promptly applied medical care, rest in bed, special nursing attendance, warmth, evacuation of the bowels by enema, the introduction of liquids into the body, lavage of the stomach, cardiac stimulants, and above all the exclusion of alkalis.”

Sadly, other centers did not pay so much attention to detail. In 1933, the death rate from ketoacidosis in Boston was only 5%, but elsewhere in North America and Europe it averaged 30% and could be as high as 75%. An important advance in management was the acceptance of relatively low-dose insulin replacement, following the example of Ruth Menzel and colleagues in Karlsburg, Germany [90]. This broke with the tradition of high-dose regimens such as that proposed by Howard Root in the USA,

which had recommended an average of 1200 U insulin during the first 24 hours of treatment [91]. Another step forward was the recognition by Jacob Holler in 1946 of the danger of hypokalemia [92]. Holler's observation helped to establish the need for monitoring plasma potassium levels, which became feasible with the introduction of the flame photometer, and replacing potassium accordingly.

### Diabetic pregnancy

As late as 1950, the outcome of pregnancy in women with diabetes was still very poor in most units, with perinatal fetal losses of 45–65%, some 10 times higher than in the general population. Exceptions to this depressing rule were the units run by Priscilla White at the Joslin Clinic in Boston, who had published excellent results as early as 1935 [93], and by Jørgen Pedersen in Copenhagen (Figure 1.19). Pedersen identified the common features underpinning success as good diabetic control and care

provided by an experienced and dedicated team consisting of a physician, obstetrician and pediatrician [94]. Pedersen's target of a fetal mortality rate of 6% was not achieved in most European or US units until the 1980s.

### Delivery of care for people with diabetes

From the earliest days of insulin injection and urine testing, it was apparent that people with diabetes needed knowledge and practical skills to manage their disease effectively. Lip-service was often paid to the importance of diabetes education, but most patients were badly informed. In 1952, Samuel Beaser (1910–2005) questioned 128 patients attending the Boston Diabetes Fair, and found that “all were distinctly deficient in knowledge of their disease” [95]; he felt that responsibility lay with both doctors and administrators. Further studies during the 1960s by Donnell Etwiler (1927–2003) in Minneapolis showed that many doctors and nurses were also ignorant about managing diabetes. Since the

1980s, diabetes specialist nurses and nurse educators have been appointed in increasingly large numbers – thus fulfilling a suggestion originally made by Joslin in 1916.

National and international diabetes associations have also played an important part by supporting scientific and clinical research, providing practical and moral help for patients, and lobbying governments on patients' behalf. The first of these organizations was the Portuguese Association for the Protection of Poor Diabetics, founded in 1926 by Ernesto Roma of Lisbon after an inspiring visit to Joslin's clinic in Boston (Figure 1.20). The Association's aim was to provide free insulin and education for people with diabetes and their families. In the UK, the Diabetic Association (later the British Diabetic Association, and now Diabetes UK) was established in 1934 by Robin Lawrence of King's College Hospital, London, helped by the novelist H.G. Wells (Figure 1.20). Similar organizations were later founded in France (1938), the USA (1940) and Belgium (1942), and now exist in most countries.

On a wider scale, the International Diabetes Foundation was established in 1950 and the European Association for the Study of Diabetes (EASD) in 1964. These organizations are devoted to the practice of diabetes care as well as the basic and clinical science of the disease, and have been valuable in coordinating treatment targets and strategies at international level; an important example was the St. Vincent Declaration, issued

jointly in 1990 by the EASD and the World Health Organization [96].

## The Classification and Diagnosis of Diabetes Mellitus

**K. George M.M. Alberti**

Endocrinology and Metabolism, Imperial College St Mary's Campus, London, UK

### Key points

- The classification of diabetes mellitus is based on four main categories: Type 1, Type 2, other specific types, and gestational diabetes mellitus
- Impaired glucose tolerance and impaired fasting glycemia are high-risk states collectively termed "intermediate hyperglycemia"
- Type 2 diabetes is a diagnosis by exclusion and as more specific causes are found these will move out of the type two category into other specific types
- Measurement of glucose continues to be the mainstay of diagnosis. In the symptomatic person a single abnormal value, either casual or fasting, is often enough to confirm the diagnosis. In asymptomatic individuals two abnormal values are required and an oral glucose tolerance test may be needed
- The diagnosis of diabetes can not be excluded by measuring fasting plasma glucose alone
- HbA<sub>1c</sub> has major advantages over glucose testing in terms of convenience and lack of variability, although it is not adequately quality assured or standardized in many places, and is costly. Nonetheless, it is already recommended in some countries as an alternative diagnostic test. This is likely to become more widespread

### Introduction

Diabetes mellitus is a disease of antiquity (see Chapter 1). A treatment was described in the Ebers papyrus and as long ago as 600 BC two main types were distinguished. Perhaps the most famous description was by Arateus the Cappadocian who talked of the melting down of flesh into urine and of the end being speedy. Over the ensuing centuries sporadic descriptions were noted, with Maimonides in Egypt pointing out its relative rarity. It was attributed to a salt-losing state although the sweetness of the urine had long been known. Undoubtedly, virtually all of these accounts referred to type 1 (T1DM) or late type 2 diabetes (T2DM).

Diabetes was better recognized in the 17th and 18th centuries, with the association with obesity noted in some cases. The obvious breakthrough came in the 17th century with the demonstration of excess glucose in the urine and later also in blood.

The presence of excess ketones was shown in the 19th century. A clear description of the two main types of diabetes appeared at the end of the 19th century, with the distinction being made between that occurring in young people with a short time course before ketoacidosis supervened, and that found in older people who were obese. Over the next decades these became known as juvenile-onset diabetes and maturity-onset diabetes, although it

was generally stated that the latter was just a milder form of the disease. Diagnosis now depended on glucose measurement with some using glucose tolerance tests. There were no standard criteria for these initially, although glucose levels were clearly above normal. Diagnosis usually occurred after clinical development of the disease with the combination of symptoms with raised glucose in the blood or glycosuria being diagnostic, together with ketonuria in the juvenile-onset form.

A further breakthrough occurred with the work of Himsworth in 1936. Himsworth's work showed that people with diabetes could be divided into insulin-resistant and insulin-sensitive types, with the former much more common in those with the maturity-onset variety [1]. The next milestone was the development of the radioimmunoassay for insulin which allowed the unequivocal demonstration of insulin deficiency, or indeed absence, in those with juvenile-onset diabetes while levels were apparently normal or raised in those with maturity-onset diabetes.

At that time, diabetes was still considered to be a relatively uncommon disorder occurring predominantly in Europeans. The World Health Organization (WHO) began to take note and held its first Expert Committee meeting in 1964 [2]. The real breakthrough, however, in terms of diagnosis and classification came in 1980 with the publication of the second Expert Committee report [3] shortly after the report from the National Diabetes Data Group (NDDG) in the USA in 1979 [4]. These events form the starting point for the diagnostic criteria and classification used today.

## Definitions

Diabetes mellitus is a metabolic disorder of multiple etiologies. It is characterized by chronic hyperglycemia together with disturbances of carbohydrate, fat and protein metabolism resulting from defects of insulin secretion, insulin action or both [6]. The relative contribution of these varies between different types of diabetes. These are associated with the development of the specific microvascular complications of retinopathy, which can lead to blindness, nephropathy with potential renal failure, and neuropathy. The latter carries the risk of foot ulcers and amputation and also autonomic nerve dysfunction. Diabetes is also associated with an increased risk of macrovascular disease.

The characteristic clinical presentation is with thirst, polyuria, blurring of vision and weight loss. This can lead to ketoacidosis or hyperosmolar non-ketotic coma (see Chapter 19). Often, symptoms are mild or absent and mild hyperglycemia can persist for years with tissue damage developing, although the person may be totally asymptomatic.

## Classification

There was awareness of different grades of severity of diabetes for many centuries; however, the possibility that there were two distinct types only emerged at the beginning of the 20th century. Even then there was no real clue to distinct etiologies. In the 1930s, Himsworth suggested that there were two phenotypes. The first real attempt to classify diabetes came with the first WHO Expert Committee on Diabetes Mellitus which felt that the only reliable classification was by age of onset and divided diabetes into juvenile-onset and maturity-onset disease [2]. There were many other phenotypes in vogue at that time including brittle, gestational, pancreatic, endocrine, insulin-resistant and iatrogenic diabetes, but for most cases there was no clear indication of etiology. Clarity began to emerge in the 1970s with the discovery of the human leukocyte antigen (HLA) genotypes common in juvenile-onset diabetes and the discovery of islet cell antibodies. This gave a clear indication that younger patients with diabetes, all of whom required insulin therapy, had an autoimmune disorder.

The beginning of the modern era came with the second WHO Expert Committee [3] which reviewed and modified the revised classification published by the National Diabetes Data Group [4]. This proposed two main classes of diabetes: insulin-dependent diabetes mellitus (IDDM; type 1) and non-insulin-dependent diabetes (NIDDM; type 2) together with “other types” and gestational diabetes. There were also two risk classes: previous abnormality of glucose intolerance (PrevAGT) and potential abnormality of glucose tolerance (PotAGT) which replaced previous types known as pre-diabetes or potential diabetes.

The 1980 classification was revised further in 1985 [5] and reverted to clinical descriptions with retention of IDDM and NIDDM but omission of type 1 and type 2. Malnutrition-related

**Table 2.1** Etiologic classification of disorders of glycemia. Adapted from World Health Organization [6].

Type 1 diabetes ( $\beta$ -cell destruction) <ul style="list-style-type: none"> <li>• Autoimmune</li> <li>• Idiopathic</li> </ul>
Type 2 diabetes (insulin resistance with insulin hyposecretion)
Other specific types (Table 2.2)
Gestational diabetes (includes former categories of gestational IGT and gestational diabetes)
IGT, impaired glucose tolerance.

diabetes mellitus was also introduced in recognition of a different phenotype found particularly in Asia and sub-Saharan Africa. Impaired glucose tolerance (IGT) was also introduced as a high risk class.

Based on increasing knowledge, WHO revisited the classification in 1999 [6] as did the American Diabetes Association (ADA) [7]. It was recognized that the terms IDDM and NIDDM, although superficially appealing, were often confusing and unhelpful – as in patients with insulin-treated T2DM. The new classification attempted to encompass both etiology and clinical stages of the disease as well as being useful clinically. This was based on the suggestion of Kuzuya and Matsuda [8]. This acknowledges that diabetes may progress through several clinical stages (e.g. from normoglycemia to ketoacidosis) while having a single etiologic process such as autoimmune attack on the  $\beta$ -cells. Similarly, it is possible that someone with T2DM can move from insulin requirement to no pharmaceutical intervention through modification of lifestyle. The main classes are T1DM, T2DM, other specific types and gestational diabetes (Table 2.1). It should be noted that T2DM is largely categorization by exclusion. As new causes are discovered so they will be included under “other specific types” as has occurred for maturity-onset diabetes of the young (MODY).

The classification was revisited by WHO in 2006, but no further modification was introduced, and it will be examined again in 2010 when at most minor amendments will be made. IGT was removed from the formal classification of types of diabetes – logically, as it is not diabetes – but was retained as a risk state. Impaired fasting glycemia (IFG) was introduced as another risk state. This was particularly important in many countries where glucose tolerance tests are rarely performed in practice outside of pregnancy so that IGT was not diagnosed and IFG, although not strictly equivalent, has been used as an easily obtained risk marker.

### Type 1 diabetes

T1DM is primarily caused by  $\beta$ -cell destruction although some insulin resistance is also present (see Chapter 9). After the initial stages, insulin is required for survival. In Europeans >90% show evidence of autoimmunity with anti-glutamine acid decarboxylase (anti-GAD), anti-insulin and/or islet cell antibodies detectable. It shows strong association with specific alleles at the DQ-A

and DQ-B loci of the HLA complex [9]. Not all subjects with the clinical characteristics of T1DM show these associations with autoimmunity although they are ketosis-prone, non-obese and generally under the age of 30 years. In non-Europid populations, up to 80% may show no measurable autoantibodies [10]; these are referred to as having idiopathic T1DM. As with autoimmune diabetes, however, there is clear loss of  $\beta$ -cell function as measured by low or absent C-peptide secretion. Diabetes occurring before the age of 6 months is most likely to be monogenic neonatal diabetes rather than autoimmune T1DM (see Chapter 15) [11].

In addition to the typically young people with acute-onset T1DM, there is an older group with slower onset disease. They may present in middle age with apparent T2DM but have evidence of autoimmunity as assessed by GAD antibody measurements and ultimately become insulin-dependent. This is referred to as latent autoimmune diabetes of adults (LADA) [12].

**Type 2 diabetes**

By far the majority of people with diabetes worldwide have T2DM. This is characterized by insulin resistance with relative insulin deficiency (i.e. patients secrete insulin, but not enough to overcome the insulin resistance) (see Chapters 10 and 11). Typically, they do not require insulin to survive but often will eventually need insulin to maintain reasonable glycemia control, often after many years.

The precise molecular mechanisms underlying T2DM are not known. Major efforts have been made to discover underlying genetic abnormalities but with only modest success (see Chapter 12). The most promising to date has been TCF7L2 [13] which may have a role in insulin secretion but this does not explain diabetes susceptibility in the majority of subjects. What is clear is that T2DM is closely associated with obesity and physical inactivity, and the westernization of lifestyles. The dramatic increase in T2DM over the past two decades has been closely paralleled by the rise in obesity worldwide. Both obesity, particularly visceral adiposity, and physical inactivity cause insulin resistance which will result in diabetes in those with only a small capacity to increase insulin secretion. The incidence of T2DM also increases with age, which may be related to decrease in exercise and muscle mass; however, as the incidence increases so T2DM is being found at younger ages and it is now not uncommon in adolescence in many ethnic groups.

T2DM occurs in families so that those with a first-degree relative with diabetes have an almost 50% life-time risk. There is also marked variation between different ethnic groups. Thus, those of Polynesian, Micronesian, South Asian, sub-Saharan African, Arabian and Native American origin are much more prone to develop diabetes than Europids.

T2DM is a diagnosis by exclusion and the prevalence may fall as causes are identified, but this is likely to be a slow process.

**Other specific types of diabetes**

Diabetes occurs both as a result of specific genetic defects in insulin secretion and action and in a range of other conditions (Table 2.2).

**Table 2.2** Other specific types of diabetes. Adapted from World Health Organization [6].

**Genetic defects of  $\beta$ -cell function**

- Chromosome 20, HNF4 $\alpha$  (MODY 1)
- Chromosome 7, glucokinase (MODY 2)
- Chromosome 12, HNF1 $\alpha$  (MODY 3)
- Chromosome 13, IPF-1 (MODY 4)
- Mitochondrial DNA 3243 mutation
- Others

**Genetic defects in insulin action**

- Type A insulin resistance
- Leprechaunism
- Rabson–Mendenhall syndrome
- Lipodystrophic diabetes
- Others

**Disease of the endocrine pancreas**

- Fibrocystic pancreatopathy
- Pancreatitis (particularly chronic)
- Trauma/pancreatectomy
- Neoplasia
- Cystic fibrosis
- Hemochromatosis
- Others

**Endocrinopathies**

- Cushing syndrome
- Acromegaly
- Pheochromocytoma
- Glucagonoma
- Somatostatinoma
- Others

**Drug- or chemical-induced**

- Nicotinic acid
- Glucocorticoids
- Thyroxine/triiodothyronine
- $\alpha$ -Adrenergic agonists
- Thiazides
- Pentamidine
- Vacor
- Others

**Infections**

- Congenital rubella
- Cytomegalovirus
- Mumps
- Others

**Uncommon forms of immune-mediated disease**

- Insulin autoimmune syndrome
- Anti-insulin receptor antibodies
- “Stiff man” syndrome
- Others

**Other genetic syndromes**

(see Table 2.3)

The best known of the defects in insulin secretion are the MODY family, which are a group of autosomal-dominant inherited disorders where there is hyperglycemia at an early age, generally of a mild nature. The most common concerns a mutation in the HNF-1 $\alpha$  gene on chromosome 12 (MODY 3) while another is caused by mutations in the glucokinase gene on chromosome 7p. These account for a small number of people with diabetes but are important in determining therapeutic approaches.

The association of diabetes with defects in insulin action has long been known, particularly in type A insulin resistance, leprechaunism and lipotrophic diabetes. Not surprisingly, diseases of the exocrine pancreas often cause diabetes through destruction of the islets. Pancreatitis secondary to alcohol is probably the most common of these (see Chapter 18). Hemochromatosis and cystic fibrosis also commonly result in diabetes.

Fibrocalculous pancreatitis is also included in this category. Originally, this was part of malnutrition-related diabetes mellitus where there were two proposed variants: one associated with cassava consumption in malnourished people but without evidence of calculi, while the other was found after tropical pancreatitis and presented with fibrocalculous disease. The latter is akin to the diabetes found with other forms of chronic pancreatitis. In 1999 it was felt that this latter form would fit into the category of “other specific types” and that more evidence was needed before a specific malnutrition-related diabetes category could be included.

Several endocrinopathies are associated with diabetes: Cushing syndrome, acromegaly, pheochromocytoma, glucagonoma and hyperthyroidism (see Chapter 17). In general, the diabetes will disappear if the endocrinopathy is treated. Many drugs and chemicals cause diabetes (Table 2.2, Chapter 16). Some of these cause  $\beta$ -cell destruction but others will cause diabetes by increasing insulin resistance in susceptible individuals.

Infections are also associated with the development of diabetes; classically, mumps, congenital rubella, coxsackie B and cytomegalovirus are the main ones implicated. Many genetic syndromes are also associated with diabetes (Table 2.4).

There are other types of diabetes that do not fit conveniently into any of the current classes. These include “Flatbush” diabetes found in Afro-Americans [14] and so-called ketosis-prone T2DM found in Africans in sub-Saharan Africa [15]. These are both characterized by periods of ketosis with absolute insulin dependence and other times when the diabetes can be controlled by diet alone.

### Gestational diabetes mellitus

Gestational diabetes mellitus (GDM) is hyperglycemia first detected during pregnancy (see Chapter 53). This is distinct from women with diabetes undergoing pregnancy, who have diabetes in pregnancy rather than gestational diabetes. Plasma glucose levels, both fasting and post-prandial, are lower than normal in early pregnancy so that raised levels at this stage are almost certainly caused by previously undetected T2DM. Screening for GDM is generally undertaken at around 28 weeks (see below for

diagnostic criteria). There is significant morbidity associated with GDM including intrauterine fetal death, congenital malformations, neonatal hypoglycemia, jaundice, prematurity and macrosomia. Risk factors for GDM include certain ethnic groups, those with previous GDM or abnormalities of glucose tolerance, age, obesity and previous large babies.

### Risk states

Prior to the 1979 and 1980 reports, the state of “borderline” diabetes had been recognized for cases where there was uncertainty about the diagnosis of diabetes but where plasma glucose was above accepted normal levels. This was formalized by the NDDG and WHO [3,4] as IGT, a higher than normal plasma

**Table 2.3** Other genetic syndromes associated with diabetes. Adapted from World Health Organization [6].

Huntington chorea
Klinefelter syndrome
Lawrence–Moon–Biedl syndrome
Myotonic dystrophy
Porphyria
Prader–Willi syndrome
Turner syndrome
Wolfram syndrome
Others

**Table 2.4** World Health Organization (WHO) recommended criteria for the diagnosis of diabetes and intermediate hyperglycemia.

#### Diabetes

Fasting plasma glucose  $\geq 7.0$  mmol/L (126 mg/dL)  
and/or  
2-hour post-glucose load  $\geq 11.1$  mmol/L (200 mg/dL)  
plasma glucose

#### Impaired glucose tolerance

Fasting plasma glucose  $< 7.0$  mmol/L (126 mg/dL)  
and  
2-hour post-glucose load  
plasma glucose  $\geq 7.8$  and  $< 11.1$  mmol/L (140 and 200 mg/dL)

#### Impaired fasting glycemia

Fasting plasma glucose 6.1–6.9 mmol/L (110–125 mg/dL)  
and (if measured)  
2-hour post-glucose load  $< 7.8$  mmol/L (140 mg/dL)  
plasma glucose

NB. All values refer to venous plasma glucose. Capillary plasma glucose values would be the same fasting but 1 mmol/L (18 mg/dL) higher than venous levels after the glucose load. The glucose load is 75 g anhydrous glucose.

glucose 2 hours after a glucose load but below the diagnostic cutoff for diabetes. Later, both the ADA and WHO introduced the concept of IFG as a fasting plasma glucose above normal but below the diabetes diagnostic level [6,7]. Both IFG and IGT are associated with a two- to threefold increased risk of developing diabetes, while IGT is also a cardiovascular risk marker. IFG was welcomed as it could indicate an at-risk individual without the need to perform a glucose tolerance test. Collectively, IFG and IGT became known as “pre-diabetes” – a misleading term as not everyone with pre-diabetes develops diabetes, and it diminishes the importance of other risk markers such as family history. The term “intermediate hyperglycemia” is preferred by WHO [16]. IGT and IFG are more likely in older people, those who are obese, people from particular high risk ethnic groups and those with cardiovascular disease or other features of the metabolic syndrome, such as dyslipidemia, hypertension or visceral adiposity.

---

## Diagnostic criteria

The diagnosis of diabetes mellitus has lifelong implications for the individual. Thus, both the clinician, and person tested, must have full confidence in the diagnosis. In the symptomatic individual this is easier but in asymptomatic people once an abnormal test has been found it must be confirmed by a further test. This is increasingly important as screening programs spread and also because 30–50% of people with T2DM are asymptomatic and unaware that they have the disorder.

### Clinical diagnosis of diabetes in symptomatic individuals

The search for diabetes in an individual is often driven by the presence of characteristic symptoms such as thirst, polyuria, weight loss, recurrent infections and, in more severe cases, precoma. In such individuals, a single elevated casual plasma glucose value is sufficient to confirm the diagnosis. A definite diagnosis can be assumed if the venous plasma glucose level is greater than 11.1 mmol/L (200 mg/dL) or 12.2 mmol/L (220 mg/dL) in capillary plasma [5]. WHO describes values of 5.0–11.0 mmol/L as uncertain. Further testing is then required as described below.

### Diagnostic tests for diabetes

A raised blood glucose has been the hallmark of diabetes mellitus for over 100 years. The oral glucose tolerance test (OGTT) was developed in the early years of the 19th century but only came into common use as methods for measuring blood glucose became easier. When the first WHO Expert Committee on Diabetes reviewed diagnostic tests [2] they first of all stated that glycosuria was an unsatisfactory test and that neither the presence of glycosuria nor its absence could rule in or rule out diabetes. They also commented on the wide range of glucose tolerance tests available at the time and recommended strongly that only the 50-g or the 100-g OGTT should be used. They suggested that a fasting venous blood glucose level over 130 mg/dL (7.2 mmol/L)

indicated the probability of diabetes. This was for whole blood so that in terms of plasma this would equate to about 150 mg/dL (8.3 mmol/L); however, at that time, most blood glucose chemical tests in use overestimated true glucose by at least 20 mg/dL (1.1 mmol/L). They placed most reliance on the OGTT. They examined both values at 1 and at 2 hours after the glucose load but decided that the 2-hour value on its own was adequate – and this was the key diagnostic test suggested. The value selected was 130 mg/dL (7.2 mmol/L) for venous whole blood and that was to be applied regardless of whether the 50-g or the 100-g glucose load was given. They also introduced the important concept of “borderline” diabetes – the forerunner of IGT – where values were to be above normal but less than those diagnostic for diabetes: 110 mg/dL (6.1 mmol/L) to 129 mg/dL (7.2 mmol/L) for venous whole blood 2 hours after the glucose load.

One further important comment is the need for people to be prepared for the OGTT with at least 250 g carbohydrate consumed for 3 days before the test. This still applies and is rarely adhered to, which may explain the large number of older people with normal fasting glucose but elevated 2-hour values. Many of these could well have “starvation” diabetes rather than genuine diabetes.

### The modern era

The big change and rationalization came in 1979 and 1980 with the work of NDDG and WHO [3,4]. They reviewed all available data and concluded that a 75-g load would be appropriate and that this should be consumed in 300 mL water over 5 minutes. They based the diagnostic levels for fasting and 2-hour values largely on bimodality observations in high prevalence groups such as the Pima Indians and on some observations of risk for retinopathy. Fasting and 2-hour venous plasma levels of 140 mg/dL (7.8 mmol/L) and 200 mg/dL (11.1 mmol/L) were recommended by NDDG and these were – somewhat unfortunately – rounded up to 8 mmol/L and 11 mmol/L by the WHO Committee. IGT was defined as a fasting venous plasma value <8 mmol/L with a 2-hour value of 8–11 mmol/L. Confusion was rife and a further evaluation took place in 1985 [5] when the WHO group adjusted their values to match the NDDG values precisely.

The next big change occurred in 1997 and 1999 with the publication of the ADA and the new WHO report. This time a considerable amount of data were available to look at risk of retinopathy at different glucose levels. The data were cross-sectional but reasonable agreement was shown between studies of Egyptians, US citizens from NHANES III and Pima Indians (for review see Expert Committee on the Diagnosis and Classification of Diabetes Mellitus [7]). Although there was some tolerance on the precise values, the existing 2-hour cut point of 11.1 mmol/L (200 mg/dL) seemed reasonable but the fasting value was lowered to 7.0 mmol/L (126 mg/dL; Table 2.4). At the same time, the concept of IFG was introduced. This was equivalent to IGT but for the fasting state and was meant to indicate a risk state for diabetes. The values chosen were 6.1–6.9 mmol/L (110–125 mg/dL).

There was one major difference between the ADA and WHO proposals. ADA recommended that a fasting glucose alone could be used for diagnostic purposes and that an OGTT was unnecessary. Similarly, the implication was that fasting glucose could be used as a screening test to identify people at risk without requiring a glucose tolerance test. This was not agreed by the WHO group who continued to promote the use of the OGTT where necessary. Part of the reason is that a considerable number of people with diabetes by the 2-hour value have normal or IFG values when fasting.

The final changes came in 2003 when a new ADA group recommended lowering the threshold for IFG to 100 mg/dL (5.6 mmol/L) which was considered by WHO in 2006 but not supported [17].

### Problems with glucose tests

Measurement of glucose has been the cornerstone and bedrock of diabetes diagnosis for the last 100 years; however, it does have problems. Initially, the assays measured reducing sugars and were not specific. Enzyme assays have largely negated this problem. Accuracy and precision are not problems in well-run laboratories with appropriate quality assurance in place but the advent of glucose meters has caused problems. They are efficient if carefully used, properly controlled and calibrated but the coefficient of variation can often be as high as 20% in field use, making them unsuitable for diagnostic purposes. There are other problems: unless blood is separated immediately after withdrawal from the subject there is a steady loss of glucose even when fluoride or other preservatives are present. This can range from 5 to 20%.

There are also potential problems with the subject tested. Fasting glucose is reasonably reproducible but can be influenced by drugs or coexisting conditions, or the patient may not have fasted appropriately. The OGTT is notoriously variable from day to day within the same individual and is unreliable when they are close to the threshold for diagnosis. It has long been deemed the gold standard but this is more by common usage and because there was no alternative. This has become more important as more screening programs take place and people with asymptomatic diabetes are sought.

### Use of HbA<sub>1c</sub> as a diagnostic test for diabetes

The introduction of HbA<sub>1c</sub> as a means to test glycemic control has had an enormous impact on patient care. It has been proposed many times that it could prove a useful means of diagnosing diabetes as it requires neither fasting nor an OGTT. It also represents glycemic status over weeks and gives real certainty that a person is indeed hyperglycemic. It is also subject to fewer errors within an individual patient although it can obviously be affected by conditions such as anemias and hemoglobinopathies. The arguments against, which were reaffirmed by WHO in 2006 and ADA in 2003, were that the test was not sufficiently standardized, the quality of assays was variable, the test is expensive and it is not available at all in many parts of the world.

Recently, the situation has changed. There is now an international standard that is coming into widespread use and assays are reliable and show only small variation within and between assays in good laboratories. In the USA, the situation has been helped by the National Glycohemoglobin Standardization Program which has promoted standardized assays based on data from the Diabetes Control and Complications Trial. Several other countries also have standardized programs in place.

A groundswell of support has appeared suggesting that it would indeed be a useful addition to the diagnostic armamentarium for diabetes. Several authors have suggested its use in addition to fasting glucose [18]. In particular, an Expert Committee led by the ADA has endorsed the use of HbA<sub>1c</sub> as a new means of diagnosing diabetes and identifying those at high risk of developing the disorder [19]. One problem concerns the appropriate diagnostic level at which to diagnose diabetes. Many suggestions have been made but that proposed by the Expert Committee [18] of 6.5% (47.5 mmol/mol) is gaining acceptance. This is based primarily on three cross-sectional studies that looked at fasting glucose, 2-hour glucose and HbA<sub>1c</sub> in relation to retinopathy [7,20,21]. These were the same studies that were used to confirm the diagnostic glucose levels, fasting and after a glucose load. This has been supported by a recent analysis of 13 studies including the earlier three which showed that moderate retinopathy was virtually never found at levels below 6.5% (<47.5 mmol/mol) [22]. One problem is that the methods to detect retinopathy are much more sensitive now than previously and recent studies show background retinopathy occurs in 10% of normoglycemic individuals [23]. It is thus probably wise to use moderate retinopathy to determine cutoff diagnostic values. It has also been suggested that HbA<sub>1c</sub> levels of 6.0–6.4% (42–47 mmol/mol) or 5.7–6.4% (39–47 mmol/mol) could be used to indicate those at high risk – similar to the use of IGT and IFG.

It seems likely that HbA<sub>1c</sub> will be accepted for use as a diagnostic test. This should only be done in countries where stringent quality assurance and standardization against international standards are possible. It is also unsuitable in pregnancy. A new WHO Expert Committee has met to consider the use of HbA<sub>1c</sub> but has not yet reported. Nevertheless, there are still various concerns about the use of HbA<sub>1c</sub>. It is likely that some different individuals will be identified by HbA<sub>1c</sub> and glucose. There is also the likelihood that prevalences of diabetes will be different. It is assumed by many that the glucose derived data are correct but the 2-hour glucose is a somewhat tarnished gold standard. It is indeed possible that HbA<sub>1c</sub> will give more accurate diagnosis as it reflects a longer period of hyperglycemia rather than a single point in time and it is not subject to the same analytical and pre-analytical problems as glucose.

In most places glucose – casual, fasting and after a glucose load – will continue to be used routinely for the diagnosis of diabetes; in some countries (e.g. USA, Australia, Japan and Northern European countries), however, HbA<sub>1c</sub> is likely to be the preferred test in the near future. This has indeed now been recommended by the ADA [24].

### Gestational diabetes mellitus

Two different tests are widely used for the diagnosis of GDM. WHO recommends that the normal 75-g glucose load be given after an overnight fast and that those with either IGT or diabetes by non-pregnant criteria are deemed to have GDM [6].

In the USA, a two-step procedure is employed. First, a 50-g glucose load is given. If the 1-hour venous plasma glucose is  $\geq 140$  mg/dL (7.8 mmol/L) then the patient returns for a further test using either a 100 or 75 g glucose load. The cutoffs for venous plasma glucose are 95 mg/dL (5.3 mmol/L) fasting, 180 mg/dL (10 mmol/L) at 1 hour and 155 mg/dL (8.6 mmol/L) at 2 hours, regardless of which glucose load is used [17]. The WHO protocol is obviously simpler and has gained widespread acceptance; however, new recommendations are expected imminently in light of the results from the recent Hyperglycemia and Pregnancy Outcomes Study [25].

### Keypoints

- Type 1 diabetes mellitus (T1DM) develops in genetically susceptible individuals after a preclinical phase of variable length usually with immune-mediated destruction of pancreatic  $\beta$ -cells, and requires lifelong treatment with insulin.
- The disease can occur at any age, but the incidence peaks around puberty. Classification of T1DM vs type 2 diabetes (T2DM) becomes increasingly difficult with age.
- In childhood, the incidence is similar in females and males, but there is a 1.3- to 2.0-fold male excess in incidence after about 15 years of age in most populations.
- The incidence in childhood varies enormously between countries. Some Asian and South American populations have low incidences (approximately 0.1–8 per 100 000/year), while Finland (>40 per 100 000/year), Sardinia (approximately 38 per 100 000/year) and Sweden (approximately 30 per 100 000/year) have high incidences. North America (15–25 per 100 000/year) and Australia (approximately 15 per 100 000/year) have moderate to high incidences, while eastern countries in Europe have low to moderate incidences (4–10 per 100 000/year).
- About 10–20% of newly diagnosed childhood cases of T1DM have an affected first-degree relative. Those with an affected sibling or parent have a cumulative risk of 3–7% up to about 20 years of age, compared to cumulative risks of 0.2–0.8% in the respective general populations. The cumulative incidence among the monozygotic co-twins of persons with T1DM is less than 50%, even after >30 years' follow-up.
- Some of the geographic differences and familial aggregation may be explained by human leukocyte antigen haplotypes.
- The incidence of childhood-onset T1DM has increased 3–4% per calendar year, and there is a tendency towards younger average age at onset over time which cannot be explained by genetic factors. The causes of this increasing trend are not known.
- Virus infections and nutritional factors have been implicated, but no specific environmental factor has been established as a risk factor.
- Even though insulin replacement therapy and other advances in the management of T1DM have improved the prognosis of patients with T1DM, their mortality is still at least two times (approximately 2- to 10-fold) higher than in the background population. This is because of both acute and chronic complications of the disease, including cardiovascular disease after about 30 years of age.

### Introduction

Type 1 diabetes mellitus (T1DM) requires lifelong treatment with insulin, and in the majority of cases results from a cell-mediated autoimmune destruction of the  $\beta$ -cells in susceptible individuals. This occurs after a long but variable preclinical period when islet autoantibodies to insulin, glutamine acid decarboxylase (GAD) and insulinoma-associated antigen 2 (IA-2) and other autoantigens can be detected [1]. Autoantibodies are not thought to cause the disease, but are markers of ongoing  $\beta$ -cell destruction. In general, the distinction between autoimmune T1DM (type 1 A

according to the WHO [2]) and non-autoimmune T1DM (type 1 B) is not necessarily useful for clinicians or epidemiologists. Problems with measurement error of autoantibodies, the likely existence of additional autoantibodies (as indicated by the recent discovery of zinc transporter 8 autoantibodies [3]) and, perhaps equally important, the transient nature of autoantibodies, make accurate estimates of the proportion of autoimmune T1DM problematic. From longitudinal studies such as DAISY, it is known that some patients with newly diagnosed T1DM are negative for all autoantibodies at diagnosis while having previously been positive.

Genetic factors influence the susceptibility to T1DM, particularly human leukocyte antigen (HLA) genes [4,5]. It is particularly the combination of HLA DR3-DQ2 and DR4-DQ8 that confers very high risk of T1DM, while those who carry only one

of the two risk haplotypes have moderately increased risk. More details on the role of genetic factors and the pathologic process are covered in the first part of Chapter 9. Diagnosis of T1DM among children is considered relatively simple, typically with very high glucose levels and clear dependence upon insulin, but classification and early detection becomes increasingly difficult with increasing age.

### Occurrence of T1DM by age, sex, place and time

The World Health Organization (WHO) DIAMOND Study (Multinational Project for Childhood Diabetes) [6] and the EURODIAB ACE Study [7,8] have collected standardized incidence data for T1DM among children aged under 15 years, based on notification by the diagnosing physician and date of diagnosis, defined as the date of first insulin injection. In both projects, the degree of undercounting of cases has been estimated using a second source of information [9].

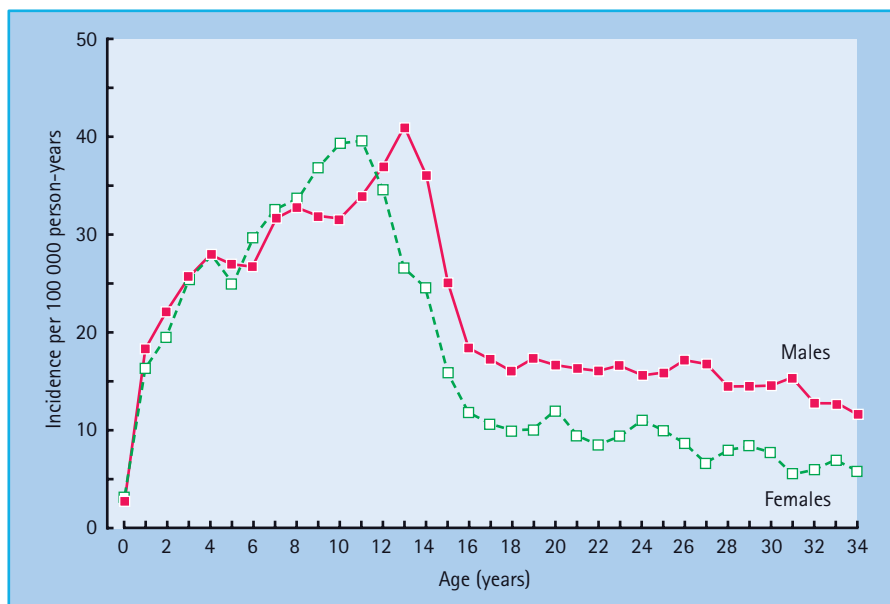

Incidence rates are calculated as the number of new cases per 100 000 person-years, where person-years are estimated as the number of individuals in the population contributing the incident patients during the study period (mean population size in each calendar year, sex and age group) multiplied by the number of years covered by the age group in question. The proportion of the population expected to develop the disease by a certain age can be approximated by multiplying the average incidence rate in an age group by the number of years covered by the age group, the cumulative incidence rate. For instance, if the average incidence rate among 0- to 14-year-olds is 20 per 100 000 person-years, then  $([20/100\,000] \times 15 = 0.003 =)$  0.3% of children in that population will develop disease before they reach 15 years of age. The prevalence of disease among 0- to 14-year-olds is thus less than the cumulative incidence up to 15 years of age.

Most of the incidence data available today come from studies of children in European countries. Incidence data from Africa are still sparse, but increased information on the incidence of T1DM among Asian and South American populations has changed the understanding of the global patterns in variation in incidence.

### Occurrence of T1DM by age

In principle, T1DM may occur at any age, but it is very rare in the first year of life and becomes increasingly difficult to distinguish from other types of diabetes after about 30 years of age. Essentially all populations display a steady increase in incidence rate with age up to around 10–15 years [6], but recent data from Finland indicate an incidence in 0- to 4-year-olds that is nearly as high as that in 10- to 14-year-olds [10]. The incidence rate increases from birth to peak at around puberty (Figure 3.1) and in most populations is lower among 15- to 29-year-olds than among 0- to 14-year-olds [11–15]. In some populations there seems to be a second rise in incidence after the age of about 25–30 years [16–18].

In the Swedish nationwide prospective incidence study of 15- to 34-year-olds, 78% of the newly diagnosed patients were classified as having T1DM and 15% as having type 2 diabetes mellitus (T2DM) at the time of the diagnosis [19]. The follow-up showed that 92% of patients diagnosed before 30 years of age were treated with insulin at a later date [20]. These findings are consistent with recent incidence data from Finland among 15- to 39-year-olds [21,22]. In these studies, the incidence of T2DM exceeded that of T1DM by the age of about 30 years. By contrast, in Turin, Italy, which has a much lower incidence of T1DM, the incidence of T2DM is about three times higher than that of T1DM at the age of 30 years [16]. Although beyond the scope of this chapter, it is important to consider the possible clinical heterogeneity and increasing difficulty of classification of diabetes with increasing

**Figure 3.1** Incidence rate of type 1 diabetes per 100 000/year in Swedish males and females by age during 1983–1998. Reproduced from Pundziute-Lyckå *et al.* [14], with permission from Springer-Verlag.

age [23,24]. A proportion of the apparent heterogeneity may represent extremes within a continuum, although there is a need for more data in this field [24].

There is a lack of population-based incidence data for age groups above 35 years of age. The only published population-based incidence studies covering the incidence of T1DM over the whole age span is one from Rochester, Minnesota, 1945–1969 [25] and from Denmark, 1973–1977 [26]. The latter study indicated that the cumulative probability of developing T1DM before age 80 years is in the range of 1–1.5%.

### Incidence by sex

The peak in incidence rate among children occurs slightly earlier in girls than boys (Figure 3.1), suggesting an influence of puberty. During the 1970s there was a male excess of T1DM in children in populations of European origin and a female excess in populations of African and Asian origin [27]; however, during the early 1990s, the sex-specific pattern in incidence among children changed towards more modest differences. Of 112 centers with data during 1990–1999, only six showed a significant excess of females (Beijing, Hong Kong and Zunyi in China, New South Wales in Australia, Puerto Rico and the Afro-American ethnic group in the USA) and six centers showed a significant male excess (West Bulgaria, Finland, Attica in Greece, Switzerland, Oxford in the UK and the Dominican Republic), and all differences were generally of modest magnitude [6]. The general impression is still that it is the high incidence countries that tend to have a slight male excess, while the opposite is seen in low incidence countries. Many studies have shown a male excess in the incidence of T1DM among young adults [15,28]. While the male:female ratio among children in most populations is 0.9–1.1 [6], the male:female ratio among young adults ranges from about 1.3 up to 2.0 in many populations [15,28].

### Incidence by country

The incidence rate of T1DM among childhood populations shows a vast geographic variation worldwide (Figure 3.2) [6–8,29]. Over the period 1990–1999, the age-adjusted incidence rate of T1DM ranged globally from 0.1 in Zunyi (China) and Caracas (Venezuela) to 37.8 in Sardinia and 40.9 per 100 000/year in Finland [6]. The most recent data from Finland indicate an incidence rate of nearly 60 per 100 000 in 2006 [10], the highest incidence ever recorded.

European countries are well represented with registries, and there is an approximately 10-fold difference between highest and lowest incidence countries in Europe [7], with the apparently lowest rate of 3.6 per 100 000/year in Macedonia during 1989–1994. Sweden has a high incidence rate (30 per 100 000/year). Centers from France and mainland Italy, for instance, report intermediate incidence rates around 10 per 100 000/year, while some other European countries have intermediate to high incidence rates [6]. In general, the incidence rates are low in eastern European countries, although the most recent EURODIAB data show that for several countries where the incidence rate previ-

ously was below 10 per 100 000/year, the incidence rate during 1999–2003 has increased to 10 per 100 000/year or more, for example in Lithuania, Bucharest in Romania and in Katowice in Poland [8].

Standardized data for the age group 15–29 years from European centers (in Belgium, Lithuania, Romania, Sardinia, Slovakia, Spain, Sweden and the UK) during 1996–1997 showed incidence rates between 5 and 12 per 100 000/year [15]. Incidence rates among 15- to 29-year-olds within this range have also been reported, albeit from earlier time periods, in other European centers, such as 5.5 per 100 000/year in Rzeszow, Poland, 1980–1992 [30], approximately 7 per 100 000/year in Turin, mainland Italy 1984–1991 [16,31] and approximately 13 per 100 000/year in two regions of Denmark, 1970–1976 [11].

While Sweden and Sardinia have higher incidence rates among children, the incidence rate among young adults was not much higher in Sardinia and Sweden than the other centers in the multicenter study [15]. Older data from Norway (1978–1982) [13] indicated a higher incidence rate of 17 per 100 000/year and recent data from Finland (1992–2001) [21] indicated an incidence rate of 18 per 100 000/year among 15- to 29-year-olds. Differences between countries in the incidence among young adults should be interpreted with caution until more data are collected using comparable methodology.

The USA is represented with the data collected during the 1990s from Allegheny County in Pennsylvania, Chicago and Jefferson County in Alabama, with incidence rates in the range 11–18 per 100 000/year among children. Alberta and Calgary in Canada had slightly higher rates (about 23 per 100 000/year; Figure 3.2) [6], while the data from the Avalon Peninsula, Newfoundland, indicated a higher incidence rate of 35.9 per 100 000/year [32].

In South America, children in centers in Venezuela, Paraguay and Colombia had incidence rates of less than 1 per 100 000/year, Chile (Santiago) had around 4 per 100 000/year, while Argentina and Brazil had an average of around 8 per 100 000/year. Many centers in Central America and the West Indies (except Puerto Rico and St. Thomas) generally have low to intermediate incidence rates, with indications of decreasing time trends [6].

Data from New Zealand and parts of Australia show moderate to high incidence rates (15–25 per 100 000/year) among children [6]. Data from other Pacific Island countries are lacking, and would be difficult to interpret because the populations in most island countries are small. In Asia, the mean incidence rate among the 23 centers in China during the early 1990s was 0.8 per 100 000/year. Japan has a slightly higher average incidence rate of 1.7 per 100 000/year among three centers, while Kuwait stands out with a high incidence rate of 22 per 100 000/year.

There is limited information on the incidence rate of T1DM from sub-Saharan Africa [33]. The five DIAMOND centers are all in North Africa (Algeria, Libya, Sudan and Tunisia) or Mauritius, an island off the coast of Madagascar. Incidence rates reported from these centers range from low to intermediate, but these countries cannot be said to be representative of Africa.

**Figure 3.2** Geographic variation in childhood onset type 1 diabetes incidence rates, 1990–1999. Note that most registries were not nationwide and that several countries display within-country variation. Reproduced from the Diamond Project Group [6] with permission from John Wiley & Sons Ltd, Chichester.

**Variation in incidence within countries, including by ethnic group**

In several countries, marked within-country variations in the incidence rate of T1DM have been reported. For instance, up to 1.5-fold differences have been described within relatively homogenous populations, such as Finland, Sweden and Norway [34–36]. In Italy, the incidence rate among children in Sardinia 1990–1999 (38 per 100 000/year) was three to six times higher than the average in mainland Italy, where the incidence rates vary twofold from 6.3 in Campania to 12.2 per 100 000/year in Pavia in the same period [37]. In China, there was a 12-fold geographic variation (0.13–1.61 per 100 000), generally with higher incidence

in the north and the east. In addition, there was a sixfold difference between the Mongol (1.82 per 100 000) and the Zhuang (0.32 per 100 000/year) ethnic groups [38].

The variation in incidence within some countries may in part be because of ethnic heterogeneity of populations. For instance, the 1.5-fold higher incidence among children in the South Island of New Zealand compared with that in the North Island was largely explained by the 4.5 times higher incidence among children of European origin compared to that among Maoris [39].

Several methodological problems arise when making inferences based on epidemiologic studies of different ethnic groups and immigrants. These include differential ascertainment and

**Figure 3.3** Seasonal variation in diagnosis of type 1 diabetes among >22,000 children diagnosed 1989–1998 in European centers, by age at onset. \*Age (years) at first insulin injection. Reproduced from Green & Patterson [7], with permission from Springer-Verlag.

definition of ethnic group, underestimation of the base population in some ethnic groups, genetic admixture and possible heterogeneity in clinical presentation [24,40,41]. Among childhood onset cases, however, it seems that the large majority, even in Japan [42], have classic autoimmune T1DM. Historically, the incidence of T1DM has been higher in populations of European origin, particularly those living in Europe, than that among populations of non-European origin [40,41]. Despite the previously reported lower incidence among African-American and Latino populations in the USA, the incidence among these groups in the USA seems currently not very different from children of European origin in the USA [6,41]. The incidence rates of T1DM in most South American studies with standardized registries seems to be much lower than that among Latino people in the USA and lower than that among Spaniards living in Spain [40].

The incidence of T1DM among children of immigrant parents to Germany, Sweden and mainland Italy has been shown to correlate with the incidence in the country or region of origin of their parents, whether the incidence in the country of origin is higher or lower [43–45]; however, the incidence among immigrants from Pakistan to the UK (or their children) is similar to that among the native Britons [46,47], despite the very much lower incidence recorded in Karachi, Pakistan [6].

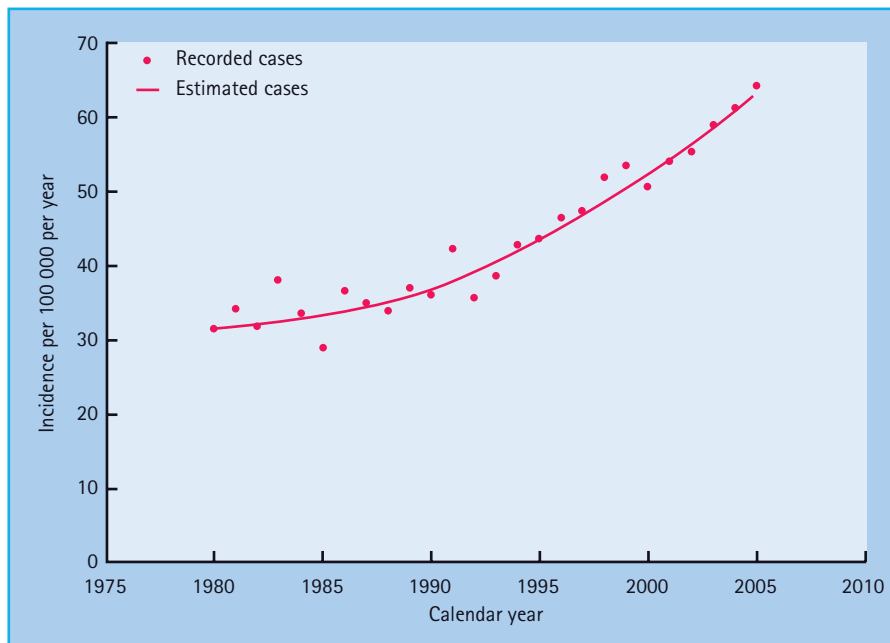

In summary, although there are clear ethnic differences in incidence rate of T1DM and strong evidence for a role of genetic factors, some of the abovementioned studies also support a role for yet unidentified environmental factors.

### Seasonal variation in diagnosis of T1DM

Several studies have reported a peak in the number of cases diagnosed in the autumn and winter, and a smaller proportion of the cases diagnosed in the spring or summer, consistent both in the northern and southern hemispheres [7,12]. Although reasonably consistent, there is some variation in exact peak and nadir between countries, age groups, sexes and periods. Generally, the degree of seasonal variation is stronger among those diagnosed at age 10–14 years than in younger children (Figure 3.3) [7]. Different methods have been used in the analysis of seasonal variations, and often with data covering relatively short periods of time and limited number of cases; the results are therefore not necessarily comparable. Interpretation of seasonal variation must be carried out in light of the long and variable preclinical period in T1DM, and it is speculated that viral or other periodic factors have a role in the timing of the precipitation or onset of the disease in susceptible individuals who would develop it sooner or later.

### Trends in incidence over time

The methodology for population-based incidence registries was not standardized until the late 1980s, but a number of older data sources have been reviewed to assess possible time trends. There is a general impression that the incidence of T1DM increased strongly after the middle of the 20th century [48,49], although in Denmark, the incidence among 0- to 29-year-olds seemed stable from 1924 to the 1970s [11]. An analysis of incidence trends of

**Figure 3.4** Time trend in incidence rate of type 1 diabetes diagnosed before 15 years of age in Finland. Reproduced from Harjutsalo *et al.* [10], with permission from Elsevier.

more standardized registry data from 1960 to 1996 in 37 populations worldwide showed a significant increase in incidence rate over time in the majority of populations, with a steeper relative increase in low-incidence than in high-incidence populations [50]. In Finland, the incidence rate has increased linearly from the mid 1960s to the mid 1990s [51] and thereafter even more steeply, reaching almost 60 per 100 000/year in 2006 (Figure 3.4) [10].

In the 103 centers participating in the WHO DIAMOND project for at least 3 years during 1990–1999, the overall relative increase in incidence rate was 2.8% per year [6]. By continent, overall increasing trends per year were estimated at 5.3% in North America, 3.2% in Europe and 4.0% in Asia [6]. The only region with an overall decreasing trend was Central America and the West Indies [6].

In general, the increasing trend appeared to be strongest in the centers with high and very high incidence rates during the 1990s. In the centers with low and very low incidence rates, there were no significant increases in incidence rates over time. However, the 15-year (1989–2003) time trends in Europe reported to EURODIAB indicated an overall mean increase in incidence rate of 3.9% per year, with a tendency towards stronger relative increases in the countries with lowest average incidence rates during the first 5 years (1989–1994) [8].

Overall, the relative increase over time during the 1990s among the DIAMOND centers was most pronounced in the younger age group: 4.0% among 0- to 4-year-olds, 3.0% in the 5- to 9-year-olds and 2.1% in the 10- to 14-year-olds, similar for boys and girls in most centers. The pattern of a steeper relative increase among the youngest was seen in Europe and Oceania,

but not in Asia and North America [6]. A smaller relative increase in incidence rate over time among older individuals than among younger ones has also been seen in European studies covering wider age ranges [14,17,18,52,53]. This latter observation is in line with a model where a certain pool of genetically susceptible individuals contract the disease at younger ages [14,17,54]. The few available data, however, are not entirely consistent with this idea. An increasing incidence rate has been seen also among older age groups in some populations [18,22,31], but the lack of standardized incidence data covering the whole age range makes it difficult to draw firm conclusions. Note that despite the time trends indicated in Sweden with decreasing average age of onset, the peak incidence rate remained around the age of puberty [14].

### Familial clustering and twin studies

Besides providing clues regarding the relative importance of genetic and non-genetic factors in the etiology of disease, data on risk of T1DM among people with affected relatives may also aid the clinician in counseling of family members of newly diagnosed patients. Around 80–90% of newly diagnosed T1DM patients do not have any affected siblings or parents, but first-degree relatives of a person with T1DM are at increased risk. By the age of 20 years, approximately 4–6% of siblings of T1DM probands have been reported to develop T1DM in European origin populations [55–57], compared with around 0.2–1.0% in the corresponding background populations. The offspring of affected fathers have

**Figure 3.5** Diabetes-free survival in non-diabetic monozygotic twins whose co-twin had type 1 diabetes, after several years of follow-up. Dotted lines represent 95% confidence intervals. Reproduced from Redondo *et al.* [63], with permission from Springer-Verlag.

1.5–3 times increased risk of T1DM compared with the offspring of affected mothers [58,59]. By 20 years of age, 5–8% of the offspring of men with diabetes, but only 2–5% of the offspring of women with diabetes have been found to be affected. There is currently no accepted explanation for this phenomenon.

Given the well-established effect of genetic factors, there is no surprise that the concordance rate for T1DM in monozygotic (MZ) twins is much higher than that in dizygotic (DZ) twins [60,61]. In one study from North America, the estimated cumulative risk 10 years after onset in the proband (diagnosed before age 40 years) was about 25% in MZ twins and about 11% in DZ twins [62]. Corresponding 10-year cumulative risks from Finland were estimated to 32% for MZ twins and 3.2% for DZ twins [61]. Comparable estimates were also found in the Danish twin registry, although the exact age at onset was not known in this study [60]. In general, the risk for the co-twins was higher and the discordance time shorter the earlier the onset in the proband [61–63]. In a long-term follow-up of discordant MZ twins from the USA and the UK, more than 50% of MZ pairs remained discordant for T1DM (Figure 3.5) [63]. Because MZ twins share 100% of their genomic DNA, this suggests that genetic susceptibility is in most cases not sufficient for the development of disease.

Despite the relatively high proportion of MZ twins being discordant for clinical T1DM, many of the non-diabetic co-twins of patients with T1DM develop islet autoimmunity [64]. Together with the limited variation in prevalence of positivity for islet autoantibodies between countries [54] and animal studies suggesting a two-stage disease process [65], this supports the idea that environmental factors may have a more important role in the progression from islet autoimmunity to overt disease.

### Environmental risk factors for T1DM: clues from epidemiologic studies

The time trends described above must be ascribed to some change in the environment, even in the event that the increase is brought about by a change in the age distribution. Some of the variation in incidence rate between European countries can be explained by differences in the frequency of HLA susceptibility genotypes [66], but clearly not all [67]. It has recently been suggested that the proportion of newly diagnosed patients with T1DM who carry the highest risk genotype (DR3-DQ2/DR4-DQ8) has decreased over time (reviewed in [68]). It may be speculated that increased exposure to some risk factor or decreased exposure to some protective factor have caused more individuals with moderate risk (“permissive”) genotypes (e.g. either DR3-DQ2 or DR4-DQ8, but not both) to develop T1DM in recent years. Although there is overwhelming evidence for an essential role of genetic factors in the etiology of T1DM, available evidence strongly suggests that one or more non-genetic factors are also involved; however, the nature of these putative factors are not well known.

In general, environmental factors may be envisioned to have a role in the following:

- 1 Initiating of the autoimmune disease process;
- 2 Modulating the progression from islet autoimmunity to clinical T1DM; or
- 3 “Precipitating” disease in individuals with advanced preclinical disease.

Little is known about the initiation of autoimmunity in humans [69], but some form of immune-mediated mechanism leading to the breakdown of self-tolerance is likely to be involved. Limited geographic variation in the prevalence of islet autoim-

munity despite the large differences in incidence of T1DM between countries suggests a major importance of environmental factors in the progression from islet autoimmunity to T1DM [54], although the hypothesis that there are environmental triggers of autoimmunity cannot be discarded [70]. Responsible factors may operate by modulating the immune system and metabolism. *In vitro* experiments have suggested that actively insulin-secreting  $\beta$ -cells hyperexpress islet autoantigens such as GAD, and are more susceptible to toxic effects of the cytokine interleukin  $1\beta$  (71). It may be speculated that factors that increase the stress on  $\beta$ -cells may non-specifically contribute to the precipitation of clinical disease [71]. This includes insulin resistance or other mechanisms implied in infections, puberty and growth spurts. Insulin resistance is not easy to measure reliably in humans, but several studies have found measures of insulin resistance relative to first-phase insulin response to an intravenous glucose tolerance test to be predictive of progression to T1DM (reviewed in [72]). Below, some of the most frequently studied non-genetic factors with a potential role in the etiology of human T1DM are discussed.

### Specific putative environmental factors

#### Viral infections

There is a large body of literature linking infections and T1DM, ranging from *in vitro* studies [73], experiments with various animal models [74], clinical and pathologic studies of patients with disease [73,75–77] and epidemiologic case–control and cohort studies [12,70,78]. Congenital rubella syndrome (CRS) has been associated with a several-fold increase in the incidence of T1DM [79]. Although not contributing to the incidence of T1DM in most countries today, this observation has been cited as a proof of principle that intrauterine factors and viral infections in general can influence the risk of T1DM in humans. It probably remains the best example of a non-genetic factor contributing to increased risk of T1DM in humans, but the consistency of the available evidence and the absolute risk associated with CRS may have been overstated [80,81].

Several early studies based on assays for antibodies to enteroviruses in cases with T1DM and controls initially seemed promising, but systematic review of the data showed too much heterogeneity in methodology and results to draw any conclusion [78]. Prospective study design and detection of enterovirus RNA represent important contributions to the methodology of such studies in recent years. Increased risk of childhood onset T1DM has been associated with evidence of maternal enterovirus infections during pregnancy in some studies, but not in all [82]. Using both serum enterovirus antibodies and RNA as indications of postnatal infection, independent prospective studies from Finland have found enterovirus to be associated with increased risk of islet autoimmunity and T1DM [70], while other similar studies have not found any significant association [83]. A recent immunohistochemical study of stored sections of pancreatic biopsies obtained postmortem in young individuals with recent onset T1DM found that the  $\beta$ -cells of multiple islets stained positive for enterovirus

capsid protein VP1 in 44 of 72 cases. Very few of the controls in that study stained positive [77]. This study substantiated previous evidence based on one or a few patients [73,74] and indicated problems with the methods used in a previous study of a similar material where no such evidence was found [84]. Nevertheless, to confirm these findings in the future, *in situ* hybridization should be used to assess the presence of enterovirus RNA (rather than protein) in a larger number of islets from people with recent onset T1DM and the lack thereof in appropriate controls. Enterovirus infections are common and there is evidence that the frequency of infection has decreased with improved hygiene in the recent decades, opposite to the trend seen for T1DM. It has been postulated that the increasing incidence of T1DM in children may in part be explained by decreased protection from maternal enterovirus antibodies [85]. A more direct test of this hypothesis is still lacking.

The so-called “hygiene hypothesis” comes in different versions but essentially proposes that the decline in microbial exposure in many populations over the past few decades has caused the concomitant increase in incidence of immune-mediated diseases including T1DM [86]. Some infections and microbial agents reduce the incidence of autoimmune diabetes in experimental animals [74]. Epidemiologic studies have investigated non-specific infections and infectious symptoms, but the results have been inconsistent. Daycare attendance is usually associated with increased exposure to microbial agents, and a recent meta-analysis concluded that there is some evidence for a lower risk of T1DM among children who attended daycare centers early in life, but the results were not sufficiently homogenous to allow a strong conclusion [87].

There are many promising observations supporting a possible role of viral infections in the etiology of T1DM, but the current evidence that infections have an important and causal role in human T1DM is not conclusive. Although the problem of identifying the potential strain of enterovirus that might be diabetogenic would pose an additional problem, vaccine development towards such a strain might be envisioned in the future as a preventive measure, but it is currently unknown whether or when this could be feasible.

#### Toxins

The rodenticide Vacor has been associated with T1DM in humans after ingestion of large doses [88]. There are structural and mechanistic similarities between Vacor and streptozotocin and alloxan [88], which are specifically toxic to  $\beta$ -cells, and used to induce diabetes in experimental animals [88,89]. Some epidemiologic studies have assessed intake of nitrates and nitrites, which may be converted to related N-nitroso-compounds, but most studies have used ecologic study designs and assessed levels in community drinking water, which is probably a poor indicator of total exposure. A potential diabetogenic role of *in utero* exposure to bafilomycin, a toxin produced by bacteria growing on the skin of root vegetables such as potatoes, has been suggested based on experiments with rodents and *in vitro* studies [90]. In a prospec-

tive study there was no support for the idea that frequent potato consumption during pregnancy could increase the risk of islet autoimmunity in the offspring, but it is unknown whether frequency of potato intake really is a marker for bafilomycin exposure [91]. In conclusion, there is little direct evidence for a widespread role of toxins in human T1DM, but this may reflect the lack of well-conducted studies.

### **Nutritional factors**

Several possible plausible mechanisms have been proposed to link dietary factors to T1DM, including “molecular mimicry” and a detrimental effect of bovine insulin in cow’s milk (reviewed in [92]). A reduced risk conferred by prolonged breastfeeding and/or delayed introduction of cow’s milk has been suggested in many case–control studies, but most of these studies were susceptible to recall bias and the issue is controversial [93]. In the largest prospective study to date involving multiple islet autoantibodies or T1DM as the endpoint, there was no significant association with duration of exclusive or total breastfeeding [94]. Duration of breastfeeding was also not associated with self-reported T1DM up to age 30 years in a recent prospective study including 61 cases [95]. It is hoped that an ongoing randomized controlled trial (TRIGR) will provide an answer to whether delayed introduction of cow’s milk protein can reduce the risk of islet autoimmunity and T1DM [96]. Two prospective studies of islet autoimmunity have provided some evidence for a role of age at introduction of cereals or gluten [97,98], although the relation is complex and difficult to interpret.

The immunomodulatory effects of vitamin D and preventive effect of pharmacologic (hypercalcemic) doses of 1,25-dihydroxyvitamin D on diabetes development in experimental animals have been documented in several studies [99]. Systemic concentration of 1,25-dihydroxyvitamin D is tightly controlled by hydroxylation of 25-hydroxyvitamin D, and this must be taken into account when evaluating experimental results from animal models. Vitamin D is also produced in the skin upon exposure to ultraviolet light, and no prospective study has yet been published of serum 25-hydroxyvitamin D, which is an established marker of vitamin D status, and risk of T1DM. A multicenter case–control study found a significantly lower risk of T1DM associated with reported use of vitamin D supplement in early life [100], although recall and selection bias may have affected these findings; however, this was also supported by a prospective Finnish study [101]. Prospective studies of maternal intake of vitamin D via food during pregnancy and risk of islet autoimmunity in children have not produced convincing evidence for any relation [102].

A case–control study in Norway found an association between use of cod liver oil in the first year of life and lower risk of T1DM [103]. Cod liver oil, which is commonly used in Norway, is an important source of both vitamin D and long-chain n-3 fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in this population. The lack of association with other vitamin D supplements in these studies supports a role of n-3

fatty acids rather than vitamin D. Although recall bias cannot entirely be ruled out from the latter study, support for the hypothesis that intake of dietary n-3 fatty acids may prevent islet autoimmunity and/or T1DM recently came from a prospective study including both dietary assessment and analysis of fatty acid composition of red cell membranes, which is a biomarker of n-3 fatty acid status [104]. Plans are underway to initiate a randomized intervention trial to prevent islet autoimmunity and/or T1DM using DHA supplements.

Despite previous indications from two prospective studies that serum alpha-tocopherol (vitamin E) could be associated with lower risk of T1DM, there was no association with advanced islet autoimmunity or T1DM in early life in the DIPP study [105]. In conclusion, the role of nutritional factors in T1DM remains uncertain.

### **Perinatal factors and postnatal growth**

Offspring of non-diabetic mothers aged 35 years or more when giving birth have an approximately 20–30% increased risk compared with offspring of mothers who are 25 years or less [106–108]. Results for birth order and for paternal age have been less consistent [106,108]. Birth by cesarean section was recently associated with an approximately 20% increased risk of T1DM in children according to meta-analysis of 20 published studies [109]. Although there is some potential for selection bias in the case–control studies included, and the mechanism is unknown, it was speculated that delayed colonization of the infant’s intestine associated with cesarean section may be involved.

Increased birth weight has been associated with a relatively weak but significant increase in risk of childhood onset T1DM in large cohort studies based on linkage of population registries, independent of maternal diabetes and other potential confounders [108,110–112]. There are also studies reporting no significant association, but these were generally smaller case–control studies. The association seems in most cases to be independent of gestational age. Indirect data suggest that the association with birth weight may in part be explained by HLA genes [113], but a study directly testing this idea found that this was not the case [114]. Birth weight is certainly only a marker of some other phenomenon and the mechanisms involved remain to be defined.

Associated factors such as postnatal growth or excess body weight might be of relevance. A number of studies have indicated that children developing T1DM are taller, heavier or gain more weight or height prior to diagnosis compared to their peers [95,115–121]. Because of the numerous size and growth variables included and the various methods of analysis used in these studies, a systematic review of the consistency of these associations is warranted.

In summary, environmental factors may influence individuals quite differently, depending on the genetic background, although direct evidence for specific gene–environment interactions from humans is scarce [80]. No specific single factor has been identified thus far. Taking into account the multifactorial nature

of T1DM, specific environmental risk factors with sufficiently large impact to be of clinical importance and detectable in epidemiologic studies may not exist; however, identification of potential environmental risk factors and their role in the disease process is important in the potential prevention of T1DM in the future, and lack of consistent findings may reflect lack of properly conducted prospective studies. There are several randomized controlled trials ongoing with various interventions that are aiming at reducing the risk of islet autoimmunity or progression from islet autoimmunity to T1DM (see the first part of Chapter 9). Given the enormous amount of resources necessary for such efforts and the negative results of completed trials, it may be wise to initiate such trials based on consistent findings from properly conducted prospective observational studies. The large multicenter longitudinal TEDDY study may contribute towards this goal (<http://www.niddk.nih.gov/patient/teddy/teddy.htm>).

---

## Mortality

Before the discovery of insulin in 1922, T1DM meant an almost certain death soon after its onset. After the initiation of insulin replacement therapy, a dramatic improvement in survival occurred [122]. Another major improvement in survival occurred in cases of diabetes diagnosed in the 1950s [123]; however, even today T1DM is associated with an approximately 2- to 10-fold excess risk of premature mortality [121,124–128]. A large variation in relative mortality has been reported from different countries. For instance, the standardized mortality ratio (SMR) for patients with T1DM in Finland was lower than that in Lithuania, Estonia and in Japan [129,130]. A higher mortality in African-American compared to white patients with T1DM in the USA has been reported, and this difference seems to be attributable to acute complications [131].

Recent data from Europe showed that the short-term mortality was two times higher in patients followed from diagnosis of T1DM in childhood than the respective general populations, with variation in the SMR from about 1.1 to 4.7 in different countries [128]. In a nationwide cohort of patients with T1DM in Norway followed from onset before 15 years of age and up to 30 years' duration (mean 24.2 years), the SMR was 4.0 [126]. In a UK cohort of more than 7000 prevalent cases of T1DM with mean age of 33 years at baseline, the SMR after up to 7 years of follow-up (mean 4.5 years) was 3.7 [125]. Many studies have reported that the SMR varies with age and with diabetes duration, or both, but results are not consistent among studies [122].

Ascertainment of cause of death is difficult, but around one-third of the early deaths in the recent European multicenter study were clearly attributable to diabetic ketoacidosis (DKA), while about half of the relatively few deaths among young people with T1DM seems to be unrelated to diabetes [127,128]. Hypoglycemia as a cause of death is currently rare compared to DKA, but potentially increasing because of the more vigorous glycemic control

suggested for the prevention of long-term complications [132]. After about 10–15 years of diabetes duration, microvascular and macrovascular chronic diabetes complications start to make an impact, and after about 30 years of age cardiovascular causes become increasingly important. The relative mortality from cardiovascular causes is at least as high for women as for men. SMRs for cardiovascular causes of death of 8–40 have been reported in patients with T1DM, and it depends strongly on nephropathy (reviewed in [133]).

There is growing evidence that better glycemic control and improved risk factor control such as lowering of blood pressure and lipids is associated with reduced risk of late complications and improved survival (reviewed in [122,133]). The trend in mortality among patients with long-term T1DM seems to be improving [122], but there is a paucity of large cohorts with long-term follow-up of incident cases of T1DM covering long time periods to assess general trends after the late 1980s. Another challenge is the continued deaths of undiagnosed cases of T1DM and patients without access to care in the developing world.

---

## Conclusions

T1DM is one of the most common chronic diseases diagnosed in childhood, but the disease can occur at any age. Its incidence varies drastically between populations and even within populations. T1DM has a strong genetic component and familial clustering, but the majority of cases have no affected siblings or parents. Only a minority of carriers of the susceptibility genes develop T1DM. The incidence of T1DM is increasing in most studied populations at an average rate of approximately 3–4% per year. The causes of this increase are not known. It is believed that some environmental factors may have contributed to it, but no definite causal environmental factor for autoimmune T1DM has yet been identified.

T1DM was a fatal disease before the insulin era. Although mortality in patients with diabetes has drastically decreased, both acute and late complications lead to increased morbidity and premature mortality in T1DM. Primary prevention of T1DM would be the only solution to these problems, but unfortunately no practical preventive measures are currently available.

## Epidemiology of Type 2 Diabetes

**Ronald C.W. Ma & Peter C.Y. Tong**

Division of Endocrinology and Diabetes, Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, Hong Kong

### Keypoints

- The prevalence of type 2 diabetes is increasing worldwide.
- Approximately 285 million people worldwide have diabetes in 2010, making it one of the most common non-communicable diseases globally.
- The largest increase is observed in regions with rapidly developing economies and urbanization.
- The aging population, with an increase in the proportion of people aged over 65 years in most countries, has contributed significantly to this increase in prevalence.
- The age of onset of diabetes is also decreasing in many countries, giving rise to an increasing proportion of young people of working age being affected by the disease.
- Several risk factors are known to be associated with increased risk of type 2 diabetes. Many of these risk factors are associated with a westernized lifestyle and increase with urbanization.
- Areas with a high ratio of impaired glucose tolerance:diabetes are at an earlier stage of the diabetes epidemic, and thus may be a particular target for preventive strategies.
- The region with the highest diabetes prevalence rate at present is in the Eastern Mediterranean and Middle East Region.
- The largest increase in diabetes prevalence is predicted to occur in India and China.
- Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age.
- The increase in diabetes prevalence, particularly among young adults, along with the increased morbidity and mortality associated with microvascular and macrovascular complications, is likely to lead to an escalation of health care costs and loss of economic growth.

### Introduction

Type 2 diabetes mellitus (T2DM) is one of the most common forms of chronic disease globally and few societies or ethnic groups are spared. It accounts for about 85% of cases of diabetes in Caucasians and virtually all in certain non-Caucasian ethnic groups. In 2010, it was estimated that 285 million people worldwide have diabetes, of whom 80% live in less developed countries and areas [1]. Among those aged 20–79 years, about 6.6% have diabetes globally [1]. The highest number of people with diabetes is in the Western Pacific Region, with 76 million, and the region with the highest prevalence rate, at 11.7%, is North America and the Caribbean [1].

The number of people with diabetes is expected to reach 438 million by 2030, an increase of 54% compared to predicted figures for 2010 [1]. The largest increases will be in countries with rapidly growing economies, such as India and China. With the increasing consumption of high-energy food, increasing adoption of sedentary lifestyles and urbanization, increasing numbers

of individuals develop T2DM, and the age of diagnosis is decreasing. Individuals exposed to longer periods of hyperglycemia will undoubtedly have increased risks of developing vascular complications related to diabetes. The potential health care costs and burden of diabetes in these regions will have a significant impact on the economic growth of these regions, as discussed further in Chapter 5.

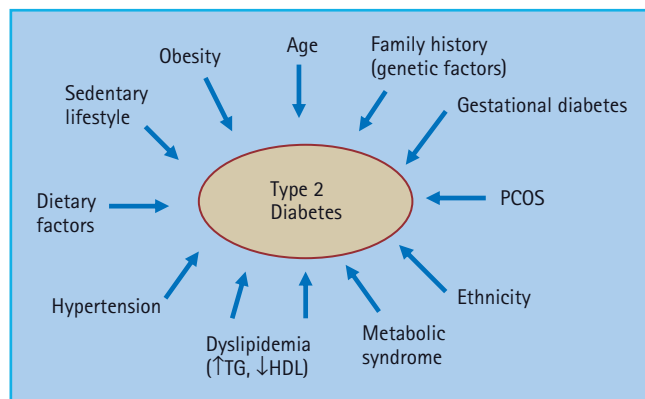

The epidemiology and prevalence of diabetes is partly determined by the diagnostic criteria used to diagnose diabetes, and these have been modified on a number of occasions. The diagnostic criteria for diabetes and impaired glucose tolerance (IGT) is based on epidemiologic evidence relating microvascular complications to specific degrees of hyperglycemia, and the fasting glucose cut-off has been modified as new data emerge. These changes have major implications on the interpretations of current and future epidemiologic studies on diabetes. In 1999, the diagnostic threshold of fasting glucose was lowered from 7.8 to 7.0 mmol/L. A fasting glucose between 6.0 and <7 mmol/L was previously considered to be pre-diabetic and the term “impaired fasting glucose” (IFG) was used. Subsequent lowering of the “normal” fasting glucose level to 5.6 mmol/L further increases the number of patients with “pre-diabetes.” IGT, however, is a state of intermediate hyperglycemia that is only identified by oral

glucose tolerance testing (OGTT), with a post-load glucose level of 7.8–11.1 mmol/L. It is estimated that about 344 million or 7.9% in the 20–79 age group have IGT in 2010 [1]. Abnormal glucose tolerance is frequently associated with visceral obesity, hypertension and dyslipidemia, a collection of cardiovascular risk factors known as metabolic syndrome. While these subjects are at high risk of developing diabetes and coronary artery disease, interventions with increased physical activity, reduced fat and energy intake can substantially reduce these risks by 40–60%.

## Risk factors for type 2 diabetes

Several risk factors are known to be associated with increased risk of T2DM. These include increasing age, obesity (especially central obesity), dietary excess, dietary factors such as increased intake of animal fats, carbonated drinks, sedentary lifestyle, a positive family history, history of gestational diabetes, polycystic ovary syndrome, severe mental illness, presence of hypertension, hyperlipidemia or cardiometabolic risk factors (Figure 4.1) (see Chapters 11, 12 and 14). The clustering of some of these risk factors – hypertension, elevated blood glucose, elevated triglyceride, low high-density lipoprotein (HDL) cholesterol, and abdominal obesity – is termed the metabolic syndrome. Many of these risk factors are associated with a westernized lifestyle and increase with urbanization and mechanization. The recognition of the role of these factors in the pathogenesis of T2DM has led to recommendations for selective screening for T2DM in subjects with these risk factors [2].

Obesity accounts for 80–85% of the overall risk of developing T2DM, and underlies the current global spread of the disease [3]. The risk of T2DM increases as body mass index (BMI) increases above 24 kg/m<sup>2</sup>, although the risk appears to be present in association with lower BMI cut-offs in Asians [4,5]. While central obesity is a particularly strong factor, it can impart further risk regardless of the overall level of general obesity. This obesity-related risk is particularly marked in certain ethnic populations such as Native Americans, African-Americans, South Asians, Chinese (and other

**Figure 4.1** Risk factors in the development of type 2 diabetes. HDL, high density lipoprotein cholesterol; PCOS, polycystic ovarian syndrome; TG, triglycerides.

Asian populations) and Pacific Islanders [6–9], and may be related to increased visceral adiposity. Obesity, particularly central adiposity, is associated with insulin resistance, as well as  $\beta$ -cell dysfunction, partly through increased free fatty acids and lipotoxicity (see Chapter 14). Obesity is also associated with other metabolic abnormalities such as dyslipidemia and hypertension. Presence of the metabolic syndrome, according to the different definitions, is associated with two- to five-fold increased risk of developing diabetes in most populations [10]. Epidemiologic studies have suggested that early life events such as low birth weight and fetal malnutrition may also be associated with increased risk of diabetes and cardiovascular disease later in life [11].

## Recent emerging risk factors

### Decreased sleep

In addition to changes in diet and level of physical activity, it is recently recognized that short sleep duration, another facet of our modern lifestyle, may also be an important contributing factor to the increasing prevalence of T2DM. Early seminal work has highlighted the detrimental effects of sleep deprivation on glucose tolerance and insulin sensitivity [12]. Subsequent cross-sectional studies have suggested an association between short sleep duration and diabetes [13] and obesity [14]. In a prospective study of more than 70 000 women in the Nurses Health Study, short sleep duration was associated with approximately 57% increase in the risk of diabetes diagnosis over the 10-year study period [15]. Similar data were obtained from the first National Health and Nutrition Examination Survey (NHANES I), which noted that subjects who have sleep durations of 5 hours or less had a 47% increase in the incidence of diabetes over a 10-year period [16]. The exact mechanism whereby sleep restriction increases diabetes risk is not clear, although it may be related to activation of the sympathetic nervous system, decrease in cerebral glucose utilization, changes in the hypothalamic-pituitary-adrenal axis as well as other neuroendocrine dysregulation [16].

### Drug-induced metabolic changes

There is increasing recognition that some commonly used medications may be associated with adverse metabolic effects and increased risk of diabetes (see Chapter 16) [17]. High dose thiazide diuretics are known to worsen insulin resistance and beta-blockers can impair insulin secretion. More recently, the use of antipsychotic agents, particularly second generation (atypical) antipsychotics, have been linked with hyperglycemia and diabetes [18]. The increasing use of highly active antiretroviral therapy (HAART) has dramatically reduced the mortality of patients with HIV infection; however, protease inhibitors and, to a lesser extent, nucleoside reverse transcriptase inhibitors, have been found to be associated with insulin resistance, deranged glucose and lipid metabolism and an increased risk for T2DM. The increasing use of such agents will likely have a significant impact

on the epidemiology of diabetes in areas where HIV/AIDS is endemic such as Africa (see Chapter 50) [19].

### Environmental pollutants

While most studies on the increasing burden of diabetes with westernized lifestyle have focused on changes in dietary patterns and the increasingly sedentary lifestyles, recent studies suggest environmental pollutants may represent a previously unrecognized link between urbanization and diabetes [20,21]. For example, there is strong cross-sectional association between serum concentrations of chlorinated persistent organic pollutants with diabetes [22], as well as components of the metabolic syndrome [23]. More recently, brominated flame-retardants have emerged as another class of organic pollutants that are associated with diabetes [24]. It is believed that these environmental toxins may accumulate in adipose tissue and act as endocrine disruptors, leading to dysregulation of glucose and lipid metabolism.

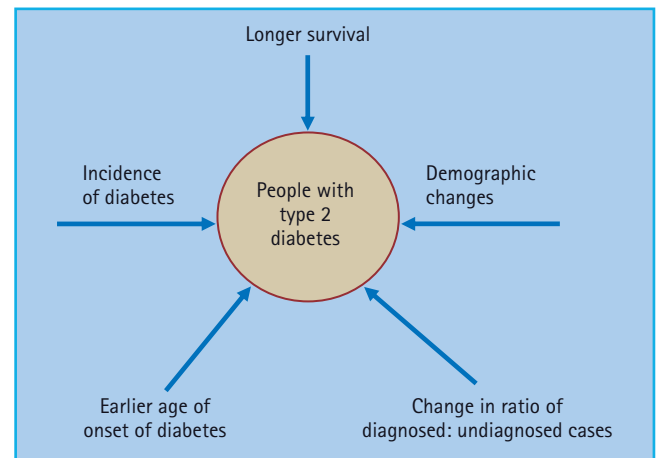

### Low birth weight and fetal malnutrition

There is now increasing evidence to support a relationship between intra-uterine environment, fetal malnutrition and the risk of diabetes and cardiovascular disease later in life [11,25]. Maternal undernutrition, low infant birth weight, along with rapid postnatal growth, has been found to be associated with increased risk of diabetes in the offspring. This “mismatch” of a metabolic phenotype programmed during intra-uterine development and the nutritionally rich postnatal environment may be most important in regions that are undergoing rapid economic development. In addition, offspring of obese women or women with diabetes have an increased risk of diabetes and cardiometabolic abnormalities [26,27]. With increasing numbers of women with young-onset diabetes, this is likely to exacerbate further the epidemic of diabetes by setting up a vicious cycle of “diabetes begetting diabetes” [1,11,28].

Despite the increasing recognition of these novel risk factors, the main risk factors associated with diabetes remain the traditional ones of increasing age, adiposity, physical inactivity, dietary factors, positive family history and presence of other cardiometabolic risk factors, as outlined in Figure 4.1.

## Methodologic issues in the epidemiology of type 2 diabetes

In comparing epidemiologic data in T2DM, one must be aware of the importance of the study methodology. Survey methods must be robust, to allow comparison and standardization. A large, truly random sample of a community, with a good response rate, is best; workplace samples may demonstrate “healthy worker” effects, while selective samples (e.g. volunteers, or subjects with another disease) are the least useful because of inbuilt recruitment bias. The age distribution of sample populations is crucial in studying T2DM, whose prevalence rises with age; study populations must be age-stratified and any comparisons age-

**Figure 4.2** Diabetes epidemiologic model. Factors directly affecting the prevalence of diabetes included in the present analysis. Adapted from Colagiuri *et al.* [29] with permission from Springer Science and Business Media.

adjusted, either within the data set, or standardized against a reference population. Finally, ascertainment methods are important – for example, whether subjects undergo an OGTT, with or without preliminary blood glucose screening.

Studies conducted in different regions of the world have highlighted an increase in the prevalence of T2DM. While few would argue that this translates into increasing burden associated with diabetes, it is important to recognize the factors that have contributed to this increased prevalence. Several factors directly affect the prevalence of diabetes, and may partly account for the increasing prevalence (Figure 4.2):

- 1 Changes in the ratio of diagnosed:undiagnosed cases of diabetes;
- 2 Population demographic changes with an aging population;
- 3 Earlier age at onset of diabetes;
- 4 Longer survival in patients with diabetes than before;
- 5 Increasing incidence of diabetes [29].

The different factors may have different contributions depending on the population being studied, although most if not all are of some importance in most populations.

### Effects of changes in the definition of diabetes

While it has long been established that diabetes is a condition associated with elevated levels of glucose in the bloodstream, there was no widespread accepted definition of the syndrome until the 1980s, when the World Health Organization (WHO) Expert Committee on diabetes mellitus defined the diabetic state as a state of chronic hyperglycemia that may result from many environmental and genetic factors, often acting together [30]. The precise degree of hyperglycemia that defines diabetes has evolved with time, and relies on epidemiologic studies regarding the distribution of glucose levels within various populations.

There are several consequences of the changes in the definition of diabetes with time on the epidemiology of the condition. First, with the American Diabetes Association (ADA) and WHO

classification of 1999, the threshold of fasting glucose diagnostic of diabetes was lowered from 7.8 to 7.0 mmol/L, thereby increasing the number of individuals in any given population that fulfills a diagnosis of diabetes. Furthermore, it is important to appreciate that in any epidemiologic survey, whether the diagnosis was based on elevated fasting glucose or post-load values during an OGTT. While the lower fasting glucose values was chosen to resemble more closely the diagnostic significance of the 2-hour post-load concentration, numerous studies have demonstrated that the fasting glucose criteria and post-load criteria identify slightly different subjects in most populations [31–33], and the use of fasting glucose alone will reduce the overall prevalence of diabetes compared with that identified by 2-hour post-load glucose criteria [34]. Furthermore, there is an increasing number of epidemiologic studies that utilize measurement of HbA<sub>1c</sub> as an indicator of dysglycemia [35]. Although HbA<sub>1c</sub> is not at present considered a suitable diagnostic test for diabetes or intermediate hyperglycemia, this is under active discussion [36].

The WHO recommendations for the diagnostic criteria for diabetes and intermediate hyperglycemia is summarized in Table 4.1 (see Chapter 2). While the lower threshold for diagnosing IFG in the recommendation by the ADA will result in a larger number of subjects diagnosed to have intermediate hyperglycemia than the WHO recommendation, increased diagnostic activity (e.g. through use of the OGTT) will lead to an increasing ratio of diagnosed:undiagnosed diabetes, and may impact on the prevalence rate reported in epidemiology studies.

In a comprehensive report on the global prevalence of diabetes [37], it was noted that the most important demographic change

to diabetes prevalence across the world was the increase in proportion of people over 65 years of age. Another major factor that has impacted on the prevalence of diabetes is the increasing age-specific prevalence of diabetes, especially in the younger age groups [37]. This suggests an earlier age of onset of diabetes, which may be of particular importance in low and middle income countries. It is also worthwhile noting the tendency for the prevalence rates of IGT to decline as that of diabetes rises, perhaps suggesting that areas with a high ratio of IGT:diabetes are at an earlier stage of the diabetes epidemic and thus may be a particular target for preventative strategies. Changes and variations in the ratio of IGT:diabetes prevalence – the so-called “epidemicity index,” may provide a useful marker for the scale of the epidemic in that particular region, as illustrated in Figure 4.3 [38].

### Regional and ethnic patterns of type 2 diabetes worldwide

This section considers the geographic distribution and secular changes in the prevalence of T2DM and intermediate hyperglycemia in the major regions of the world. Whenever possible, the most comprehensive and up-to-date source of data is the *Diabetes Atlas* produced by the International Diabetes Federation [1]. In addition, a review by Wild *et al.* [37] utilized age- and sex-specific estimates for diabetes prevalence from available epidemiologic surveys to extrapolate prevalence in related countries using a combination of criteria including geographic proximity, ethnic and socioeconomic similarities.

Current estimates of the total number of people with diabetes in each region of the world and in those countries with the highest overall numbers are shown in Figure 4.4. A list of countries with the highest prevalence and projected prevalence is listed in Table 4.2, and a list of countries with the most number of people with diabetes in Table 4.3.

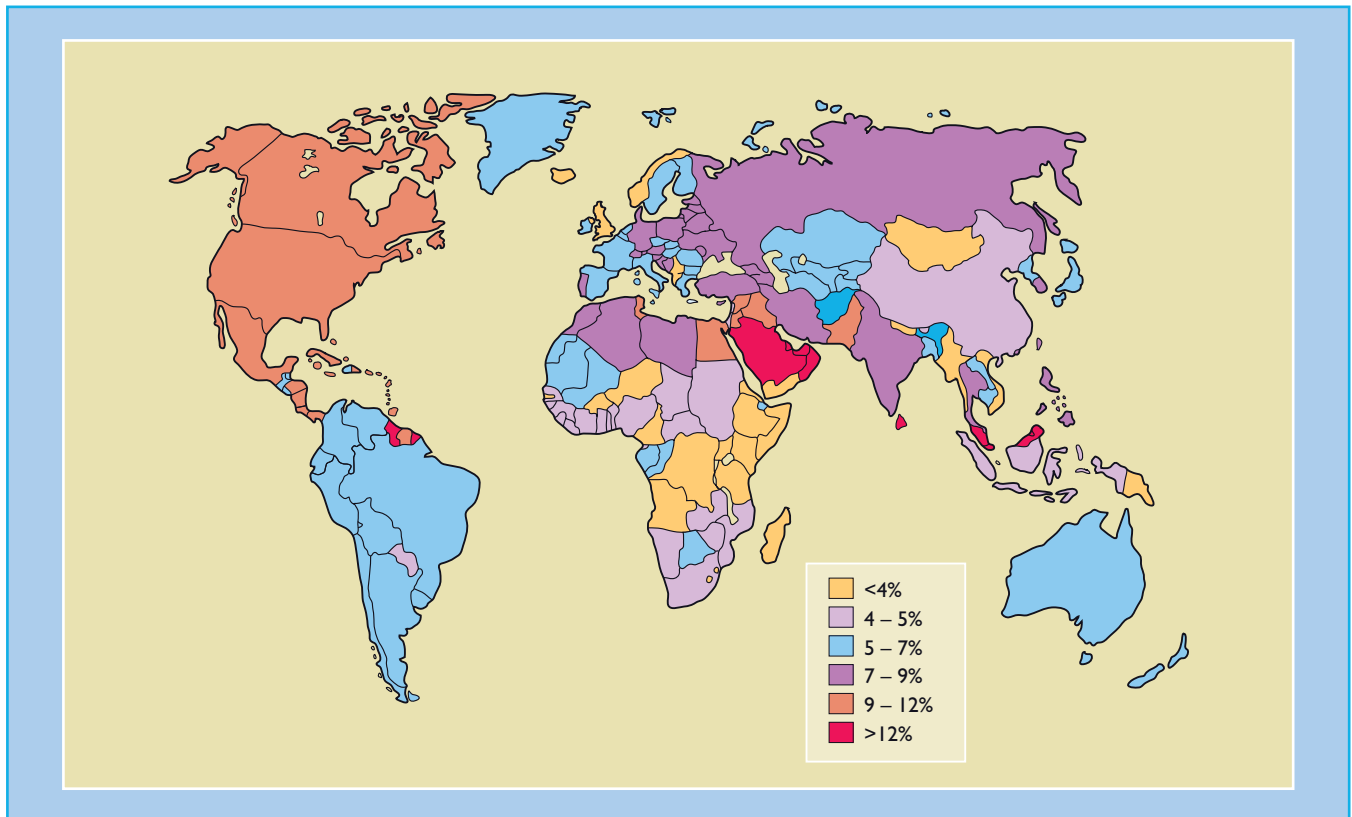

#### Africa

T2DM in the African continent provides contrasting pictures between regions that are more urbanized and the more rural areas. While poverty and malnutrition is still a major problem affecting sub-Saharan Africa, a region where diabetes is comparatively rare, urbanized areas such as North Africa are reporting increasing prevalence rates [39]. It has been estimated that, overall, 3.8% of the adult population in the African region in 2010 are currently affected by diabetes, which is projected to increase to 4.7% by 2030 [1]. Other important epidemiologic issues in the region include a low incidence of type 1 diabetes (T1DM), which is complicated by the occurrence of atypical “ketosis-prone” diabetes, an atypical presentation of diabetes characterized by an initial clinical presentation of apparent T1DM with severe hyperglycemia and ketosis, and subsequent long-term remission with a clinical course more compatible with T2DM [40]. In addition, there is also a form of early onset diabetes termed malnutrition-related diabetes mellitus (MRDM) that is associated with past or

**Table 4.1** Comparison of the 2006 WHO recommendations for the diagnostic criteria for diabetes and intermediate hyperglycemia.

	WHO (2006)	ADA (2003)
<b>Diabetes</b>		
Fasting plasma glucose	≥7.0 mmol/L (126 mg/dL)	≥7.0 mmol/L (126 mg/dL)
	or

**Figure 4.3** Global prevalence estimates of diabetes (20–79 years), 2010. Adapted from International Diabetes Federation [1].

present malnutrition and sometimes accompanied by pancreatic calcification [19]. Although infective diseases such as HIV infection and tuberculosis are currently the main causes of mortality in sub-Saharan Africa, the increasing prevalence of diabetes and other non-communicable diseases is likely eventually to overtake infections as major causes of mortality. In sub-Saharan Africa, only a small proportion of the population at present reaches ages at which T2DM becomes a major health problem. While greater access to HAART has led to markedly reduced mortality, the improvement in life expectancy, coupled with the adverse metabolic effects of HAART, are likely to contribute to further increases in the prevalence of T2DM within the region [19,41].

#### North Africa

Prevalence rates are relatively high (4.2–9.3%) in Sudan and Tunisia as well as Egypt. The Egyptian study, of adults aged over 20 years, also showed an IGT prevalence rate of 10% [42]. Interesting urban–rural differences were also demonstrated; in Cairo city, diabetes was more common (prevalence 14–20%, depending upon socioeconomic status), while the IGT prevalence was lower (6–9%). The converse applied in a rural setting, with a diabetes prevalence of only 5% but a higher IGT prevalence of 13%. This may reflect the diabetes epidemic being at an earlier stage in rural populations (Figure 4.4). In the recent Tunisian National Nutrition Survey, prevalence of diabetes was 9.9%,

giving age-adjusted prevalence of 8.5%, with marked urban–rural differences [43].

#### Sub-Saharan Africa

There is a paucity of prevalence data from sub-Saharan Africa, with most of the prevalence data derived from studies in Ghana, Cameroon, Nigeria, Tanzania and South Africa [39]. In a recent systematic review of prevalence data from Ghanaians and Nigerians, diabetes was rare at 0.2% in urban Ghana in 1963 and 1.65% in urban Nigeria in 1985. The prevalence of diabetes had risen to 6.8% in Nigeria in 2000 (for adults aged  $\geq 40$  years) and 6.3% in Ghana in 1998 (for adults aged  $\geq 25$  years) [44,45]. In Cameroon (West Africa), adults aged 24–74 years had an overall diabetes prevalence of 1.1%, with an IGT rate of 2.7%. Prevalence rates in the capital of Cameroon (Yaounde) were 1.3% for diabetes and 1.8% for IGT, compared with rural prevalences of 0.8% for diabetes and 3.9% for IGT [46]. Undiagnosed cases accounted for the majority of cases in these studies, again reflecting a region at the early stages of a looming diabetes epidemic.

In South Africa, both diabetes and IGT are more common in both urban and rural communities. In Cape Town, age-adjusted prevalences were 8% for diabetes and 7% for IGT [47]. A recent study conducted in a rural South African community based on a 75-g OGTT and the 1998 WHO criteria reported an overall age-adjusted prevalence of diabetes of 3.9%, IGT 4.8% and IFG 1.5%.

**Figure 4.4** Relationship between impaired glucose tolerance (IGT) prevalence and diabetes prevalence and the relationship to the Epidemicity Index. h, high socioeconomic status; l, low socioeconomic status; r, rural; u, urban; Sudan-D, Dangla tribe; OFS, South Africa Free State. Adapted from Dowse *et al.* [38].

**Table 4.2** Prevalence of diabetes (20–79 age group) in 2010 and 2030. Data from International Diabetes Federation, 2009 [1].

Rank	Country	2010 Prevalence (%)	2030 Prevalence (%)
1	Nauru	30.9	33.4
2	United Arab Emirates	18.7	21.4
3	Saudi Arabia	16.8	18.9
4	Mauritius	16.2	19.8
5	Bahrain	15.4	17.3
6	Reunion	15.3	18.1
7	Kuwait	14.6	16.9
8	Oman	13.4	14.9
9	Tonga	13.4	15.7
10	Malaysia	11.6	13.8

Notably, 85% of the cases with diabetes were uncovered by the survey [48].

In addition to exposure to urban environment, other factors that determine the risk of T2DM in African populations include

positive family history, ethnic origin, central adiposity and physical inactivity [39]. Possible ethnic differences have been examined in several studies. In both Tanzania and South Africa, migrant Asians have higher diabetes prevalence rates than indigenous Africans [49] but this could reflect lifestyle differences. In Tanzania the difference was particularly marked (1.1% in Africans vs 9.1% in Asians), which again emphasizes the low prevalence in urban East Africans.

The emerging epidemic of T2DM is further compounded by the various problems hampering the delivery of effective diabetes care within this region. This has resulted in poor glycemic control among most patients, as well as a high frequency of chronic microvascular complications. Better access to health care and treatment, improvement in infrastructure to support services and health care information systems as well as primary prevention measures are urgently needed in order to reduce the burden of acute and chronic complications of diabetes in the region [19,39,41].

### The Americas

#### North America (USA and Canada)

Diabetes and its complications are common and a significant cause of morbidity in North America. The NHANES study

**Table 4.3** Estimated numbers of people with diabetes in 2010 and 2030 in the 20–79 year age group. Data from International Diabetes Federation, 2009 [1].

Rank	Country	Persons (millions) 2010	Rank	Country	Persons (millions) 2030
1	India	50.8	1	India	87.0
2	China	43.2	2	China	62.6
3	United States of America	26.8	3	United States of America	36.0
4	Russian Federation	9.6	4	Pakistan	13.8
5	Brazil	7.6	5	Brazil	12.7
6	Germany	7.5	6	Indonesia	12.0
7	Pakistan	7.1	7	Mexico	11.9
8	Japan	7.1	8	Bangladesh	10.4
9	Indonesia	7.0	9	Russian Federation	10.3
10	Mexico	6.8	10	Egypt	8.6

reported a crude prevalence of total diabetes in 1999–2002 as 9.3%, consisting of 6.5% diagnosed and 2.8% undiagnosed [50]. This was significantly increased compared with a crude prevalence of total diabetes in 1988–1994 of 5.1%, mainly because of an increase in diagnosed diabetes. There was marked variation in prevalence in different ethnic groups, with age- and sex-standardized prevalence of diagnosed diabetes approximately twice as high in non-Latino African-Americans (11%) and Mexican-Americans (10.4%) compared with White people of Northern European ancestry (5.2%). The prevalence of diabetes among the elderly of these minority groups was particularly high, exceeding 30% [50].

The high prevalence rates in US Latino people and African-Americans is well documented. In 1991, the age-adjusted prevalence of diabetes was 6% in White people, 9% in Cubans, 10% in African-Americans, 13% in Mexican-Americans and 13% in Puerto Ricans [51]. Rates have risen in all groups, but these differences appear to persist. Between 1987 and 1996, the 7- to 8-year incidence of T2DM approximately tripled in both Mexican-Americans and White people of Northern European ancestry, although the absolute rate was twice as high in the Mexican-Americans [52]. T2DM is also significantly more common among older Puerto Ricans (38%) and Dominicans (35%) than among White people of Northern European ancestry (23%) [53]. Economic disadvantage may explain much of the excess prevalence of T2DM among African-American women [54].

Other populations in the USA that are particularly at risk of T2DM are the Native American Indian communities, notably the Pima Indians, of whom 50% have diabetes [55]. Reports have highlighted the developing epidemic of T2DM in Native American Indian youth [56]. Among 15- to 19-year-olds, diabetes now affects 5.1% of Pima Indians (a sixfold increase in prevalence over the last 20 years) and 0.2% for Canadian Cree and Ojibway Indians. The overall prevalence among all US Native American Indians of this age is 0.5%. This epidemic of T2DM in young Native American Indians is supported by secular trends in the

incidence rate of T2DM over the past 40 years in Pima Indians, which showed a more than fivefold increase in incidence rates among Pima Indians aged 5–14 years [57].

A similar situation was seen in Canada, where aboriginal peoples living in Canada had more than twofold increase in prevalence compared with the non-aboriginal population [58]. Other minority groups are also not spared. Among native Hawaiians (Polynesians), the crude (i.e. not age-adjusted) prevalence rates of T2DM and IGT were reported in 1998 to be 20% and 16%, respectively. The age-adjusted rate for T2DM was four times higher than among the US NHANES II study population [59]. In 1991, second-generation Japanese-Americans had prevalence rates of 16% (diabetes) and 40% (IGT) [60], and incidence rates remain high at 17.2 per 1000 person-years [61]. This is believed to be a result of the increase in visceral adiposity in a population predisposed to impaired  $\beta$ -cell function [62]. Other Asian populations living in the USA that are particularly prone to diabetes include Chinese-Americans, in whom linguistic barriers may be a particularly relevant barrier to diabetes education and effective care delivery [63].

It has been estimated that the number of Americans with diagnosed diabetes will rise from 11 million in 2000 (overall prevalence, 4.0%) to 29 million in 2050 (prevalence 7.2%). The fastest growth is expected to be among African-Americans. The projected increase of 18 million is accounted for by approximately similar contributions from changes in demographic composition, population growth and secular rises in prevalence rates [64]. In 2010, it is estimated that 26.8 million people in the USA have diabetes, of which 5.7 million is undiagnosed. The direct and indirect medical costs attributed to diabetes in the USA in 2007 was \$174 million [65].

An increasing number of younger people will be affected. In the SEARCH for Diabetes in Youth Study, a multi-ethnic population-based study, the incidence of diabetes was 24.3 per 100 000 person-years. The incidence rates of T2DM was highest among Native American Indians and African-American adolescents, with incidence rates of 17–49.4 per 100 000 person-years,

**Table 4.4** National estimates of diabetes and IGT prevalence in Europe in 2010. Data from International Diabetes Federation, 2009 [1].

Country	Prevalence (%)		Prevalence IGT (%)	
	National population*	Comparative population†	National population	Comparative population

compared with 5.6 per 100 000 person-years in White people of Northern European ancestry [66].

### Central and South America

Data from these regions are scarce. In the Mapuche native people from rural Chile, the prevalence of T2DM estimated in 2001 was 3% in men and 5% in women [67]. This represents a substantial rise above the very low prevalence (<1%) reported in 1985 [68]. Diabetes is clearly much more common in urban communities, for example 14% in Mexico City in 1994 [69], compared with 5–10% prevalence nationwide [70]. Surveys in Brazil and Colombia in the early 1990s indicated age-adjusted prevalence rates of approximately 7% [71,72]. A high prevalence of abdominal obesity was noted in these populations, affecting more than 80% of women [70].

### Caribbean

Studies from Jamaica exemplify the secular trend in the West Indies. Rates in the 1960s (underestimated because of the screening procedure used [73]) were low but rose in the 1970s to 4% in those aged 44 and 8–10% in those aged 45–64 years [74,75], and to an overall rate of 7.4% in 1996 [76]. The most recent report, which dates from 1999, indicates prevalence rates of 16% in women and 10% in men (13% overall). As elsewhere, this exceeds the rate of rise among European-origin populations and parallels the spread of obesity [77].

## Europe

This region contains a diverse mix of countries that have marked differences in affluence, and includes some of the most developed countries in the world. Nevertheless, updated nationwide survey data are only available in some of the countries. In the recent *Diabetes Atlas*, less than half of the 54 European countries and territories in the European region had recently published data on national prevalence of diabetes, which ranged from 2.1% in Iceland to 12% in Germany (Table 4.4).

### UK

T2DM imposes particular burdens in inner cities with multi-ethnic populations, as those originating from the Indian subcontinent have a high prevalence of the disease. In typical studies [78,79], the age-adjusted prevalence rates were 3% and 5% in Caucasian males and females, respectively, compared with 12% and 11% in their Asian counterparts in the UK. Asians also show a higher prevalence of IGT, a male preponderance, a younger age at diagnosis and a lower proportion of undiagnosed diabetes [79].

Poverty and social deprivation apparently contribute to the increasing prevalence of T2DM among inner-city residents. This was manifest in all ethnic groups in inner-city Manchester, including a surprisingly high age-standardized prevalence rate of 20% among White people) [80]. Social deprivation, obesity, physical inactivity and smoking tend to co-segregate, which may

explain this phenomenon. The importance of dietary factors was highlighted by two recent studies, which demonstrated association between high dietary energy density or unhealthy dietary patterns characterized by high intake of soft drinks, sugar-sweetened beverages, burgers, sausages and snacks with incident T2DM [81,82]. In the Ely study, a population-based longitudinal study, the 10-year cumulative incidence of diabetes was 7.3 per 1000 person-years [83].

### Scandinavia

In Scandinavia, the more homogenous population may indicate more accurately the true prevalence of T2DM among white Caucasians. A survey in Northern Sweden revealed a prevalence of diabetes of 8.1% [84]. Similar data were obtained in a recent study in Finland, with age-standardized prevalence of diabetes in 45- to 64-year-olds being 10.2% for men and 7.4% for women [85]. Lower prevalence data were noted for Iceland [86].

In the early 1990s, T2DM was rare in Northern Finland but the prevalence of IGT was 29% in men and 27% in women [87], comparable with that in a homogeneous white Caucasian female Swedish population aged 55–57 years (28%) [88]. In Denmark, around 15% of the population have IGT [89]. The high prevalence of IGT in Finland prompted the Finnish Diabetes Prevention Study [90], which examined whether lifestyle changes could prevent the development of T2DM. Strikingly, nutritional advice and increased physical activity were shown to reduce the risk of developing diabetes by 58% in subjects with IGT, and the effect was sustained over subsequent follow-up [90]. A more recent study in three regions in Finland noted prevalence of IGT of 10.5% in men and 9.2% in women, which was substantially lower than the previous reported figures from Northern Finland. It is unclear whether this difference is a result of regional differences or changes in the diabetes:IGT ratio [85].

Using a register of patients with diabetes, it was calculated that the incidence rate of diabetes in Denmark was 1.8 per 100 000 at age 40 years and 10 per 100 000 at age 70. The incidence rate increased 5% per year before 2004 but then stabilized. The lifetime risk of diabetes was estimated at 30% [91]. A recent study in Finland noted an alarming increase in the incidence of T2DM among young adults, with age-adjusted incidence of T2DM among 15- to 39-year-olds being 11.8 per 100 000/year. The incidence rate increased by 7.9% per year. Interestingly, despite having the highest incidence of childhood T1DM in the world, the incidence of T2DM among young adults in Finland is approaching that of T1DM among the 15–39 year age group (age-adjusted incidence of T1DM 15.9 per 100 000/year) [92].

### Continental Europe

A population-based survey in Verona, Italy, revealed an overall prevalence of T2DM of 2.5% which increased significantly after the age of 35 years [93]. In northern Italy, the age-adjusted prevalence of T2DM was 9% in males and 8% in females over the age of 44 years [94]. In a study that compared the prevalence of dia-

betes in Casale Monferrato in northwest Italy in 1988 and 2000, it was noted that the age- and sex-adjusted prevalence of diabetes had increased from 2.13% in 1988 to 3.1% in 2000, with higher age-specific prevalence rates of diabetes in every age group in the later survey, including a twofold increase in the risk for those aged  $\geq 80$  years [95].

In France, the MONICA study estimated the adjusted prevalence of T2DM to be 7% in men and 5% in women aged 35–65 years, and the adjusted prevalence of IFG as 12% in men and 5% in women [96]. The prevalence of diabetes increases to 19% in males and 9% in females aged over 60 years [97].

In the Netherlands, T2DM affects 8% of elderly Caucasians [98]; 65% of those with IFG and post-load glucose levels went on to develop diabetes within 6 years [99]. In a prospective population-based study between 1998 and 2000, age- and sex-adjusted prevalence of diagnosed diabetes was 2.2% at baseline and 2.9% after 2 years of follow-up, with elderly patients aged 70 or over accounting for 50% of the T2DM population [100].

In Greece, the prevalence of diabetes increased from 2.4% in 1974 to 3.1% in 1990 [101], and aging and obesity were associated with both T2DM and IGT [102,103]. Prevalence of T2DM was 7.6% in men and 5.9% in women in a survey conducted in 2001–2002 [104]. In a follow-up study of those free of cardiovascular disease at baseline, the incidence rate of diabetes within a 5-year period was 5.5% [105]. In Turkey, the overall prevalence rates of T2DM and IGT were 6% and 9%, respectively. Low levels of occupational activity, family history and obesity were all associated risk factors [106,107]. Adherence to a Mediterranean diet may also have protective effects against diabetes [108].

Prevalence data from Eastern Europe are comparatively sparse. The age-adjusted prevalence of T2DM for men and women in Fergana, Uzbekistan, is estimated to be 8% in both urban men and women, with IGT affecting 5% of men and 6% of women. Lower prevalence rates for both T2DM and IGT are reported for semi-rural inhabitants [109]. A survey in the rural area in the Sirdaria province of Uzbekistan confirmed similar age-adjusted prevalence rates of diabetes for men (10%) and women (7.5%); however, prevalence rates of IGT in Sirdaria women (14%) and in men (11%) were higher than for semi-urban or urban inhabitants in Fergana [110]. In Russia, the estimated prevalences were 6% in males and 7% in females for diabetes, and 6% and 13%, respectively, for IGT; clustering of hyperlipidemia, obesity, hypertension and low 10-year survival were observed among subjects with diabetes [111]. A survey conducted in Moscow reported low incidence of reported diagnosis of diabetes (2%) [112], which was supported by another study based on self-reported doctor diagnosis [113]. In addition to underdiagnosis, undertreatment and infrequent insulin use are also likely to contribute to the burden of morbidity [113]. Much of the estimated prevalence data in other Eastern European countries have been extrapolated from data from Poland, where prevalence of T2DM increased from 3.7% to 10.8% between 1986 and 2000, with a similar increase in prevalence of IGT from 2.9% to 14.5% during this period [114].

## Asia

### India

India is the second most populous country in the world, but currently has the highest number of people with diabetes, with an estimated 40.9 million affected in 2007, a figure that is set to rise to 69.9 million by 2025 [115]. Sequential surveys from India indicate that the prevalence of diabetes has risen steadily since the 1970s [116–119], although methodologic differences hamper comparisons between these studies.

The National Urban Diabetes Survey, carried out in six cities in 2001, found age-standardized prevalence rates of 12% for diabetes (with a slight male preponderance) and 14% for IGT; subjects under 40 years of age had a prevalence of 5% (diabetes) and 13% (IGT) [119]. Diabetes was positively and independently associated with increasing age, BMI and waist:hip ratio, and also with a family history of diabetes, a higher monthly income and physical inactivity. IGT showed associations with age, BMI and family history of diabetes. Subsequent studies showed increasing prevalence, with prevalence rates of 14.3% reported in the Chennai Urban Rural Epidemiology Study (CURES-17) [120], and 18.6% in the city of Chennai in the most recent study [121]. In addition to the increasing prevalence of diabetes, there appears to be a decreasing prevalence of IGT (120). Another secular trend is the shift towards younger onset of diabetes, especially in urban areas, where up to 36% of those with diabetes are aged 44 years or less [120,121].

Urban–rural differences in the prevalence of diabetes have been consistently reported by different studies in India. A study from Chennai noted a progressive increase in prevalence rate with increasing urbanization; 2.4% in rural areas, 5.9% in semi-urban areas and up to 11.6% in urban areas [118,122]. Likewise, the most recent data revealed a prevalence of 18.6% in the city of Chennai compared with 16.4% in a town and 9.2% in peri-urban villages [121]. In a study carried out in 77 centers in India (40 urban and 37 rural), the standardized prevalence rate for diabetes in the total Indian, urban and rural, populations was 4.3, 5.9 and 2.7%, respectively. While the prevalence rates of diabetes and IGT are significantly higher in urban compared with rural areas, it appears that the rural–urban gradient is becoming increasingly attenuated [123].

The Chennai Population Study (CUPS) has recently revealed alarming rates of incident diabetes, which occurred at a rate of 20.2 cases per 1000 person-years [124]. Identification of high-risk subjects and increasing the awareness of the population is much needed. A risk score specific for Indian population, the Indian Diabetes Risk Score has been developed. It utilizes four clinical variables (age, family history, regular exercise and waist circumference) and a score of >21 is able to identify subjects with diabetes with a sensitivity and specificity of close to 60% [125]. This will help identify high-risk subjects for early intervention, because lifestyle modification has been shown to be effective in reducing progression from IGT to diabetes in the Indian population [126]. Recently, the pilot phase of a National Program on Diabetes, Cardiovascular Diseases and Stroke (NPCDS) has been launched

in seven states in January 2008. It is hoped that this will help coordinate the multisectoral effort that is urgently needed in order to address the epidemic of obesity and diabetes in India [127].

### Pakistan, Bangladesh and Sri Lanka

The situation in these countries largely mirrors that in India. Diabetes is particularly common (16% of men, 12% of women) in the rural Sindh Province in Northern Pakistan [128]. A more recent study from Pakistan indicates similar prevalence rates of 10–11% in urban and rural males and urban women, although lower rates were seen in rural females (5%); however, IGT rates in females were twice those in males [129]. Combining data from the four provinces of Pakistan, the prevalence of diabetes in the urban areas was 6.0% and 3.5% in women, with a total of 22% of the urban population estimated to have some degree of glucose intolerance [130]. Using data from the National Diabetes Survey, the WHO has estimated a marked increase in T2DM in Pakistan from 4.3 million in 1995 to 14.5 million in 2025 [37]. In rural Bangladesh, diabetes prevalence is 2.1% compared with an IGT prevalence of 13% despite the mean BMI being only 20.4 kg/m<sup>2</sup> [131].

In addition to urbanization, the main factor for the high prevalence of diabetes and metabolic abnormalities among Asians is the tendency to central obesity and insulin resistance [5,118,132–134]. Despite being born smaller, with lower birth weight, Indian babies have more body fat, which persists into adulthood, thus putting them at increased risk of cardiometabolic complications [135]. Interestingly, a recent study showed maternal nutrition, and in particular, low maternal vitamin B<sub>12</sub> and high folate might be associated with increased adiposity and risk of T2DM in the offspring [136], suggesting that in addition to increased intake of fat and calorie-rich foodstuffs, other dietary factors may also have a contributory role.

### Mauritius

The high prevalences of diabetes and cardiovascular disease on the island of Mauritius, in the India Ocean, have been intensively studied. Here, diabetes is common in an urbanized setting, across several ethnic groups (Asian Indian, Chinese and Creole); prevalence rates are 10–13% among the different ethnic groups, rising to 20–30% in those aged 45–74 years [137]. A repeat survey in 1998 revealed a rise in prevalence of T2DM to 17.9%. In both studies, the highest prevalence was seen in the Asian Indians [137,138].

### The Middle East

Marked socioeconomic changes in many countries in the region, especially among the affluent oil-producing countries, has led to dramatic changes in lifestyle with changes in nutritional intake, decreased physical activity, increased obesity and smoking. This, coupled with increasing urbanization and improved life expectancy, has led to a marked increase in the prevalence of diabetes

and IGT (Table 4.5). Compared with European patients, immigrants from the Middle East were noted to have an earlier onset of disease, more rapid decline in islet  $\beta$ -cell function, and have a stronger family history [139]. In terms of prevalence rate, the United Arab Emirates, Saudi Arabia, Bahrain, Kuwait, Oman and Egypt all feature among the top 10 countries with the highest prevalence rate of diabetes [115], highlighting this region as one that requires concerted public health action in order to reduce the potential impact of diabetes [140].

## Western Pacific region

### Australia

The Report of the AusDiab Study [141], published in 2000, provides up-to-date information about diabetes in a developed country. The overall prevalence of diabetes in Australians aged  $\geq 25$  years was 7.5% (8% for males and 7% for females), rising from 2.5% in those aged 25–44 years to 24% among subjects aged  $\geq 75$  years; the prevalence has more than doubled since 1981 [142,143]. Fifty percent of cases discovered in this survey were previously undiagnosed. The combined prevalence of IFG and IGT was 16% (males 17%, females 15%); thus, almost 25% of Australians aged 25 years or more have abnormal glucose metabolism. In Australia, T2DM accounts for over 85% of cases and T1DM for 10%. Using data from the AusDiab study, it has been estimated that the prevalence of diabetes is likely to rise from 7.6% in 2000 to 11.4% by 2025 [144].

T2DM is more common in Native Australian populations (e.g. 16–30% of adults in the Aborigine and Torres Strait

Islander communities) [145]. In this population, diabetes was associated with higher rates of hypertension (69% vs 21%), obesity (44% vs 16%), elevated triglyceride and lower HDL cholesterol concentrations than subjects who have normal glucose tolerance.

### New Zealand

In New Zealand, T2DM is consistently more common among Polynesians (Maoris and Pacific Islanders) than in Caucasians; it accounts for 89% of diabetes in Caucasians and 95% in Polynesians. Polynesians are also diagnosed, on average, 5–10 years younger than Caucasians and have a four- to eightfold higher prevalence of diabetic nephropathy. Strikingly high prevalence rates of 37–75% were reported for unemployed males, again emphasizing the role of socioeconomic status [146]. In the 2006–2007 New Zealand Health Survey, prevalence rates reported for adults aged  $>30$  years were 4.3% for Europeans, 5.8% for Maoris, 6.5% for Asians and 10.0% for Pacific Islanders [147,148].

### Pacific Island countries

The Melanesian, Micronesian and Polynesian populations of the Pacific Islands show great variations in diabetes prevalence, largely attributable to differences in economic development and lifestyle. Some of the highest prevalence rates worldwide come from this region, notably from Nauru and Papua New Guinea. The Micronesian population of Nauru, made wealthy by bauxite mining and with a longer history of westernization than other Pacific Island countries, currently have an age-standardized prevalence rate of 40%. High prevalence rates in Nauru have been maintained since the late 1970s, but now appear to have stabilized [149].

Fiji has a largely bi-ethnic population consisting of native Fijians of Melanesian ancestry together with migrants from India. Recent surveys from Fiji are lacking, but a survey conducted 20 years ago showed that diabetes prevalence rates were already higher among Indian migrants than in Melanesians. In adults above 20 years of age, crude prevalence rates were 13% among the Indian migrants (with no significant urban–rural gradient), but 7% and 1.7% among urban and rural Melanesians, respectively [150]. At the time, these results were thought to indicate a difference in ethnic (genetic) predisposition but this conclusion has since been tempered by the finding of high prevalence rates in urbanized Melanesians in Papua New Guinea.

The situation in Papua New Guinea provides an excellent example of the damage inflicted by rapid urbanization; diabetes is virtually non-existent in highland populations [151], a stark contrast to the age-standardized prevalence rate of over 40% among urbanized Koki people (Melanesians) in Port Moresby [152]. Intermediate rates are reported in Austronesians of coastal ancestry.

High prevalence rates have also been reported in Polynesian populations, conspicuously associated with obesity, both of which are particularly common in Polynesian women. In Western Samoa, diabetes prevalence was reported in 1991 to be 7–9% in

**Table 4.5** Prevalences of diabetes in selected countries from the Middle East.

Year	Country	Prevalence (%)	
		T2DM	IGT
1998	Lebanon [220]	13.2	6
2000	Oman [221]		
	Males	11.8	7.1 (IFG)
	Females	11.6	5.1 (IFG)
1995	Oman [222]		
	Males	9.7	8.1
	Females	9.8	12.9
2000	Saudi Arabia [223]		
	Males	26.2	14.4
	Females	21.5	13.9
1995	Saudi Arabia [224]		
	Males	11.8	10
	Females	12.8	9
1992	Iran [225]		
	Urban males	7.1	8.9
	Urban females	7.6	14.9
	Rural	7.3	7.2

IFG, impaired fasting glucose; IGT, impaired glucose tolerance; T2DM, type 2 diabetes mellitus.

two rural communities and 16% in Apia; the prevalence had doubled since 1978 [153]. In the Kingdom of Tonga, situated south of Samoa, the age-standardized prevalence of diabetes was 15.1% [154].

Evidence suggests that diabetes remains undiagnosed in most Pacific Island people with the disease – perhaps 80–100% in some communities – compared with less than 50% in developed countries [143]. This is likely to contribute to high rates of complications and frequent presentation with diabetes-related problems such as foot sepsis [155].

**Japan**

T2DM has become more common in Japan since the 1960s, and data from rural parts of Japan suggested a prevalence of 9.1% in men and 10.8% in women, with corresponding IGT prevalence of 12% and 16.5% for Japanese men and women, respectively [156]. A National Diabetes Survey conducted in 2002 estimated a prevalence of 9% [157]. The emerging problem of T2DM among Japanese children is now recognized as a critical problem. T2DM outnumber T1DM in children and adolescents by a ratio of 4:1 [158], and the incidence rate of T2DM for 1981–1990 was 4.1 per 100 000 person-years, approximately twice the incidence rate of T1DM [159]. Nutritional factors are believed to play an important part, with the prevalence of diabetes among Japanese-Americans approximately twice that of Japanese in Japan [160].

The causes of death in people with T2DM have also shifted, possibly because of westernization of diet and increased fat and total calorie intake; higher death rates from renal disease than in Caucasian populations are now being supplanted by rising deaths from coronary artery disease [161]. In order to reduce the burden of diabetes, the Japanese government has launched a large national strategic research project named J-DOIT to reduce diabetes, improve patient adherence to follow-up and to reduce complications of diabetes [162].

**Korea**

In the Korean National Health and Nutrition Survey conducted in 2001, age-adjusted prevalence of diabetes was reported to be 7.6%. The prevalence of IFG was an alarming 23.9% [163], thus predicting a future epidemic of diabetes in the Korean population, similar to other Asian countries [164].

**China and Chinese populations**

The rapid increase in prevalence of T2DM in China provides one of the most striking examples of the impact of urbanization on increasing diabetes prevalence. The People’s Republic of China, with its population of 1.3 billion, is the world’s most populous country. Diabetes used to be rare; prevalence rates reported between 1980 and 1990 were consistently 1.5% or less, even in urban areas such as Shanghai [165], and as low as 0.3% in rural Guangdong Province. Recently, however, the prevalence has risen rapidly, a trend first demonstrated by studies conducted in the Da Qing area of north-eastern China. There,

the prevalence in 1986 was 1.0% but by 1994 this had increased over threefold to 3.5% [166,167]. The 1994 survey of 200 000 subjects aged 25–64 years in 19 provinces that included Da Qing found overall prevalence rates of 2.3% for diabetes and 2.1% for IGT. A community-based survey of 40 000 people aged 20–74 years in China between 1995 and 1997 confirms this rising trend and also demonstrates urban–rural gradients in prevalence rates. Age-standardized prevalence rates were 3.2% for diabetes and 4.8% for IGT, with the highest prevalence in provincial cities and the lowest in rural areas [168]. The International Collaborative Study of Cardiovascular Disease in Asia, conducted in 2000–2001, revealed a further increase in prevalence of diabetes (undiagnosed and diagnosed) to 5.5%, with another 7.3% affected by IGT (Figure 4.5) [169]. Furthermore, amongst the 20 million Chinese people estimated to have diabetes based on fasting blood glucose, only 30% were previously diagnosed [169]. The large proportion of subjects with IGT is particularly alarming. In the community-based Shanghai Diabetes Study, subjects with IGT and/or IFG had 11.7-fold increased risk of diabetes compared with those with normal glucose tolerance over a 3-year follow-up period [170].

Chinese populations in affluent societies such as Hong Kong, Singapore, Taiwan and Mauritius all show higher prevalence rates compared with the People’s Republic of China. In Hong Kong, prevalence of diabetes has been reported to have increased from 8% to 10% between 1990 and 1995 [171,172]. Recent studies from Taiwan indicate prevalence rates of 9–11%, although methodological discrepancies make direct comparisons difficult [165]. The annual incidence rate in Taiwan has been reported to be 1.8% [173]. In a review summarizing the findings from prevalence studies conducted in Chinese populations, it was noted that Chinese in Hong Kong and Taiwan have a 1.5- to 2.0-fold increased risk of diabetes adjusted for age and diagnostic criteria when compared with their mainland counterparts [174].

**Figure 4.5** Changes in prevalence of diabetes among Chinese adults aged 35–64 years. Data from the 1994 Chinese National Survey and the 2000–2001 InterASIA study. Reproduced from Gu *et al.* [169], with permission from Springer Science and Business Media.

The rapid increase in diabetes prevalence in China is likely to be driven by the increase in obesity, particularly among children and adolescents [5,175]. Analysis of data from the 2002 National Nutrition and Health Survey noted prevalence of overweight among children aged 7–12 years of 4.1%, and 5.6% for those aged 12–18 years, with obesity prevalence of 2.5% and 1.6%, respectively, for the two age groups [176]. In Hong Kong, a community-based study involving more than 2000 adolescents aged 11–18 years found alarming rates of obesity, with 8–10% of those aged 12–13 years fulfilling criteria for obesity [177]. In a national screening program among schoolchildren in Taiwan, 1992–1999, the rate of newly identified diabetes was 9.0 per 100 000 for boys and 15.3 per 100 000 for girls. Obesity was found to be the major risk factor for the development of T2DM, whereby children with BMI in the 95th percentile or higher had an approximately 19-fold increased risk of T2DM compared with those with BMI <50th percentile [178].

Such alarming data from Chinese populations highlight the potential for future rises within China itself. Unless effective measures can be implemented, given the huge population in China, the consequences could be devastating. The International Diabetes Federation has forecasted that by 2030, there will be 67 million people affected by diabetes in China [1].

### South-East Asian Peninsula

There is considerable economic diversity within this region, although the recent emerging data from this region showed that despite the relatively traditional lifestyle in many of the countries, diabetes is increasingly common within the region. A survey performed in two villages in Cambodia in 2004 revealed a diabetes prevalence rate of 5% in the rural community in Siemreap but up to 11% in a semi-urban community [179]. A study conducted in adults in Ho Chi Minh City in Southern Vietnam indicated that the prevalence of diabetes has increased substantially from 2.5% in 1993 to 6.9% in 2001 [180]. Similar increases has been reported in Indonesia [181] and the Philippines [182]. Prevalence rates in Thailand appear to be approaching those reported from Malaysia and Singapore, with prevalence of diabetes and IGT in a recent national survey reported to be 6.7% and 12.5%, respectively [183].

In Singapore, serial studies since 1975 have shown a rising prevalence of diabetes from 2% in 1975 to 4.7% in 1984, 8.6% in 1992 and 9% in 1998. Two most recent surveys indicate that the rate of rise may have stabilized. Ethnic Malays (especially Malay women) and Indians have the highest rates of diabetes (14.3–16.7%) and also the highest rates of obesity. A further 15% of the adult population have IGT. In a recent survey conducted in 2004 by the Ministry of Health, Singapore, the prevalence of diabetes among the adult population is estimated to be 8.2% [184]. Obesity and adoption of a westernized diet and lifestyle are again closely associated. T2DM in childhood is also highlighted as an emerging problem.

## Impact of diabetes

The epidemic of diabetes is having major impacts on both individuals and societies. These impacts are discussed in Chapter 5. The major burden is from the treatment cost of its complications, such as stroke, blindness, coronary artery disease, renal failure, amputation and infection. In 2007, about 3.8 million people died of diabetes and its related diseases. Most patients die from cardiovascular disease (particularly coronary artery disease and stroke) and end-stage renal disease. There are geographic differences in both the magnitude of these problems and their relative contributions to overall morbidity and mortality. In Caucasian populations, macrovascular complications such as coronary artery disease and amputation are major causes of disability. In contrast, end-stage renal disease and stroke are prevalent among Chinese and Asian ethnic groups. Other issues include the apparent vulnerability of Pacific Island populations to neuropathy and metabolic problems, and South Asian to coronary artery disease.

It is well established that the occurrence of vascular complications of diabetes is related to the duration of hyperglycemia. With the earlier onset of T2DM, most patients will have increased risk of developing these devastating complications. Despite the high prevalence of complications of diabetes and hence the high costs of management, simple low-cost measures are effective in preventing the development of diabetes and its vascular complications. Rather than merely focusing on the control of hyperglycemia, global risk reduction with attention on cardiovascular risk factors has been proved to be the most effective way of reducing the burden of diabetes. The challenge is to provide a platform whereby effective care can be delivered at an affordable cost.

### Mortality and morbidity

Diabetes is associated with approximately twofold increased mortality in most populations, with the excess risk decreasing with increasing age [185–187]. While initial data suggest the excess mortality associated with diabetes may be higher in Asian populations, this is probably related to differences in death certificates coding practices [188–190]. It was recently estimated that about 4 million deaths in the 20–79 age group may be attributed to diabetes in 2010, accounting for 6.8% of global all-cause mortality in this age group. Over two-thirds of these deaths attributable to diabetes are believed to have occurred in low and middle income countries [1].

Most patients with T2DM die from cardiovascular disease (particularly ischemic heart disease and stroke) and end-stage renal disease [191]. Geographic differences exist in both the magnitude of these problems and their relative contributions to overall morbidity and mortality.

The most systematic comparative data, using standardized methodology, originate from the WHO Multinational Study of Vascular Disease in Diabetes, which has drawn from 14 centers in 13 countries since the 1980s. A follow-up report from 10 of

these centers [192] shows that coronary heart disease and limb amputation rates varied 10- to 20-fold among different centers; there was also marked variation in prevalence of clinical proteinuria and renal failure, but less variation in retinopathy and severe visual impairment. Striking features include the relative rarity of ischemic heart disease and lower extremity amputation in Hong Kong and Tokyo, contrasting with a high incidence of stroke, especially in Hong Kong. A high incidence of stroke was also found in Arizona and Oklahoma, the two Native American Indian centers. The highest rates of ischemic heart disease were seen in the European centers, notably among women from Warsaw. Myocardial infarction was also common in Native American Indians, especially among men, while renal failure and proteinuria rates were highest among Native American Indians and in Hong Kong.

Other issues include the apparent vulnerability of Pacific Island populations to diabetic foot problems associated with neuropathy and of South Asians to coronary heart disease. Importantly, the risk of coronary heart disease is already increased twofold at the stage of IGT [193].

Another cause of morbidity and mortality is the increased risk of cancer in patients with diabetes. Various epidemiologic studies from different populations have suggested a link between diabetes and increased risk of pancreatic, hepatocellular, endometrial, breast and colorectal carcinoma [194–196]. While some of this may be because of the presence of common risk factors such as obesity and dietary factors, it has been shown in a large prospective study that cancer risk increases with increasing fasting glucose at baseline [197].

Intensive multifactorial intervention to reduce cardiovascular risk factors has been shown to be effective in reducing cardiovascular mortality in diabetes [198,199]. While intensive blood

glucose control has not been shown to lower cardiovascular mortality in the short term [200,201], it may have beneficial effects in reducing cardiovascular and total mortality in the longer term, as suggested by recent long-term follow-up data from the UK Prospective Diabetes Study [202]. It appears that the relative mortality of diabetes is decreasing in some countries [203,204], and this may be related to the increased utilization of drugs to control hyperlipidemia, hyperglycemia and hypertension [205].

**Health care burden and economic costs**

The increase in diabetes prevalence, particularly among young adults, along with the increased morbidity and mortality associated with microvascular and macrovascular complications, is likely to lead to escalation of health care costs and loss of economic growth. WHO predicts that between 2005 and 2015, net losses in national income from diabetes and cardiovascular disease will reach international dollars (ID) 557.7 billion in China, ID303.2 billion in the Russian Federation, ID336.6 billion in India, ID49.2 billion in Brazil and ID2.5 billion in the United Republic of Tanzania [115]. The annual global health expenditure for diabetes in 2007 is estimated to fall between \$232.0 and \$421.7 billion, of which half will be spent in the USA (around \$119.4 billion) and one-quarter in Europe (\$64 billion). In the USA, the estimated total costs (direct and indirect) of diabetes increased from \$23 billion in 1969 to \$132 billion in 2002 [206,207]. The cost of diabetes in the USA in 2007 was estimated by the ADA to be \$174 billion, which includes \$116 billion in excess medical expenditures and \$58 billion in reduced national productivity (Figure 4.6). The largest components of medical expenditures attributed to diabetes are hospital inpatient care, accounting for 50% of total costs, and medications and supplies (12%) [208]; however, the actual burden is likely to be even

**Figure 4.6** Economic costs of diabetes in the USA according to different cost of care for different diabetes-related complications [208]. Reproduced from American Diabetes Association (2008), with permission from American Diabetes Association.

**Table 4.6** Estimated direct medical costs of diabetes by region, 2003. Adapted from Narayan *et al.* [226].

Region	Direct medical costs (millions)	
	Low estimate	High estimate
<b>Developing countries</b>	<b>\$12 304</b>	<b>\$23 127</b>
East Asia and the Pacific	\$1368	\$2656
Europe and Central Asia	\$2884	\$5336
Latin America and the Caribbean	\$4592	\$8676
Middle East and North Africa	\$2347	\$4340
South Asia	\$840	\$1589
Sub-Saharan Africa	\$273	\$530
<b>Developed countries</b>	<b>\$116 365</b>	<b>\$217 760</b>
<b>World</b>	<b>\$128 669</b>	<b>\$240 887</b>

greater, because other non-monetary effects such as changes in quality of life, disability and suffering, care provided by non-paid caregivers cannot be included in such analyses. The burden of diabetes affects all sectors of society; higher insurance premiums paid by employees and employers, reduced earnings through productivity loss and reduced overall quality of life for people with diabetes and their families and friends. The cost of medical care for diabetes varies greatly among the different regions (Table 4.6). While diabetes is a very costly disease, interventions used to prevent or control diabetes differ greatly in their cost-effectiveness [209]. The cost-effectiveness and feasibility of diabetes interventions in low and middle income countries, as assessed by the World Bank, is listed in Table 4.7. Cost-effective interventions that are technically and culturally feasible should be implemented with the highest priority [210].

## Prevention of type 2 diabetes

*“There are entirely too many diabetic patients in the country. Statistics for the last thirty years show so great an increase in the number that, unless this were in part explained by a better recognition of the disease, the outlook for the future would be startling. Therefore, it is proper at the present time to devote attention not alone to treatment, but still more, as in the campaign against the typhoid fever, to prevention. The results may not be quite so striking or as immediate, but they are sure to come and to be important”.*  
[Elliot Joslin, 1921]

T2DM is a very expensive disease. As illustrated above, a significant proportion of health care expenditure in developed countries is spent on the treatment of diabetes and its complications. It is therefore beneficial to prevent diabetes or delay its onset, thereby also reducing its associated complications. With improved understanding of the natural history of the development of

T2DM and the role of various modifiable risk factors in its pathogenesis, a number of randomized clinical trials have been performed to examine the effect of lifestyle intervention on prevention of T2DM. A large body of evidence has accumulated from these studies on the effectiveness of lifestyle measures in the prevention of diabetes, summarized in Table 4.8. Most of these interventions include structured education and exercise programs, reducing fat intake and increasing fiber intake, moderate exercise for 30 minutes per day or more, and moderate weight reduction of 5% or more. Importantly, in addition to being highly cost-effective, the effect of structured lifestyle intervention on reduction of diabetes risk appears to be maintained over a long duration of follow-up [211,212]. In a follow-up of the Chinese Da Qing Diabetes Prevention Study, participants who received lifestyle intervention had a 51% lower incidence of diabetes during the 6-year active intervention period, and 43% lower incidence of diabetes over the 20-year period [212].

In addition to lifestyle intervention, several agents used in the treatment of T2DM and obesity have been evaluated in clinical trials and found to be effective in preventing diabetes. These include meformin, the thiazolidinedione class of compounds, acarbose and orlistat (Table 4.9). In addition, several clinical trials indicated that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers may reduce incident diabetes in high-risk patients with hypertension [213–217]. A large randomized clinical trial compared the ACE inhibitor ramipril with placebo in subjects with IGT or IFG. It did not show a significant reduction in incident diabetes after median follow-up of 3 years, although ramipril was associated with increased regression to normoglycemia [218]. A large number of pharmacologic agents are currently in development or undergoing clinical trials for the treatment of T2DM or obesity. This should provide a constant supply of promising agents for evaluation in their effectiveness for preventing T2DM. At present, however, lifestyle intervention remains more cost-effective as a strategy for diabetes prevention.

More detailed discussion on epidemiologic aspects of diabetes can be found elsewhere [219].

## Conclusions

The interaction between genetic predisposition, popularization of fast food and sedentary lifestyle has a major role in the increase in the prevalence of impaired glucose tolerance and T2DM globally. Countries in the Asia Pacific regions with a growing economy will bear the major burden in the increase in number of subjects with diabetes. The significant increase in macrovascular and microvascular complications of diabetes induces a heavy burden on the health care resources. Recent studies confirmed the benefit of intensive multifactorial risk management in reducing all-cause mortality and cardiovascular adverse events. Measures such as dietary restriction and exercise have been shown to be effective in preventing the progression of IGT to

**Table 4.7** Summary of cost-effectiveness of interventions for treatment and prevention of diabetes in developing countries. Reproduced from Narayan *et al.* [226].

Intervention	Cost/QALY (2001 US\$)						Feasibility*	Implementing priority†
	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa		
<b>Level 1</b>								
Glycemic control in people with HbA <sub>1c</sub> higher than 9%	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++++	1

Screening for undiagnosed diabetes	5140	6910	8550	7260	4280	3870	++	3
Annual screening for microalbuminuria	3310	4450	5510	4680	2760	2500	++	3

\* Feasibility was assessed based on difficulty of reaching the intervention population (the capacity of the health care system to deliver an intervention to the targeted population), technical complexity (the level of medical technologies or expertise needed for implementing an intervention), capital intensity (the amount of capital required for an intervention), and cultural acceptability (appropriateness of an intervention in terms of social norms and/or religious beliefs). +++++ indicates feasible for all four aspects, +++ indicates feasible for three of the four, ++ indicates feasible for two of the four, and + indicates feasible for one of the four.

† Implementing priority was assessed by combining the cost-effectiveness of an intervention and its implementation feasibility; 1 represents the highest priority and 3 represents the lowest priority.

diabetes. Hence, despite being one of the most common chronic diseases, diabetes can be prevented or controlled effectively with interventions that are relatively cost-effective compared with the cost of treating vascular complications.

*“Some 246 million people worldwide have diabetes in 2007. It is now one of the most common non-communicable diseases globally. Diabetes is the fourth or fifth leading cause of death in most developed*

*countries and there is substantial evidence that it is epidemic in many developing and newly industrialized nations.*

*Complications from diabetes, such as coronary artery and peripheral vascular disease, stroke, diabetic neuropathy, amputations, renal failure and blindness are resulting in increasing disability, reduced life expectancy and enormous health costs for virtually every society. Diabetes is certain to be one of the most challenging health problems in the 21st century.” [115]*

## The Global Burden of Diabetes

**Mohammed K. Ali,<sup>1,2</sup> Mary Beth Weber<sup>2</sup> & K.M. Venkat Narayan<sup>1,3</sup>**

<sup>1</sup>Hubert Department of Global Health, Rollins School of Public Health, Emory University, Atlanta, GA, USA

<sup>2</sup>Global Diabetes Research Center, Emory University, Atlanta, GA, USA

<sup>3</sup>Department of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA, USA

### Keypoints

- Diabetes results in a range of distressing symptoms, altered daily functioning (requiring attentive monitoring and treatments), changed family roles, higher costs, lost productivity and premature mortality, which are felt by households, communities, and national economies.
- Diabetes is the fifth leading cause of death in the world (4 million deaths annually), outnumbering global deaths from HIV/AIDS; 80% of this mortality occurs in low and middle income countries, disproportionately affecting the young and economically active populations.
- Cost appraisal methods require epidemiologic, clinical, and economic data, and utilize different approaches to calculate the direct medical costs (of treatment, diagnosis, monitoring), indirect costs (of lost outputs from disability and premature death) and intangible losses (psychosocial burdens) attributable to diabetes.
- Even though there are large variations in methods of cost appraisal, cost items incorporated and purchasing power, as well as accessibility to and patterns of clinical care resulting in widely varied between-country per capita expenditures, it is clear that the presence of diabetes results in excess consumption of resources worldwide.
- Progressive severity of disease complications, co-morbidities and complexity of therapy all increase the monetary, infrastructural and human resource costs of care.
- Individuals in vulnerable subpopulations are at an elevated risk of developing diabetes and progression toward significantly harmful outcomes, and devote a large proportion of resources toward their therapies and diabetes care; confronting the increased susceptibility and burdens will require addressing the underlying political, socioeconomic and behavioral factors that perpetuate disparities.

### Introduction

Diabetes has emerged as a major health problem worldwide, with serious health-related and socioeconomic impacts on individuals and populations alike. Furthermore, the pandemic growth of diabetes is being spurred on by transitioning demographic (e.g. population aging), socioeconomic, migratory, nutritional and lifestyle patterns, and an affiliated proliferation in overweight and obese adults and children [1–2]. The International Diabetes Federation estimates there are 285 million people with diabetes worldwide in 2010 [3], and projects the absolute number will surpass 400 million in the coming twenty years. The overwhelming majority of this escalation will be attributable to growth of type 2 diabetes (T2DM). Rapid socioeconomic transformations seen with globalization, increasing urbanization, industrialization and marketization of developing regions will also result in a parallel growth of diabetes precursors (impaired fasting glucose [IFG] and impaired glucose tolerance [IGT]) and ensuing health consequences [4–6].

Current estimates suggest that two-thirds of those affected by diabetes live in low and middle income countries (LMIC). This challenges traditional paradigms that segregated chronic non-communicable diseases (NCDs) as problems of affluent countries alone. Eight out of the top 10 countries with the highest absolute numbers of people with diabetes are developing or transitioning economy countries [3]. While this burden of greater absolute numbers may be partially explained by larger population size, the rates at which NCDs are increasing in these countries amid transition are much steeper when compared with those in more developed affluent countries [7]; by 2025, the number of diabetes cases will increase by 170% in low and middle income countries, compared to a 41% increase in developed countries [8].

Thus far, the attention on health burdens in the developing world has focused justifiably on the persistence of infectious diseases and nutritional deficiencies; however, these same countries must also contend with 80% of global mortality associated with chronic diseases [9,10]. Projections suggest that this already overwhelming “double burden” will be exacerbated by the growth of NCDs. Altogether, projected increases in diabetes in all corners of the globe will result in corresponding escalation of burdens in the form of serious morbidity, disability, diminished life expectancy, reduced quality of life, loss of human and social capital, as well as individual and national income losses. This chapter

describes these burdens in a global context, and systematically introduces data regarding regional patterns and associated themes.

---

## Distribution and trends

Epidemiologic evidence quantifies the impacts and predictors of disease, identifies vulnerable populations and their needs, and facilitates formulation of appropriate disease prevention and control strategies; however, there are still limited representative epidemiologic data originating from a great many LMICs. Moreover, the utility of currently available estimates is hampered by methodological deficiencies (inconsistent diagnostic criteria, poor standardization of methods) and limited coverage (regional sampling with a predominance of urban studies whereas the vast majority of the populations in question are rural inhabitants). Despite this, notable patterns can be discerned and can be described by giving examples from regions where they are particularly noteworthy.

In Africa, there is:

- A general lack of awareness about chronic diseases and their risk factors.
- Limited data originating from a few localized centers in certain regions (western, eastern and southern) of the continent. The latest data (1998–2004) show prevalence rates of 1–3% in rural areas and 6–10% in urban environments [11].
- A growing double burden of communicable diseases and nutritional deficiencies, along with NCDs, especially where there is rapid economic development and globalization. Between-country differences in NCD prevalence likely reflect different stages of socioeconomic and epidemiologic transitions [12].
- A tendency for cultural (perceptions of excess weight and imported processed foods as symbols of status and luxury) and societal (stigmas regarding loss of weight as a sign of HIV infection) factors to influence health-seeking behavior [11,13].
- Variation in risk by ethnicity, with Black Africans showing a greater preponderance toward hypertension, while those of Egyptian and Asian Indian origin demonstrate higher prevalence of diabetes [14].

In Europe, the USA and Canada:

- Available data are derived from population studies, records of insulin and antidiabetic medication sales and/or reimbursement claims. Estimates still suggest 30–50% of people in these high income countries (HIC) have undiagnosed diabetes [4].
- Annual incidence of type 1 diabetes (T1DM) is increasing in Europe (+3.2% per year) and North America (+5.3% per year); the highest reported incidence rate is in Finland (40.9/100,000 per year) [15,16].
- Prevalence of T2DM is highest and growing fastest in vulnerable subgroups such as lower socioeconomic groups and the elderly [4].

- Life expectancy of people with diabetes, although reduced when compared with the general population, is markedly higher than in developing regions of the world. This is largely attributable to differences in access to self blood glucose monitoring and therapies to control glycemia.
- Uptake and costs related to newer and more expensive investigations and therapies are associated with inflated national health expenditures.

In Latin America:

- There is wide variation in prevalence rates (1.2–8%) of diabetes, reflecting the diversity of ethnicities and stage of development between countries.
- The pattern of T1DM incidence seems to correspond to the size of the population of Caucasoid origin.
- Diagnosis of diabetes frequently occurs late in the course of disease. Thus, complications may be present in 30–40% of cases at time of presentation for health care.
- Poor accessibility to health services results in only 30–40% of cases actually receiving therapy [17].

Asia is emerging as the epicenter of the cardiometabolic pandemic, because:

- Populous countries in this region are confronted with diabetes risk being manifest at younger ages and at lower body mass indices compared with populations in other regions.
- Patterns of genetic and/or ethnic propensity; South Asians and peninsular Arabs have markedly elevated metabolic risk [18]; Japanese are reported to have the highest prevalence of genetic polymorphisms [19]. Rural–urban differences in prevalence together suggest both gene–environment interactions and influences of the “thrifty” genotype.
- Estimates suggest a three- to fivefold increase in prevalence of T2DM over the last three decades, and an increasing prevalence of T2DM in children, with major implications for future burden in this region [20,21].
- India is estimated to have 50.8 million people living with diabetes [3], the highest absolute number in any country [22] and projections suggest that one-fifth of all people with T2DM will be living in the Indian subcontinent by 2030 [23].
- The “Asian Indian phenotype” is characterized by a preponderance to deposition of metabolically active visceral adiposity which may explain the greater vulnerability to diabetes in this population [24–26], while Western Pacific Islanders also demonstrate a markedly elevated risk.

Diabetes is renowned as a “silent epidemic” [22]. The slow progression and lack of symptoms in the early stages of disease preclude seeking medical attention and preventative care. As such, reported prevalence reflects an underestimate of the number of cases because it does not account for undiagnosed cases. Population studies estimate that 30–50% of diabetes cases are as yet unrecognized, even in the most advanced countries [4,17]. Also, almost half of all newly diagnosed cases will have already developed diabetes-related complications in the form of nerve, eye, kidney, and/or vascular diseases [23,27,28]. Target organ

damage of this nature can be life-threatening and/or seriously disabling [29].

The traditional socioeconomic gradient associated with chronic diseases may itself be transitioning. As the world's urban population size begins to outnumber those living in rural areas, many developing economies face enormous challenges related to the growth of peri-urban slums and squatter settlements, the disparities in provision of basic amenities and lack of adequate sanitation and nourishment. Further challenges include subsequent exposure to contemporary dietary choices, tobacco use and mechanization of transport with consequent growth in the incidence of NCDs. Thus, the paradigm is shifting *globally* towards the inverse relationship found in established market economies where the greatest burdens of NCDs are felt by the least well-off segments of the population [30–35]. In India for example, Ramachandran *et al.* [36] demonstrated that although family history and prevalence of glycemic abnormalities in high-income groups were double those of low-income groups, the reverse was true for smoking, alcohol consumption, prevalence of co-morbid cardiovascular risks and occurrence of complications (macrovascular disease, cataracts, proteinuria and neuropathy). Recent prevalence and trend data show greater disease susceptibility in lower socioeconomic groups in India [37,38], mimicking patterns in wealthier nations [39–42]. As this chapter progresses, it will become evident that the countries with the greatest burdens of disease are also those least equipped to manage the growing epidemics.

## Major burdens

The burden of any disease, including diabetes, can be described by its health-related impacts: the morbidity and mortality caused, and the social and economic costs to individuals, families, communities and national economies (Box 5.1). Evaluation of resources utilized or lost, be they human, social, monetary or infrastructural, and placing objective “values” on them may be inherently partial to the perspective taken. The term “value” may be used to describe the measured and/or perceived net worth of resources consumed or lost because of illness and/or infirmity which is the mode used in this chapter. Economists use this term to express the net benefit derived from an investment in health care in proportion to the amount of resources used [43].

### Acute and chronic disease complications

The patterns of major health-related burdens of diabetes vary by the type of disease. T2DM accounts for 90–95% of all cases worldwide. Both T1DM and T2DM, the two most common forms, may be associated with acute and chronic metabolic consequences, but the frequency of events varies according to the underlying pathophysiology and level of glycemic control.

Acute fluctuations in serum glucose may rapidly spiral into emergency situations, with potentially fatal repercussions if untreated. Episodes of severe acute hyperglycemia (e.g. diabetic ketoacidosis [DKA] and hyperosmolar hyperglycemic syndrome)

### Box 5.1 Evaluation of burden

#### *Health-related burdens*

- Health seeking and utilization (frequency and costs)
- Disease events and/or ill health
- Morbidity (physical and psychosocial)
- Mortality

#### *Social implications of disease*

- Disability
- Alteration of social roles or family structure
- Caregiver or “intangible” burdens

#### *Economic costs of disease*

- Direct medical expenditure
- Ancillary expenses of health seeking and care
- Indirect costs (losses in productivity)

or, conversely, severe hypoglycemia, most often require immediate medical management. Longer term follow-up is then intended to promote better blood glucose regulation and avoidance of precipitants of diabetic emergencies (e.g. infection, non-compliance with treatments, missing meals, alcohol abuse). Apart from atypical variants such as ketosis-prone T2DM in African subjects [11], the vast majority of acute complications occur in patients with T1DM, while approximately 10–12% occur in subjects with T2DM. When treated properly, the mortality from acute hyperglycemic episodes such as DKA is extremely low (e.g. DKA mortality in Taiwan, USA and Denmark were estimated to occur in 0.67–4.0% of cases) [44,45]. In contrast, in some African countries, mortality from DKA can be as high as 25–33% [46], although the incidence of these complications from LMIC settings is limited [47]. Individual patient (e.g. age, additional comorbidities) and resource (e.g. hospital facilities, experience of staff) characteristics may also modify the outcomes. In under-resourced settings for example, complex, cumulative and interconnected barriers (poor accessibility, inadequate therapeutic instruments and medication, and insufficient numbers of trained staff) result in poor glycemic control and higher risk of mortality [48]. As such, early life mortality in patients with T1DM in low-resource settings is commonplace. The post-diagnosis life expectancy in some regions of Africa is just 1 year [49].

Apart from glucose dysregulation, both T1DM and T2DM are associated with damaging effects on tissues, with eventual progression to devastating complications. Diabetes increases the risk of macrovascular diseases (cardiovascular diseases [CVD], which comprise coronary heart disease and cerebrovascular disease or “stroke,” and peripheral vascular disease [PVD]), microvascular diseases (retinopathy and nephropathy), neuropathies, and the consequences that stem from these (e.g. congestive heart failure, diabetic foot). These complications are associated with considerable morbidity, reduced quality of life, disability, premature mortality and high economic costs.

In addition, T2DM is associated with the “metabolic syndrome,” a collection of cardiovascular risk factors (abdominal obesity, hyperinsulinemia, hypertension, dyslipidemia, proinflammatory and procoagulant states). It is believed that these biochemical and inflammatory derangements are intimately linked, possibly by a central mediating factor. In Latin America, it is estimated that 53–69% of people with diabetes have abnormal serum lipid subfractions, and 34–67% have hypertension [17]. As such, these factors increase the likelihood of developing additional risks, and with each added risk, predispose one to an exponentially increasing risk of atherosclerotic vascular disease events and mortality [50].

Moreover, T2DM has a distinctive association with coronary heart disease (CHD). Those with diabetes have a two- to fourfold higher risk of developing CHD than people without diabetes [51]. More significantly, however, the age- and sex-adjusted cardiovascular mortality risk in patients with diabetes is equivalent to that of individuals without diabetes who have had a previous myocardial infarction (MI) [50,52,53]. Precursors common to both T2DM and CVD (insulin resistance, visceral adiposity and excess inflammation) [54–58], and a complex mix of mechanistic processes such as oxidative stress, enhanced atherogenicity of cholesterol particles, abnormal vascular reactivity, augmented hemostatic activation and renal dysfunction, cumulatively confer this elevated risk of CHD [59]. As such, simply controlling glucose has not been found to reduce CVD events and mortality in large randomized controlled trials at least in the short term [60–62]. The implications therefore are that individualized comprehensive multifactorial risk management, involving the treatment of all co-morbidities, has been advocated for people with T2DM [63,64], adding to the burdens placed on patients, providers and health systems.

Diabetes also increases the risk of renal dysfunction. In Africa, it is estimated that within 5–10 years following diagnosis, 32–57% of people with diabetes will have developed microalbuminuria [48,65]. Also, diabetes is the primary cause in approximately 45% of patients with end-stage renal disease (ESRD) requiring dialysis or transplantation in the USA [66,67]. Meanwhile, approximately one in four persons with diabetes have some visual impairment, and 5% of all cases of blindness globally are caused by diabetes [68]. Particularly in the case of retinopathy and nephropathy, duration of disease, age, glycemic control and blood pressure control have all been found to be prominent modifying factors of disease onset, progression and outcomes.

Neuropathies are also common consequences of diabetes. One-third of Sri Lankan people with diabetes surveyed had lower extremity sensory loss putting them at risk of ulceration [69], while a similar proportion of people with diabetes in African countries were found to have either neuropathy or compromised peripheral vascular circulation [70,71]. The combination of neuropathy, increased susceptibility to infection, poor wound healing and poor distal circulation increases the risk of lower extremity amputation 15- to 40-fold [67,72].

The most significant repercussion of the asymptomatic early natural history of the diabetes and low community awareness is

that subclinical disease results in progressive tissue injury. Microvascular and macrovascular complications cause morbidity, greater health-seeking and increased mortality risk in all regions of the world [23,27,73].

### Health utilization patterns

Health seeking and health utilization behaviors are influenced by a number of individual, provider and system level factors. In the case of diabetes, ill health and morbidity as well as preventative care motives result in incrementally more health service utilization. In Costa Rica, for example, people with diabetes made 55% more medical visits than those without diabetes, and German patients with diabetes averaged 31 yearly consultations with general practitioners (GPs) and/or specialists [74,75]. In Sweden and Italy, approximately half of diabetes-related consultations were at hospital outpatient departments or dedicated diabetes centers, respectively, and the remainder were with GPs [76,77]. In Latin America, diabetes accounts for an estimated 35 million medical visits annually [74].

Various studies have shown that having diabetes doubles one’s risk of hospitalization compared to not having diabetes, and this risk is amplified by the development of diabetes-related complications. The presence of poor peripheral circulation increases the risk of hospitalization by 70%, while CVD increases this risk by 310% [67]. The Cost of Diabetes in Europe Type II Study (CODE-2) reported 13% of people with T2DM were hospitalized (with an average stay of 23 days) over the 6-month study follow-up, while Germany’s Cost of Diabetes Mellitus (CoDiM) study reported that 28.8% of people with diabetes had at least one hospital admission in 2001 [75]. Although studies from most regions of the world report late-stage macrovascular or microvascular complications as the leading cause of diabetes-related hospitalizations, lower income settings such as Ethiopia confront a greater proportion (almost two-thirds) of admissions in the form of acute episodes of dysglycemia.

Health care infrastructure and financing have strong impacts on health seeking and utilization. In India, estimates suggest that 85–95% of all health care costs are borne by individuals and their families from household income [78–81]. In Latin America, 40–60% of diabetes expenses are derived from out-of-pocket payments. A survey in Jamaica showed that 57% of the sample reported financial difficulties as a result of illness, and of these, half disclosed that they had avoided therapy because of economic constraints [74]. Financial limitations to accessing treatment are not confined to LMICs, as illustrated by 19% of elderly Americans revealing curtailed purchases of diabetes medications as a result of costs [82,83].

When one considers that the average number of medications used by people with diabetes in India is 3.5 [79], the cost implications are substantial. These drugs include antihypertensives, lipid-lowering, antidepressant medications and aspirin in addition to glucose-lowering drugs). The use of oral hypoglycemics increases health expenditure by 40% compared to the general population, while regular insulin use is a further twofold greater expense. As such, data from Germany show that use of insulin

with or without oral agents increases total costs 3.1–3.4 times [75,84].

Increased health seeking and utilization in people with diabetes and associated complications result in greater medical costs incurred, compared to the general non-diabetic population.

### Disability

Aside from the medical or biologic dysfunction caused by disease, there are implications of ill health for individual and interactive functioning in society. This concept of “disability” is distinctive from simple biomedical models of disease and signifies that psychosocial illness or physical deviations from generally accepted norms of anatomical structure or physiologic function may impair one’s ability to perform domestic and occupational activities, and assume societal roles. As a result, diabetes may inhibit one’s general utility and ability to integrate fully in society.

Diabetes can lead to disability through a variety of ways. Excluding the medical aspects of diabetes-related complications that directly restrict bodily function, diabetes may be considered a “hidden” disability, whereby the individual concerned is hampered from routine activities, but displays no physical manifestation of this illness. For example, children with diabetes may be unable to participate in all activities their contemporaries are engaged in and may suffer wrongful discrimination. Adults in the workplace may have lower work performance by virtue of any number of symptoms (impaired fine motor skills and concentration, grogginess, urinary frequency) [85] or even decline in cognitive functioning [86–88]. Those requiring insulin may be limited additionally by highly structured activities of daily living (the requirement of meticulous glucose monitoring, insulin administration, timed eating), recurrent hospitalizations, hyperglycemic and hypoglycemic episodes, and by regular preventative or therapeutic medical visits.

Indeed, the physical manifestations of diabetes become more significant with the development of complications. As such, visual impairment, restricted mobility (from shortness of breath, chest pain or even amputation) and general ill health (ranging from increased susceptibility to infection all the way to uremia related to irreversible renal dysfunction) are all considerable impediments to productive work and engagement in socially valuable activity. Cross-sectional studies in the USA have demonstrated that elevated glycated haemoglobin (HbA<sub>1c</sub>) is associated with a higher likelihood of missing work, greater hours absent [89] and reduced at-work efficiency [85].

Depending on the health status of the individual and severity of disease, disability can be temporary or permanent. There is limited country-specific data on the permanent disability resulting from diabetes, although diabetes is the leading cause of adult-onset blindness, non-traumatic amputations and irreversible kidney failure worldwide [22]. Data from Chile showed that 8% of people with diabetes had some form of permanent disability [74].

Less tangible, but no less severe, are the psychosocial burdens that may accompany diabetes and affect functioning [90,91]. In a health maintenance organization cohort of 1642 people with

diabetes, 12% were unemployed, 7% of those employed had missed more than 5 working days in the previous month and 4% of employed subjects reported difficulties with completing work tasks. Of those with any form of work disability inducing absence and/or poor productivity, over half had minor and/or major signs and symptoms of depression [92].

The complexity of disability as a limitation of individual and societal function is in quantifying this shortcoming. There are several methods that have been used which factor in age, education and occupation, but most have at least some imperfection because of the necessity of making judgments about the value of activities. This is especially difficult where there are cultural and ideological dissimilarities between the evaluator and the population being appraised.

### Mortality

Ascertaining the global mortality attributable to diabetes is no easy task. Most mortality statistics rely on documented causes of death and do not acknowledge the roles of glucose dysregulation in underlying mortality associated with CVD and renal diseases. Danaei *et al.* [29] have therefore argued that evaluating actual diabetes-related mortality should take into account that diabetes contributes to 21% of CHD and 13% of stroke mortality worldwide. The World Health Organization (WHO) incorporated these sentiments into calculating that diabetes is the fifth leading cause of death worldwide in 2000 [93]. The International Diabetes Federation’s most recent *Diabetes Atlas* approximates that diabetes is responsible for 6.8% of total global mortality (4 million deaths) annually [22,94]. In addition, the mortality attributable to diabetes would be even higher if deaths related to IGT were also included. This diabetes precursor independently increases the risk of mortality, and has a prevalence of 15–40% in adults [6].

Altogether, diabetes is associated with premature mortality, shortening life expectancy by approximately 7–15 years [95,96]. In developed countries, CVDs account for an overwhelming 65–75% of deaths in people with diabetes [97,98]. In low-resource settings, infections and acute metabolic emergencies are still the prevailing causes of death in people with diabetes [11,12,65,99]. ESRD also carries inexorably high mortality, mainly because of inaccessibility (physical and financial) of treatment (dialysis and/or transplantation) in most LMICs [11]. As a result, globally, CVD and nephropathy are the most prominent fatal endpoints, and occurrence is analogous to duration of disease in that early life survival and long-standing diabetes increase susceptibility to succumbing from these illnesses [27].

There is regional variation in the global distribution of diabetes-related mortality. Estimates for the percentages of deaths attributable to diabetes by region are shown in Table 5.1. Although the proportion of deaths in LMICs is lower than in more developed countries, the absolute numbers of deaths, by virtue of larger population size, outnumber those in economically developed countries. South Asia is currently reported to have the highest absolute number of diabetes-related deaths annually [100]. Also, there is a noticeably greater proportion of deaths in

**Table 5.1** Estimated percentage of deaths attributed to diabetes by age and World Health Organization (WHO) region. All figures are presented as male/female percentages. Adapted from Roglic *et al.* [93].

Region	Age (0–34 years)		Age (35–64 years)		Age (≥65 years)		All ages	
	Male	Female	Male	Female	Male	Female	Male	Female
African Region	0.5	0.8	7.1	7.9	2.7	4.1	2.2	2.5
Region of the Americas	0.4	0.5	11.6	17.8	5.4	7.7	6.0	8.6
Eastern Mediterranean	0.5	0.8	14.8	22.3	6.6	10.0	6.1	8.8
European Region	1.0	0.9	9.5	11.3	5.8	4.4	6.5	5.1
Southeast Asia Region	0.8	0.9	12.7	18.2	5.1	8.2	5.4	6.9
Western Pacific Region	0.2	0.3	6.4	9.2	3.01	5.1	3.4	4.8

younger age groups in LMICs, resulting in higher loss of life years, and affecting the economically active subpopulations in these countries.

It must be mentioned that in Africa, the HIV/AIDS epidemic has already altered patterns of mortality and life expectancy and is projected to modify these further. Irrespective of the fact that sub-Saharan Africa accounts for 72% of HIV-related deaths worldwide [101], projections based on demographic trends alone suggest that the prevalence of diabetes will continue to grow in this region. Widespread use of antiretroviral therapy will also directly (in the form of pancreatic dysfunction associated with therapy) and indirectly (increasing longevity of life) affect diabetes prevalence. The scarcity of data emanating from this continent does not allow a greater comprehension of the relative impacts of these forces versus contemporary sociodemographic and epidemiologic transitions.

## Economic and social implications

The prototypical chronic nature of diabetes requires empowered self- and clinician-guided management for the duration between diagnosis and death. Forestalling complications and premature mortality is the central theme underlying glucose control and preventative management. Together, the care and serious consequences of diabetes are burdensome and costly. Quantifying the costs of diabetes from the perspectives of diabetes patients as well as national resource use and losses are critical towards informing appropriate health care planning, resource allocation and response strategies.

Approaches used to estimate economic costs of disease vary, not only by the perspective taken, but also by methodology applied, data sources used, year of estimation, as well as purchasing power and clinical practice patterns in different settings (Table 5.2). Needless to say, between-country comparisons are even more problematic where issues emerge regarding uncertainty of incidence and prevalence estimates, and standardization of measures and criteria. General principles and concepts of estimating cost are described [1,67,102,103].

**Table 5.2** Examples of different treatment patterns in high-income countries.

Country	Proportion of diabetes patients receiving treatment			
	Diet and/or exercise (%)	OHA (%)	Insulin (%)	Both OHA and insulin (%)
USA [124]	16	57	14	13
Germany [75]	28	44	16	11
France [84]	—*	80	14.7	5.3

OHA, oral hypoglycemic agents.

\* Database query only recognizes medications prescribed for diabetes.

### Types of costs

#### Direct costs (inputs)

These include costs of treatment and care of the disease, broadly encompassing all outpatient consultations, inpatient care, diagnostic investigations, therapeutic procedures, pharmacotherapy, paramedical care (e.g. home nursing, physiotherapy), patient time, transportation and rehabilitation.

#### Indirect costs (lost output)

These costs represent the present and future value of economic productivity lost by society on account of temporary or permanent disability, excess morbidity and premature mortality from disease; they are typically calculated by estimating foregone income by investigating the cumulative impacts of absenteeism, employment status and income, for both the individual and caregiver(s).

#### Intangible costs

Costs are associated with the psychosocial impacts (e.g. stress, depression, emotional problems) and altered quality of life from an illness; they may include diminished family role, informal care and foregone income by family members; these costs are typically difficult to estimate because of relative lack of standardized methods.

### Cost appraisal methods

#### Cost-of-illness method

This is the most widely used approach to describe the direct and

indirect costs of disease to society and is conducted by exploring costs in a group of selected persons either over a defined finite period (e.g. 1 year) or through the natural progression of the disease.

#### **Human capital approach**

This is a method of estimating indirect costs of disease, with an emphasis on foregone earnings and employment; it is criticized as a tool because of the tendency for overestimating future values, accepting wage disparities and disregarding socially valuable activities such as housekeeping and volunteer work.

#### **Friction cost approach**

This approach is a more conservative measure of indirect costs that considers lost productivity as finite where restoration of productivity (return to work or replacement of worker) occurs within a timeframe and therefore limits production losses; it does, however, require detailed data.

#### **“Top-down” approach**

This calculates costs from national databases and/or estimates, partitioning costs of different illnesses according to diagnoses; it requires accurate data entry, especially when indirect costs are being investigated but avoids the risk of double counting.

#### **“Bottom-up” approach**

This follows the trail of illness-related costs of a defined subpopulation with the illness, over a finite period.

Studies that have examined costs of diabetes vary in their estimates of the excess costs generated through resource consumption. The major drivers of direct health care costs include health service utilization (outpatient or ambulatory care comprising health practitioner consultations as well as inpatient care); medication usage; diagnostic tests; self glucose monitoring and therapeutic medical devices; and therapeutic procedures. In more developed settings, auxiliary services such as paramedical care (dietitians, physiotherapists, occupational therapists and home nursing) and preventative checks (foot care, urine and eye testing) may contribute to costs. The relative contributions of these cost drivers in various regions of the world are shown in Table 5.3. Themes that surface from these studies affirm the high costs of complications and associated hospitalization in developed countries, but also point to higher relative costs of purchasing medications in LMICs. Indeed, the supplemental costs of drugs for co-morbid CVD risk management are also pronounced.

Demographic and clinical characteristics have profound influences on costs. In Germany, compared to the diabetes-free population of the same age, younger people with diabetes (under 40 years of age) had greater incremental costs (4.1 times) than the people in the elderly age group (only 1.5 times higher) [75]. The types of diabetes have different costs. T1DM accounts for 5.7% of people with diabetes in the USA; medical costs of US\$10.5 billion (bn) and indirect losses amount to US\$4.4bn, totaling US\$14.9bn. This is comparatively much lower than the

US\$159.5bn that cumulatively account for T2DM care and lost productivity, but the cost burden per case is greater for T1DM [104]. It has been postulated that more consultations and faster progression to retinopathy and nephropathy are the main drivers of cost and mortality risk in those with T1DM [27,76]. In T2DM, coexistence of hypertension and dyslipidemia have relatively more significant roles in mediating risk, outcomes and associated costs.

The presence of diabetes-related complications greatly increases both the magnitude and duration of resource consumption. In particular, CVD and nephropathy are associated with the highest health care costs in most regions of the world. In the USA, medical costs increase by a factor of 1.5 when early CVD manifestations develop, and escalate to 3.6 times with the occurrence of a serious CVD event. Similarly, early renal dysfunction is the basis for 65% more costs, and the onset of ESRD signifies a 771% increase in costs [105–107]. Brandle *et al.* estimated that 1-year direct costs of suffering and surviving a major vascular event in the USA totaled US\$24 500 for a myocardial infarction, US\$26 600 for a stroke and US\$37 600 for an amputation [130]. The Diabetes Health Economics Study Group estimated that complications contribute up to 60% of all direct costs, and 80–90% of indirect losses from absenteeism and lost productivity [108]. A rudimentary, but possibly practical finding by Gilmer *et al.* [109] reports that for every 1% (11 mmol/mol) increase in HbA<sub>1c</sub> over 7% (>53 mmol/mol), there is a corresponding 10% increase in costs.

National perspectives reveal large differences in the health care expenditure in developed and developing country settings. Although the metrics used are different, per capita expenditure on health in Tanzania (US\$4) and South Africa (US\$158), as well as annual direct costs of diabetes from Argentina (US\$330), France (US\$675) and Denmark (US\$3535) demonstrate sizeable between-country disparities [110]. Industrialized countries are also advantaged in the organization of health care infrastructure, as well as the financing of the system. For example, nationalized insurance and social security schemes in France and Germany cover 83.4% and 86% of these populations, respectively, which ensures high accessibility to care for citizens [75,84].

The imbalance between resource expenditure and needs is further exemplified by estimates that only 20% of global expenditure occurs in the regions where 80% of people with diabetes live [111], demonstrating that Julian Tudor Hart’s [112] “inverse care law” is very relevant to global diabetes burden. This states that “the availability of good medical care tends to vary inversely with the need for it in the population served”. As a result of inadequate public spending on health in LMICs (e.g. in India, only 2% of the government’s annual budget is devoted to health care), sizeable proportions of household income are spent on health care costs. In Africa, 40% of people are said to earn less than US\$1 per day (~\$300 per annum) [11,12], and in countries such as Sudan, almost two-thirds of family incomes are required to pay for the care of one child with diabetes [113]. In Mozambique, less than one-fifth of all health facilities have the wherewithal to offer blood glucose and urinary ketone measurement [49]. The other end of

**Table 5.3** Regional and country estimates of costs of diabetes.

Country	Year	Method	Annual total cost per patient	Annual total costs for country/region	Main drivers of cost	Limitations
<b>Europe</b>						
8 countries (Belgium, France, Germany, Italy, Netherlands, Spain, Sweden, UK) – CODE-2 Study [125]	1999	Cost-of-illness, prevalence-based study, patient and practitioner surveys, n = 7000 T2DM	€2834 (range: €1305–3576)	€29 billion	Hospitalizations (55%); other drugs – mainly cardiovascular (21%); ambulatory care (18%); antidiabetic drug costs (7%)	6-month retrospective design subject to recall bias, extrapolation error that excludes seasonal variation
France [84]	1998–2000	Retrospective patient reimbursement data (national database)	€3680 (1998) – €3914 (2000)	€5.7 bn (2000); €2.4 bn directly on diabetes care	Inpatient care (42%), outpatient care (58%); ambulatory care (18%); antidiabetic drug costs (7%)	Excluded patients with diabetes controlled on lifestyle measures; excluded indirect and intangible costs
Sweden [77]	1994	Cost-of-illness, top-down, prevalence design	n/a	US\$766.1 million (43% direct, 57% indirect)	Direct: hospital care (58%), drugs (18%), ambulatory care (13%), devices (11%) Indirect: early retirement (55%), absenteeism (24%), mortality (22%)	Excluded costs of other illnesses related to diabetes; excludes those treated by dietary modification alone
Italy [76]	1998	Cost-of-illness, bottom-up, multicenter, retrospective database query of OPD costs; n = 2260	2 month costs: €136.8 (T1DM) and €123.3 (T2DM)	n/a	T1DM patients (n = 592) had more consultations; T2DM patients (n = 1668) had more diagnostic tests and day-hospital procedures Drug costs: 32–36% (T1DM) and 13–24% (T2DM)	Study limited to 2 months; Excluded costs of hospital care (known to be 30–50%); excluded indirect costs
Germany – CoDiM Study [75]	2001	Cost-of-illness, prevalence-based, retrospective database query; n = 26971	€10 281; €5262 (direct) and €5019 (indirect)	€30.6 bn (including €14.6 bn directly due to diabetes)	Excess costs related to: inpatient care, medications (insulin, drugs to treat co-morbidities, and complications); increasing age; use of medical devices	Indirect costs not included; data protection requirements preclude validating diagnoses; cross-sectional observation; illness severity varied
<b>Africa</b>						
Sudan [113]	2001	Cost-of-illness, bottom-up approach: parent interviews of 147 children with T1DM	US\$283 per child	n/a	Direct costs: insulin (36%), glucose testing, physician visits Indirect costs: poor school performance, 65% of family expenses were used for care of one T1DM child	Subject to recall bias; sample may not be representative of wider population (private clinics); subjects had ≤5 years duration of diabetes

South Asia						
India (South India) [80]	Pre-1998	Cost-of-illness, bottom-up approach: interviews and billing data; private (n = 422) and government-funded (n = 174) clinics	Median Rs.4510 (surgery = Rs.13 880; inpatients = Rs.7505; OPD = Rs.3310)	Estimated Rs.90.2 bn (~US\$ 2.2 bn)	Surgical or inpatient care; duration of diabetes	Quality and costs at government-funded institutions are unknown (no fee charged)
Other studies in India: North India [79]; CODI study; others [81,126,127]	Unknown	Cost-of-illness, bottom-up approach: questionnaires and disability assessments; n = 50 at OPD Community-based surveys of diabetes costs (national perspective)	Rs.14 508 (€264); direct (68%), indirect (29%) Rs.19 914; direct (36%), indirect (64%)	n/a	Direct: drug costs (62%), dietary changes (20%), travel costs, investigations Indirect: loss of income, loss of caregiver income (education and income correlates such that higher levels result in greater loss) Direct: hospitalization (35%), monitoring and doctor visits (34%), drug costs (31%)	Small sample size; short follow-up (6 months) with extrapolation; did not evaluate intangible and social burdens Wide variation in annual cost-per-patient estimates (e.g. Rayappa <i>et al.</i> [122] Rs.8595 = \$191–208; Bjork <i>et al.</i> [129] Rs.7189)
Pakistan [129]	2006	Cost-of-illness: questionnaires; human capital approach; n = 345 (age = 20–60) at 6 OPD clinics	PKR 11 580 (= US\$197)	Direct costs projection = PKR 71 bn (= US\$1.21 bn) annually	Direct: medication (46%), laboratory investigations (32%); age, complications, and duration of disease were drivers of cost	Inclusion restricted to 20–60 year age group; did not include costs of self-monitoring; calculation of lost productivity limited to those employed
Americas						
USA [130]	2000–2001	Cost-of-illness study: surveys, chart reviews, and claims data; n = 1364 T2DM subjects from Michigan HMO	US\$1684 (for diet-controlled, no CVD risks or complications) to US\$10 500 (obese, insulin-treated, high BP, renal, and vascular disease)	n/a	Multipliers: ESRD with dialysis (×10.53), history or MI (×1.9), insulin treatment (×1.59), PVD (×1.31), Cvd (×1.3), treated BP (×1.24) † Redekop <i>et al.</i> showed age, insulin use, micro- and macrovascular complications, and dyslipidemia are cost drivers	Analysis limited to T2DM; not representative of general population of USA; costs excluded out-of-pocket expenses and indirect costs
USA [131]	2007	Cost-of-illness, prevalence-based study: Cost of Diabetes Model utilizing national surveys and claims database (16.3 million people in 2006)	US\$ 11 774 (\$6649 directly for diabetes care)	US\$174 bn; \$116 bn (direct), \$58 bn (indirect costs)	Direct medical costs: complications (50%), diabetes care (23%), general medical costs (27%) Indirect: premature mortality (46%), disability and lost productivity (54%)	Estimates do not include: intangible costs, caregiver opportunity costs and undiagnosed diabetes

Table 5.3 Continued

Country	Year	Method	Annual total cost per patient	Annual total costs for country/region	Main drivers of cost	Limitations
Latin America and Caribbean [74]	2000	Cost-of-illness, prevalence-based study: cost estimates for groups of countries and human capital approach	US\$703 (range: \$442–1219)	US\$ 65.2 bn; \$10.7 bn (direct), \$54.5 bn (indirect)	Direct: drug costs (44%), consultations (24%), complications (23% – especially nephropathy) Indirect: disability and productive life years lost (93%), mortality (7%)	General lack of data forced use of estimates in heterogeneous countries Diabetes-related deaths undercounted on death certificates; high indirect cost may reflect poor access to medical care
Mexico [132]	2003–2005	Extracted data for a standard case and natural history; human capital approach; 50% of population are insured, 40% are low-income uninsured	Villareal-Rios <i>et al.</i> [134] report US\$708–1488 per patient	US\$317 m; \$140 m (direct), \$177 m (indirect) Phillips <i>et al.</i> [135]: US\$100 m (direct); \$330 m (indirect)	Direct: drug costs (39%), complications (32%, especially nephropathy), hospitalizations (12%), consultations (11%) Indirect: permanent disability (94%), mortality (4.5%), temporary disability (1.5%)	Restricted to T2DM and patients attending public institutions; excludes out-of-pocket expenses and the private sector
Canada [135]	1998	Cost-of-illness, prevalence-based, top-down, national database query	n/a	CAN\$3.7 bn; 70% (direct), 30% (indirect); CAN\$ 4.8–5.2 bn if undiagnosed cases included	Direct: hospital costs (50%), medications (31%), physician care (19%) – medical costs of complications 1.6 times more than diabetes alone Indirect: diabetes (45%), complications (55%)	Reliance on coding of cases subject to error; limited indirect cost evaluations; prevalence estimates and practice patterns vary across provinces; home, nursing care, and glucose testing not included in costs
<b>Australia</b> Australia [136]	2000	Cost-of-illness, prevalence-based, bottom-up study; n = 1294 T2DM	n/a	A\$636 m	Age, co-morbidities	Changes in practice patterns between recruitment and cost appraisal may bias results; indirect costs or hospitalization for other illnesses not included
Australia – DiabCost Study	2003	Cost-of-illness, bottom-up: T2DM patients; self-reported surveys	A\$9625 (if no complications); \$15 580 (with complications)	A\$3 bn	–	Data were self-reported; costs not associated with DM could not be separated out

A\$, Australian dollar; BMI, body mass index; bn, billion; BP, blood pressure; CAN\$, Canadian dollar; Cbvd, cerebrovascular disease or stroke; DM, diabetes mellitus; €, European Union Euro; ESRD, end-stage renal disease; GP, general practitioner or primary care doctor; HMO, health maintenance organization; m, million; MI, myocardial infarction; OHA, oral hypoglycaemic agent; OPD, outpatient department; PKR, Pakistani rupee; PVD, peripheral vascular disease; QOL, quality of life; Rs., Indian rupee; SES, socioeconomic status; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus; US\$, US dollar.

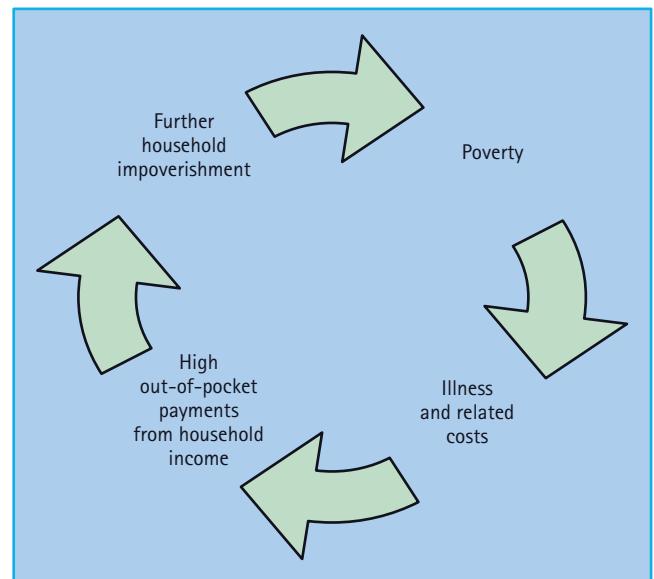

the spectrum comprise developed countries such as Germany and the USA, which spend €31.3 billion and US\$116 billion annually on direct costs of diabetes, respectively. Of the estimated US\$2.2 trillion in health care expenditures in the USA in 2007, one out of every US\$7 spent was for diabetes [114]. These expenses are partially related to differences in pricing and prescription, but are also linked to the high costs of new diagnostic and therapeutic options (e.g. while annual cost of treating a patient with maximal daily doses of metformin is US\$46, the equivalent costs of using thiazolidinediones are US\$710–980) [115].

Additional considerations with regard to national economic impact concern the distribution of diabetes burden *within* populations. In low and middle income countries, diabetes and its complications disproportionately affect the economically productive age range (15–69 years), while in mature market economies, the disease affects the older ( $\geq 65$  years), disadvantaged and ethnic minority subpopulations. The implications emanating from these trends are that economic development in transitioning countries may be subdued because of loss of unrealized productivity, while direct health costs for the aging and uninsured populations in developed countries will continue to escalate [1].

In LMICs, the lowest income groups bear the greatest burdens, paying a larger proportion of their household incomes towards diabetes care (34% and 27% for the urban and rural poor, respectively, vs 4.8% and 5.0% for the high income urban and rural groups in India, respectively) [116]. Year-on-year increases in this proportion are greater in impoverished groups, and worsen with duration of diabetes, presence of complications, hospitalization, surgical therapy and glycemic control requiring insulin [81,116,117].

Furthermore, LMICs contain large and growing populations of people with pre-diabetes, as well as groups of people unaware that they have an asymptomatic metabolic disorder. Pre-diabetes is independently associated with the development of complications and increased specialist consultations, adding up to at least US\$443 in supplementary expenses per person in the USA [118]. For individuals with undiagnosed diabetes, proxy measures of health service utilization suggest that annual costs are approximately US\$2864, and may escalate depending on the severity of complications that have developed by the time of recognition and formal diagnosis [119].

Augmented expenditures associated with complications further perpetuate destitution and socioeconomic disadvantage (i.e. opportunity costs of health care expenses are often endured by foregoing children's education). Meanwhile, hardship amplifies vulnerability to disease. The Cost of Diabetes in India (CODI) [43] and Bangalore Urban District (BUD) [120,121] diabetes studies showed a later age at diagnosis of diabetes and occurrence of disabling complications were associated with lack of awareness, and being unemployed and less educated (e.g. a 7-year difference in age of diagnosis was demonstrated between illiterate people and those with college education). Similar observations substantiate a bidirectional link between poor health and poverty (Figure 5.1).

**Figure 5.1** Cycle of poverty and ill health. Poverty predisposes one to illness, and costs of illness in a system of fee-for-service care have the potential to impoverish households, further perpetuating poverty.

Broadly speaking, diabetes results in roughly 1.5–5 times greater health care expenditure than the general population, depending on the context and the cost appraisal methodology employed [75,77,80,84,103,114]. In addition, it is important to note that the complex overlaps and interconnections between the underlying pathophysiology of T2DM and associated co-morbidities of the broader metabolic syndrome may alter the scope of costs. As such, depending on the viewpoint and chosen values, resource use attributable to diabetes alone may in fact underestimate the broader range of costs associated with diabetes-related illnesses as a group. Also, undiagnosed diabetes may not be described as a contributor to morbidity, mortality and resource use, suggesting that we may be underestimating the true burden of this disease. This is particularly relevant in regions of the world where there are few or no representative data regarding disease prevalence and causes of death. Finally, the value placed on the opportunity cost of diabetes-related infirmity has not been widely quantified or even qualitatively described.

### Changing trends in costs

The global burdens associated with diabetes have been growing rapidly, and are projected to escalate even further in the future. The hypothesized explanations for this trend of increasing burden include, and are not limited to, the rising prevalence of diabetes and pre-diabetes worldwide; aging and longevity accompanied by costly co-morbidities; lowered diagnostic thresholds; more attentive detection of cases; availability of newer, more costly treat-

ment methods on the basis of industry research and development; and changes in clinical management, especially growth in use of self glucose monitoring and medical devices, new therapeutic drugs and increasing demand for paramedical services. While it is evident that these latter reasons are more relevant in HICs, the continued epidemiologic transitions will no doubt affect LMICs too. It is unfortunate that scarcity of resources and inadequate access in these settings will result in greater disability and mortality, perpetuating the obstacles to socioeconomic development.

## Gaps and future directions

Diabetes imposes serious health, social and economic burdens worldwide. Quantitative calculations suggest that direct and indirect costs of diabetes worldwide cumulatively total US\$376 bn in 2010 [111]. Almost half of all global expenditure occurred in the USA, which is home to only 8% of those affected by diabetes worldwide. Given the disparities in burdens, access and expenditures described previously, more widespread and reliable data are a first step towards greater equity [122]. In addition, studies are needed that include both long-understood and emerging diabetes complications, such as cognitive function, in the models, to create better estimates of diabetes-attributable mortality, morbidity and cost. Assessing burdens using reliable consistent methods will aid our comprehension of the complex mix of programmed, predisposing and modifiable factors associated with diabetes, and lays a foundation for policy development and advocacy for greater global consciousness.

Despite varied estimates of expenditure, the pattern is consistent: people with diabetes experience greater symptoms, morbidity, co-morbidities and mortality than those without diabetes; they have diminished functional capacity and psychosocial illness; and incur greater costs for health care, self-care and losses in earning potential and societal role. While reductions in quality of life are less numerically evident, they are no less distressing. Needless to say, intervening before diabetes onset may hold great benefit in reducing global burdens; however, although there is evidence from large trials demonstrating that prevention can forestall conversion from pre-diabetes to diabetes, widespread translation of these findings is hampered by multiple levels of barriers (political, social, cultural, behavioral and economic factors).

In the future, preparation for the increasing diabetes burden requires progress in wider collection of reliable data (especially assuaging the scarcity from low and middle income countries regarding diabetes-related mortality, complications, disability and costs), and a greater emphasis on cost-effectiveness studies which may inform better resource allocation. On the shoulders of compelling evidence, greater investment and political will are required to overcome low accessibility and awareness, as well as to translate the evidence into practical real-life implementation of proven and effective prevention strategies [123].

## 2 Normal Physiology

# 6

## Islet Function and Insulin Secretion

**Peter M. Jones & Shanta J. Persaud**

Diabetes Research Group, King's College London, UK

### Keypoints

- Regulation of fuel homeostasis in mammals is dependent on numerous small endocrine organs known as islets of Langerhans, which are located in the pancreas.
- Islets contain  $\beta$ -cells which are the only source of the polypeptide hormone insulin.
- $\beta$ -Cells are equipped to detect changes in circulating nutrients.
- $\beta$ -Cells respond to elevated levels of nutrients by initiating an insulin secretory response which will induce the storage of circulating nutrients in liver, muscle and adipose tissue.
- $\beta$ -Cells can also respond to a wide range of other signals including hormones, neurotransmitters and neuropeptides, which modify the insulin secretory response to circulating nutrients.
- Complex interactions between islet cells, the autonomic nervous system and gastrointestinal incretin hormones allow precise integration between metabolic fuel intake, usage and storage.

### Introduction

The German anatomy student Paul Langerhans first described in 1869 the “islands of clear cells” distributed throughout the pancreas [1] but he did not realize the physiologic significance of these cell clusters, which are today known as islets of Langerhans. We now know that islets are the endocrine compartment of the pancreas, comprising around 2–3% of the total pancreatic volume. Islets are approximately spherical (Figure 6.1a), with an average diameter of 100–200  $\mu\text{m}$ , and a healthy human pancreas may contain up to a million individual islets, each having its own complex anatomy, blood supply and innervation.

### Islet structure and function

#### Islet anatomy

A typical mammalian islet comprises several thousand endocrine cells including the insulin-expressing  $\beta$ -cells (~60% of adult human islet cells), glucagon-expressing  $\alpha$ -cells (20–30%), somatostatin-expressing  $\delta$ -cells (~10%), pancreatic polypeptide-expressing cells (<5%), and ghrelin-expressing cells (~1%). The anatomic arrangement of islet cells varies between species. In rodents, the majority  $\beta$ -cell population forms a central core surrounded by a mantle of  $\alpha$ -cells and  $\delta$ -cells (Figure 6.1a), but

human islets show less well-defined organization with  $\alpha$ -cells and  $\delta$ -cells also being located throughout the islet (Figure 6.1b) [2].

Islets are highly vascularized, and receive up to 15% of the pancreatic blood supply despite accounting for only 2–3% of the total pancreatic mass. Each islet is served by an arteriolar blood supply that penetrates the mantle to form a capillary bed in the islet core. Earlier studies using vascular casts of rodent islets suggested that the major route of blood flow through an islet was from the inner  $\beta$ -cells to the outer  $\alpha$  and  $\delta$ -cells [3], but more recent studies using optical imaging of fluorescent markers to follow islet blood flow *in vivo* [4] reveal more complex patterns of both inner-to-outer and top-to-bottom blood flow through the rodent islet.

Islets are well supplied by autonomic nerve fibers and terminals containing the classic neurotransmitters acetylcholine and norepinephrine, along with a variety of biologically active neuropeptides [5]. Vasoactive intestinal polypeptide (VIP) and pituitary adenylate cyclase-activating polypeptide (PACAP) are localized with acetylcholine to parasympathetic nerves, where they may be involved in mediating prandial insulin secretion and the  $\alpha$ -cell response to hypoglycemia [6]. Other neuropeptides, such as galanin and neuropeptide Y (NPY), are found with norepinephrine in sympathetic nerves where they may have a role in the sympathetic inhibition of insulin secretion, although there are marked inter-species differences in the expression of these neuropeptides [5].

#### Intra-islet interactions

The anatomic organization of the islet has a profound influence on the ability of the  $\beta$ -cells to recognize and respond to physio-

**Figure 6.1** Anatomy of the islet of Langerhans. (a) Mouse islet. The figure shows a section through a mouse pancreas in which insulin and glucagon are identified by red and green immunofluorescence, respectively, demonstrating the typical  $\beta$ -cell core surrounded by a thin mantle of  $\alpha$ -cells. In mouse islets  $\beta$ -cells comprise approximately 80% of the endocrine cell mass. Scale bar is 10  $\mu\text{m}$ . Image courtesy of V. Foot, King’s College London. (b) Human islet. The figure shows a section through a human pancreas in which insulin and glucagon are identified by red and green immunofluorescence respectively, demonstrating the

less organized structure of the human islet when compared with mouse islets. In human islets  $\beta$ -cells comprise approximately 50–60% of the endocrine cell mass. Scale bar is 10  $\mu\text{m}$ . Image courtesy of V. Foot, King’s College London. (c) Transmission electron micrograph of human islet cells. The figure shows a transmission electron micrograph of several cells within a human islet. The two cells in the top left with the electron dense secretory granules surrounded by a clear halo are  $\beta$ -cells. The cells in the lower half of the micrograph are  $\alpha$ -cells. Scale bar is 2  $\mu\text{m}$ . Data from Jones & Persaud, unpublished.

logic signals [7–9]. There are a number of mechanisms through which islet cells can communicate, although the relative importance of the different mechanisms is still uncertain [10]. Islet cells are functionally coupled through a network of gap junctions, and gene deletion studies in mice have highlighted the importance of gap-junctional coupling via connexin 36 in the regulation of insulin secretory responses [11,12]. Cell–cell contact through cell surface adhesion molecules offers an alternative communication mechanism, and interactions mediated by E-cadherin [13,14] or ephrins [15] have been implicated in the regulation of  $\beta$ -cell function. A further level of control can be exerted via intra-islet paracrine and autocrine effects in which a biologically active substance released by one islet cell can influence the functional status of a neighboring cell (paracrine), or of itself (autocrine). Figure 6.2 shows some of the molecules that have been implicated in this type of intra-islet cell–cell communication. Thus, islet cells can interact with each other via the classic islet hormones – insulin, glucagon and somatostatin [16–19]; via other products secreted by the endocrine cells, such as neurotransmitters or adenine nucleotides and divalent cations that are co-released with insulin [20–23]; and via other less well-known mechanisms, including the generation of gaseous signals such as nitric oxide and carbon monoxide [24–27]. The wide range of intra-islet interactions presumably reflects the requirement for fine-tuning and coordinating secretory responses of many individual islet cells to generate the rate and pattern of hormone secretion appropriate to the prevailing physiologic conditions.

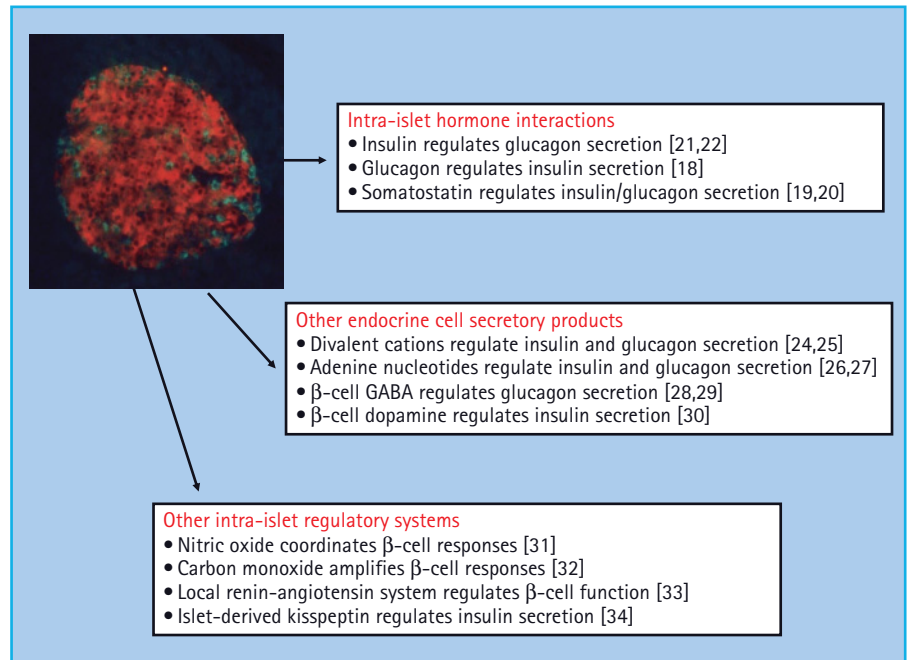

### Insulin biosynthesis and storage

The ability to release insulin rapidly in response to metabolic demand, coupled with the relatively slow process of producing polypeptide hormones, means that  $\beta$ -cells are highly specialized for the production and storage of insulin, to the extent that insulin comprises approximately 10% (~10 pg/cell) of the total  $\beta$ -cell protein.

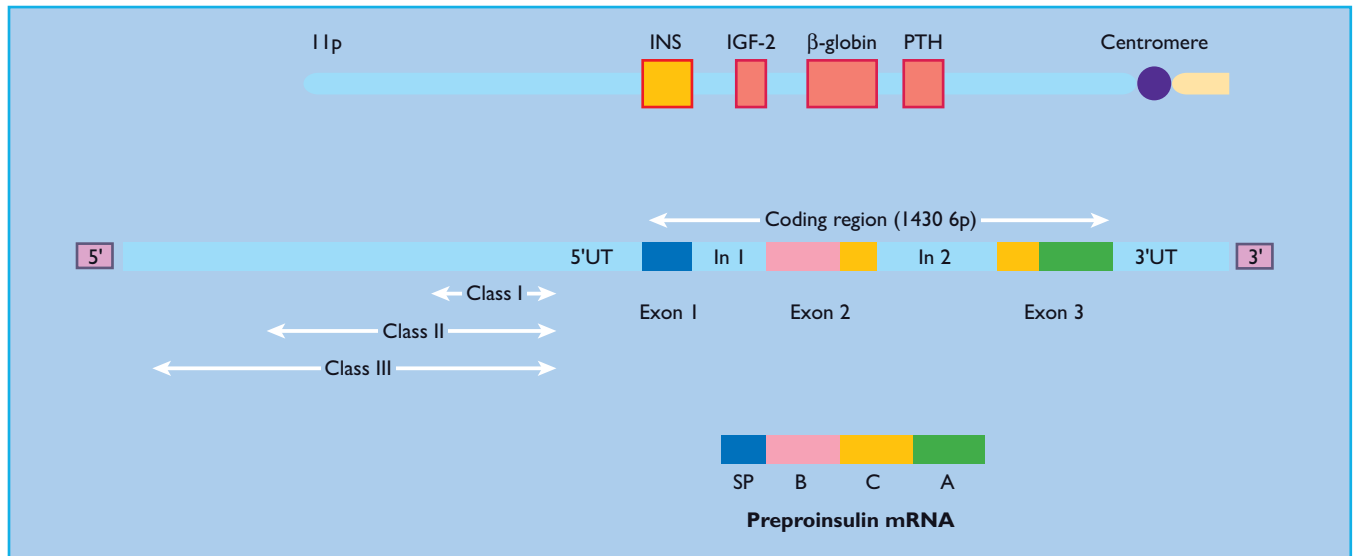

#### Biosynthesis of insulin

In humans, the gene encoding preproinsulin, the precursor of insulin, is located on the short arm of chromosome 11 [28]. It is 1355 base pairs in length and its coding region consists of three exons: the first encodes the signal peptide at the N-terminus of preproinsulin, the second the B chain and part of the C (connecting) peptide, and the third the rest of the C peptide and the A chain (Figure 6.3). Transcription and splicing to remove the sequences encoded by the introns yields a messenger RNA of 600 nucleotides, translation of which gives rise to preproinsulin, an 11.5-kDa polypeptide. The cellular processes and approximate timescales involved in insulin biosynthesis, processing and storage are summarized in Figure 6.4.

Preproinsulin is rapidly (<1 min) discharged into the cisternal space of the rough endoplasmic reticulum, where proteolytic enzymes immediately cleave the signal peptide, generating proinsulin. Proinsulin is a 9-kDa peptide, containing the A and B chains of insulin (21 and 30 amino acid residues, respectively) joined by the C peptide (30–35 amino acids). The structural

**Figure 6.2** Intra-islet autocrine–paracrine interactions. The heterogeneous nature and complex anatomy of the islet enables numerous interactions between islet cells that are mediated by the release of biologically active molecules.

**Figure 6.3** Structure of the human insulin gene. The coding region of the human insulin (INS) gene comprises three exons, which encode the signal peptide (SP), the B chain, C peptide and A chain. The exons are separated by two introns (In1 and In2). Beyond the 5' untranslated region (5'UT), upstream of the coding sequence, lies a hypervariable region in which three alleles (classes I, II and III) can be distinguished by their size.

conformations of proinsulin and insulin are very similar, and a major function of the C peptide is to align the disulfide bridges that link the A and B chains so that the molecule is correctly folded for cleavage (Figure 6.5). Proinsulin is transported in microvesicles to the Golgi apparatus, where it is packaged into membrane-bound vesicles known as secretory granules. The conversion of proinsulin to insulin is initiated in the Golgi complex and continues within the maturing secretory granule through the

sequential action of two endopeptidases (prohormone convertases 2 and 3) and carboxypeptidase H [29], which remove the C peptide chain, liberating two cleavage dipeptides and finally yielding insulin (Figure 6.5). Insulin and C peptide are stored together in the secretory granules and are ultimately released in equimolar amounts by a process of regulated exocytosis. Under normal conditions, >95% of the secreted product is insulin (and C peptide) and <5% is released as proinsulin. However, the secre-

**Figure 6.4** The intracellular pathways of (pro)insulin biosynthesis, processing and storage. The molecular folding of the proinsulin molecule, its conversion to insulin and the subsequent arrangement of the insulin hexamers into a regular pattern are shown at the left. The time course of the various processes, and the organelles involved are also shown.

tion of incompletely processed insulin precursors (proinsulin and its “split” products; Figure 6.5) is increased in some patients with type 2 diabetes.

The  $\beta$ -cell responds to increases in the circulating concentrations of nutrients by increasing insulin production in addition to increasing insulin secretion, thus maintaining insulin stores [30]. Acute (<2 hours) increases in the extracellular concentration of glucose and other nutrients result in a rapid and dramatic increase in the transcription of preproinsulin mRNA and in the rate of proinsulin synthesis [31]. There is a sigmoidal relationship between glucose concentrations and biosynthetic activity, with a threshold glucose level of 2–4 mmol/L. This is slightly lower than the threshold for the stimulation of insulin secretion (~5 mmol/L), which ensures an adequate reserve of insulin within the  $\beta$ -cell.

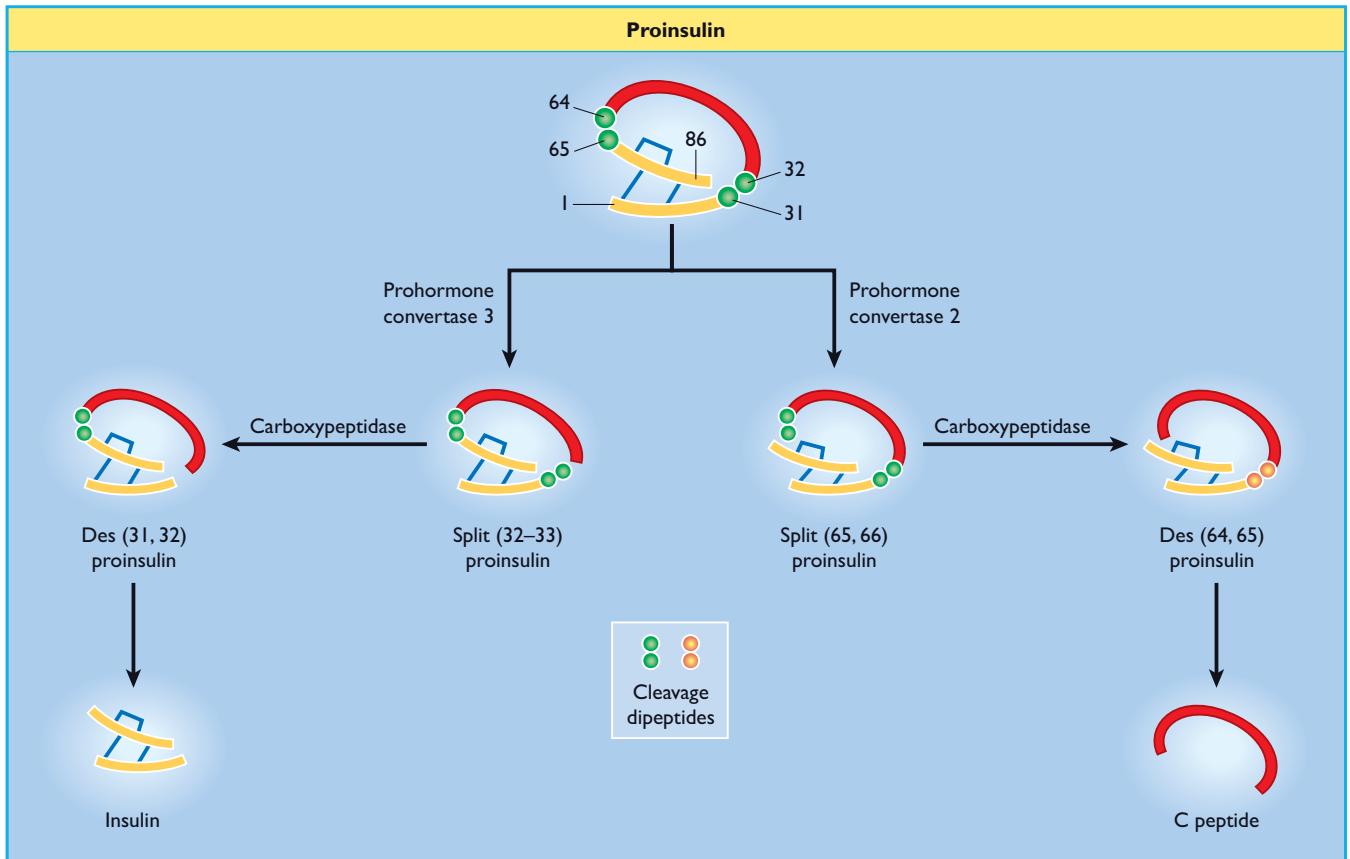

### Storage and release of insulin

The insulin secretory granule has a typical appearance in electron micrographs, with a wide space between the crystalline electron-opaque core and its limiting membrane (Figure 6.1c). The major protein constituents of the granules are insulin and C peptide,

which account for approximately 80% of granule protein [31], with numerous minor components including peptidases, peptide hormones and a variety of (potentially) biologically active peptides of uncertain function [32,33]. Insulin secretory granules also contain high concentrations of divalent cations, such as zinc (~20 mmol/L), which is important in the crystallization and stabilization of insulin within the granule [34,35]. The intra-granular function(s) of calcium (~120 mmol/L) and magnesium (~70 mmol/L) are uncertain, but as they are co-released with insulin on exocytosis of the secretory granule contents they may have extracellular signaling roles via the cell surface calcium-sensing receptor [20]. Similarly, the adenine nucleotides found in insulin secretory granules (~10 mmol/L) may have a signaling role when they are released into the extracellular space [21].

The generation of physiologically appropriate insulin secretory responses requires complex mechanisms for moving secretory granules from their storage sites within the cell to the specialized sites for exocytosis on the inner surface of the plasma membrane, and the role of cytoskeletal elements, notably microtubules and microfilaments, in the intracellular translocation of insulin

**Figure 6.5** Insulin biosynthesis and processing. Proinsulin is cleaved on the C-terminal side of two dipeptides, namely Arg<sup>31</sup>-Arg<sup>32</sup> (by prohormone convertase 3) and Lys<sup>64</sup>-Arg<sup>65</sup> (prohormone convertase 2). The cleavage dipeptides are liberated, so yielding the “split” proinsulin products and ultimately insulin and C peptide.

storage granules has been studied extensively [36,37]. Microtubules are formed by the polymerization of tubulin subunits and normally form a network radiating outwards from the perinuclear region [38]. The microtubular network is in a process of continual remodeling and the dynamic turnover of tubulin, rather than the total number of microtubules, is important for the mechanism of secretion. The microtubule framework may provide the pathway for the secretory granules but microtubules do not provide the motive force [39] so other contractile proteins are likely to be involved. Actin is the constituent protein of microfilaments which exists in cells as a globular form of 43 kDa and as a filamentous form which associates to form microfilaments. Microfilament polymerization is regulated by agents that alter rates of insulin secretion [40], and the pharmacologic disruption of microfilament formation inhibits insulin secretion. Myosin light and heavy chains are expressed at high concentrations in  $\beta$ -cells, suggesting that actin and myosin may interact to propel granules along the microtubular network. It also seems likely that other molecular motors, including kinesin and dynein [41-43], are also involved in the movement of secretory granules, and perhaps other organelles, in  $\beta$ -cells.

Insulin is released from secretory granules by exocytosis, a process in which the granule membrane and plasma membrane

fuse together, releasing the granule contents into the interstitial space. Much of our knowledge of the molecular mechanisms of exocytosis is derived from studies of neurotransmitter release from nerve cells, and similar mechanisms operate in  $\beta$ -cells. The docking of the granules at the inner surface of the plasma membrane is via the formation of a multimeric complex of proteins known as the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) complex, which consists of proteins associated with secretory granules and the plasma membrane, and soluble fusion proteins [44,45]. The docked granules will only fuse with the membrane and release their contents in the presence of elevated levels of intracellular calcium which is sensed by synaptotagmins, a class of calcium-binding granule proteins [44,46]. Secretory granules are distributed throughout the  $\beta$ -cell cytoplasm (Figure 6.1c), and it is likely that the transport of granules from distant sites to the plasma membrane is regulated independently from the final secretory process, with a reservoir of granules stored close to the inner surface of the plasma membrane. Fusion of this “readily-releasable” pool of granules may account for the rapid first-phase release of insulin in response to glucose stimulation [39,40]. Direct electrophysiologic measurements have demonstrated that the  $\beta$ -cell exocytotic response consists of a short-lived first phase, with a very rapid rate of granule

exocytosis, followed by a sustained second phase with a slower rate of exocytosis [45,46].

### Regulation of insulin secretion

To ensure that circulating levels of insulin are appropriate for the prevailing metabolic status  $\beta$ -cells are equipped with mechanisms to detect changes in circulating nutrients, in hormone levels, and in the activity of the autonomic nervous system. Moreover,  $\beta$ -cells have fail-safe mechanisms for coordinating this afferent information and responding with an appropriate secretion of insulin. The major physiologic determinant of insulin secretion in humans is the circulating concentration of glucose and other nutrients, including amino acids and fatty acids. These nutrients possess the ability to initiate an insulin secretory response, so when nutrients are being absorbed from the gastrointestinal system the  $\beta$ -cell detects the changes in circulating nutrients and releases insulin to enable the uptake and metabolism or storage of the nutrients by the target tissues. The consequent decrease in circulating nutrients is detected by the  $\beta$ -cells, which switch off insulin secretion to prevent hypoglycemia. The responses of  $\beta$ -cells to nutrient initiators of insulin secretion can be modified by a variety of hormones and neurotransmitters which act to amplify, or occasionally inhibit, the nutrient-induced responses (Table 6.1). Under normoglycemic conditions these agents have little or no effect on insulin secretion, a mechanism that prevents inap-

propriate secretion of insulin which would result in potentially harmful hypoglycemia. These agents are often referred to as potentiators of insulin secretion to distinguish them from nutrients which initiate the secretory response. The overall insulin output depends on the relative input from initiators and potentiators at the level of individual  $\beta$ -cells, on the synchronization of secretory activity between  $\beta$ -cells in individual islets, and on the coordination of secretion between the hundreds of thousands of islets in a human pancreas. This section considers the mechanisms employed by  $\beta$ -cells to recognize and respond to nutrient initiators and non-nutrient potentiators of insulin secretion.

### Nutrient-induced insulin secretion

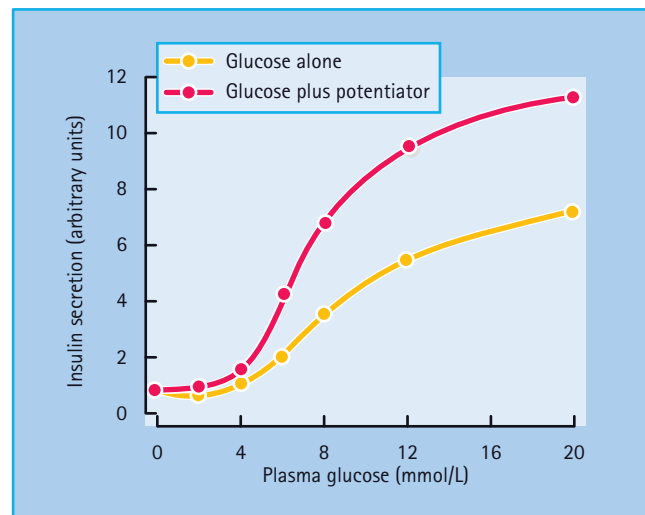

#### Nutrient metabolism

Pancreatic  $\beta$ -cells respond to small changes in extracellular glucose concentrations within a narrow physiologic range and the mechanisms through which  $\beta$ -cells couple changes in nutrient metabolism to regulated exocytosis of insulin are becoming increasingly well understood. Glucose is transported into  $\beta$ -cells via high capacity glucose transporters (GLUT; GLUT2 in rodents, GLUT1, 2 and 3 in humans [47,48]), enabling rapid equilibration of extracellular and intracellular glucose concentrations. Once inside the  $\beta$ -cell glucose is phosphorylated by glucokinase which acts as the “glucose sensor,” coupling insulin secretion to the prevailing glucose level [49]. The dose–response curve of glucose-induced insulin secretion from isolated islets is sigmoidal (Figure 6.6) and is determined primarily by the activity of glucokinase. Concentrations of glucose below 5 mmol/L do not affect rates of insulin release, and the rate of secretion increases progressively at extracellular glucose levels between 5 and ~15 mmol/L, with half-maximal stimulation at ~8 mmol/L. The time-course of the insulin secretory response to elevated glucose is characterized by

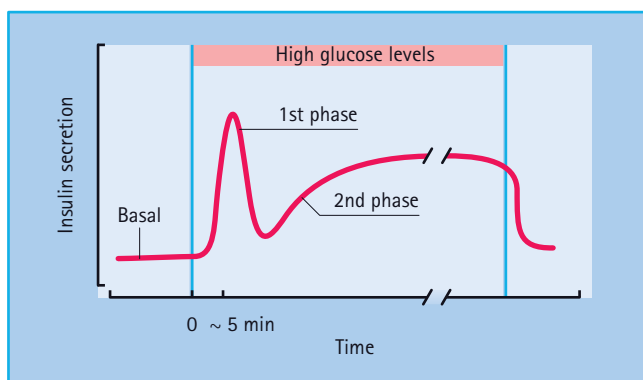

**Table 6.1** Non-nutrient regulators of insulin secretion.

Stimulators	Inhibitors
<b>Islet products</b>	
Glucagon	SST-14
Adenine nucleotides	Ghrelin
Divalent cations	
<b>Neurotransmitters</b>

CCK, cholecystokinin; GIP, glucose-dependent insulinotropic peptide; GLP-1, glucagon-like peptide-1; GRP, gastrin-releasing polypeptide; NPY, neuropeptide Y; PACAP, pituitary adenylate cyclase activating polypeptide; SST; somatostatin; VIP, vasoactive intestinal polypeptide.

**Figure 6.6** Glucose-induced insulin secretion from islets of Langerhans. No stimulation is seen below a threshold value of approximately 5 mmol/L glucose. Potentiators amplify insulin secretion at stimulatory concentrations of glucose, but are ineffective at subthreshold glucose levels.

**Figure 6.7** Glucose-induced insulin release *in vitro*. The figure shows the pattern of glucose-induced insulin secretion from perfused pancreas, in response to an increase in the glucose concentration. An acute first phase, lasting a few minutes, is followed by a sustained second phase of secretion which persists for the duration of the high-glucose stimulus.

a rapidly rising but transient first phase, followed by a maintained and prolonged second phase, as shown in Figure 6.7. This profile of insulin secretion is obtained whether insulin levels are measured following a glucose load *in vivo*, or whether the secretory output from the perfused pancreas or isolated islets is assessed, suggesting that the characteristic biphasic secretion pattern is an intrinsic property of the islets.

#### ATP-sensitive potassium channels and membrane depolarization

In the absence of extracellular glucose, the  $\beta$ -cell membrane potential is maintained close to the potassium equilibrium potential by the efflux of potassium ions through inwardly rectifying potassium channels. These channels were called ATP-sensitive potassium ( $K_{ATP}$ ) channels because application of ATP to the cytosolic surface of  $\beta$ -cell membrane patches resulted in rapid, reversible inhibition of resting membrane permeability to potassium ions [50]. This property of the  $K_{ATP}$  channel is pivotal in linking glucose metabolism to insulin secretion. Thus, it is now well established that ATP generation following glucose metabolism, in conjunction with concomitant lowering of ADP levels, leads to closure of  $\beta$ -cell  $K_{ATP}$  channels. Channel closure and subsequent reduction in potassium efflux promotes depolarization of the  $\beta$ -cell membrane and influx of calcium ions through voltage-dependent L-type calcium channels. The resultant increase in cytosolic  $Ca^{2+}$  triggers the exocytosis of insulin secretory granules, thus initiating the insulin secretory response (Figure 6.8).

At around the time that the  $K_{ATP}$  channels were established as the link between the metabolic and electrophysiologic effects of glucose, they were also identified as the cellular target for sulfonylureas. The capacity of sulfonylureas to close  $K_{ATP}$  channels explains their effectiveness in type 2 diabetes where the  $\beta$ -cells no longer respond adequately to glucose, as the usual pathway for coupling glucose metabolism to insulin secretion is bypassed. The

$\beta$ -cell  $K_{ATP}$  channel is a hetero-octamer formed from four potassium channel subunits (termed Kir6.2) and four sulfonylurea receptor subunits (SUR1) [51]. The Kir6.2 subunits form the pore through which potassium ions flow and these are surrounded by the SUR1 subunits which have a regulatory role (Figure 6.8, inset). ATP and sulfonylureas induce channel closure by binding to Kir6.2 and SUR1 subunits, respectively, while ADP activates the channels by binding to a nucleotide-binding domain on the SUR1 subunit. Diazoxide, an inhibitor of insulin secretion, also binds to the SUR1 subunit to open the channels. The central role of  $K_{ATP}$  channels in  $\beta$ -cell glucose recognition makes them obvious candidates for  $\beta$ -cell dysfunction in type 2 diabetes. Earlier studies in patients with type 2 diabetes, maturity-onset diabetes of the young (MODY) or gestational diabetes, failed to detect any Kir6.2 gene mutations that compromised channel function [52,53]. Since then, larger scale studies of variants in genes encoding Kir6.2 and SUR1 have demonstrated polymorphisms associated with increased risk of type 2 diabetes [54]. Similarly, activating mutations in the Kir6.2 gene have recently been shown to be causal for cases of permanent neonatal diabetes (PNDM) [55], which has enabled insulin-dependent PNDM patients to achieve glycemic control with sulfonylurea treatment alone. In contrast, loss of  $\beta$ -cell functional  $K_{ATP}$  channel activity has been implicated in the pathogenesis of persistent hyperinsulinemic hypoglycemia of infancy (PHHI) [56], a condition characterized by hypersecretion of insulin despite profound hypoglycemia. Numerous mutations in both the Kir6.2 and SUR1 subunits have been identified in patients with PHHI and these are thought to be responsible for the severe impairment in glucose homeostasis in these individuals [57].

#### Calcium and other intracellular effectors

Intracellular calcium is a principal effector of the nutrient-induced insulin secretory response, linking depolarization with exocytosis of insulin secretory granules (Figure 6.8). A large electrochemical concentration gradient ( $\sim 10,000$ -fold) of calcium is maintained across the  $\beta$ -cell plasma membrane by a combination of membrane-associated calcium extruding systems and active calcium sequestration within intracellular organelles. The major route through which calcium is elevated in  $\beta$ -cells is by influx of extracellular calcium through voltage-dependent L-type calcium channels that open in response to  $\beta$ -cell depolarization, and it has been estimated that each  $\beta$ -cell contains about 500 L-type channels [58].

Studies with permeabilized  $\beta$ -cells have demonstrated that elevations in intracellular calcium are alone sufficient to initiate insulin secretion [59], and conditions that elevate intracellular calcium usually stimulate insulin release. An increase in cytosolic calcium is essential for the initiation of insulin secretion by glucose and other nutrients: preventing calcium influx by removal of extracellular calcium or by pharmacologic blockade of voltage-dependent calcium channels abolishes nutrient-induced insulin secretion. Glucose and other nutrients also induce a calcium-dependent activation of  $\beta$ -cell phospholipase C (PLC) [60],

**Figure 6.8** Intracellular mechanisms through which glucose stimulates insulin secretion. Glucose is metabolized within the  $\beta$ -cell to generate ATP, which closes ATP-sensitive potassium channels in the cell membrane. This prevents potassium ions from leaving the cell, causing membrane depolarization, which in turn opens voltage-gated calcium channels in the membrane and allows calcium ions to enter the cell. The increase in cytosolic calcium initiates granule exocytosis. Sulfonylureas act downstream of glucose metabolism, by binding to the SUR1 component of the  $K_{ATP}$  channel (inset). GLUT, glucose transporter.

leading to the generation of inositol 1,4,5-trisphosphate ( $IP_3$ ) and diacylglycerol (DAG), both of which serve second-messenger functions in  $\beta$ -cells [61]. The generation of  $IP_3$  leads to the rapid mobilization of intracellular calcium, but the significance of this in secretory responses to nutrients is uncertain, and it is likely to have little more than a modulatory role, amplifying the elevations in cytosolic calcium concentration induced by the influx of extracellular calcium.

The elevations in intracellular calcium are transduced into the regulated secretion of insulin by intracellular calcium sensing systems within  $\beta$ -cells. Important among these are the calcium-dependent protein kinases, which include myosin light chain kinases, the calcium/phospholipid-dependent kinases and the calcium/calmodulin-dependent kinases (CaMKs). CaMKs are protein kinases that are activated in the presence of calcium and the calcium-binding protein, calmodulin, and a number of studies have implicated CaMK II in insulin secretory responses

[61]. It has been proposed that CaMK II activation is responsible for the initiation of insulin secretion in response to glucose and other nutrients, and for enhancing nutrient-induced secretion in response to receptor agonists that elevate intracellular calcium [61]. Cytosolic  $PLA_2$  ( $cPLA_2$ ) is another  $\beta$ -cell calcium-sensitive enzyme. It is activated by concentrations of calcium that are achieved in stimulated  $\beta$ -cells, and it generates arachidonic acid (AA) by the hydrolysis of membrane phosphatidylcholine. AA is capable of stimulating insulin secretion in a glucose and calcium-independent manner, and it is further metabolized in islets by the cyclo-oxygenase (COX) pathways to produce prostaglandins and thromboxanes, and by the lipoxygenase (LOX) pathways to generate hydroperoxyeicosatetraenoic acids (HPETES), hydroxyeicosatetraenoic acids (HETES) and leukotrienes.

The precise roles(s) of AA derivatives in islet function remains uncertain because experimental investigations have relied on COX and LOX inhibitors of poor specificity, but earlier reports

that prostaglandins are largely inhibitory in rodent islets [62] have not been supported by more recent studies using human islets [63]. Calcium sensors are also important at the later stages of the secretory pathway, where the calcium-sensitive synaptotagmin proteins are involved in the formation of the exocytotic SNARE complex, as described above, to confer calcium sensitivity on the initiation and rate of exocytotic release of insulin secretory granules [44].

The elevations in intracellular calcium induced by nutrients activate other effector systems in  $\beta$ -cells, including PLC and cPLA<sub>2</sub>, as discussed above, and calcium-sensitive adenylate cyclase isoforms, which generate cyclic AMP from ATP. Although these signaling systems are of undoubted importance in the regulation of  $\beta$ -cells by non-nutrients, their role in nutrient-induced insulin secretion is still uncertain. Thus, DAG generated by glucose-induced PLC activation has the potential to activate some protein kinase C (PKC) isoforms. PKC was first identified as a calcium and phospholipid sensitive, DAG-activated protein kinase, but it has become apparent that some isoforms of PKC require neither calcium nor DAG for activation. The isoforms are classified into three groups: calcium and DAG sensitive (conventional); calcium independent, DAG-sensitive (novel); and calcium and DAG independent (atypical), and  $\beta$ -cells contain conventional, atypical and novel PKC isoforms [64]. The early literature on the role of PKC in nutrient-induced insulin secretion is confusing but several studies have shown that glucose-induced insulin secretion is maintained under conditions where DAG-sensitive PKC isoforms are depleted, suggesting that conventional and novel PKC isoforms are not required for insulin secretion in response to glucose [61,65].

The role of cyclic AMP in the insulin secretory response to nutrients is similarly unclear. Cyclic AMP has the potential to influence insulin secretion by the activation of cyclic AMP-dependent protein kinase A (PKA), or via the cyclic AMP-regulated guanine nucleotide exchange factors known as exchange proteins activated by cyclic AMP (EPACs) [66]. However, elevations in  $\beta$ -cell cyclic AMP do not stimulate insulin secretion at substimulatory glucose concentrations, and the secretagogue effects of glucose can be maintained in the presence of competitive antagonists of cyclic AMP binding to PKA or EPACs [67]. These observations suggest that cyclic AMP does not act as a primary trigger of nutrient-stimulated  $\beta$ -cell secretory function, but more recent observations linking glucose-induced oscillations in  $\beta$ -cell cyclic AMP to oscillations in insulin secretion [68] suggest that a role for this messenger system in nutrient-induced insulin secretion cannot be ruled out.

#### **K<sub>ATP</sub> channel-independent pathways**

Since the early reports linking K<sub>ATP</sub> channel closure to the exocytotic release of insulin, it has become apparent that  $\beta$ -cells also possess a K<sub>ATP</sub> channel-independent stimulus–secretion coupling pathway: this is termed the amplifying pathway to distinguish it from the triggering pathway that is activated by K<sub>ATP</sub> channel closure [69]. Studies in which  $\beta$ -cell calcium is elevated by depo-

larization and K<sub>ATP</sub> channels maintained in the open state by diazoxide have indicated that glucose, at concentrations as low as 1–6 mmol/L, is still capable of stimulating insulin secretion [70]. The mechanisms by which glucose stimulates insulin secretion in a K<sub>ATP</sub> channel-independent manner have not been established [71]. However, it is clear that glucose must be metabolized and there is convincing evidence that changes in adenine nucleotides are involved [72], while it has been established that activation of PKA and PKC is not required. It has been suggested that the K<sub>ATP</sub>-independent amplifying pathway is impaired in type 2 diabetes and that identification of novel therapeutic strategies targeted at this pathway may be beneficial in restoring  $\beta$ -cell function in patients with type 2 diabetes [69].

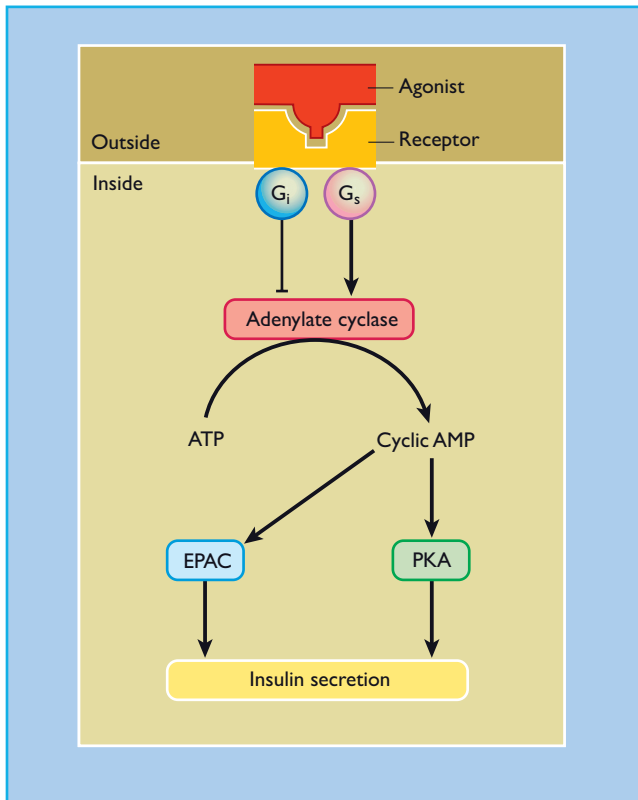

#### **Amino acids**

Several amino acids stimulate insulin secretion *in vivo* and *in vitro*. Most require glucose, but some, such as leucine, lysine and arginine, can stimulate insulin secretion in the absence of glucose, and therefore qualify as initiators of secretion. Leucine enters islets by a sodium-independent transport system and stimulates a biphasic increase in insulin release. The effects of leucine on  $\beta$ -cell membrane potential, ion fluxes and insulin secretion are similar to, but smaller than, those of glucose [73]. Thus, metabolism of leucine within  $\beta$ -cells decreases the potassium permeability, causing depolarization and activation of L-type calcium channels through which calcium enters the  $\beta$ -cells and initiates insulin secretion. Leucine is also able to activate the amplifying pathway of insulin secretion in a K<sub>ATP</sub> channel-independent manner, as described above for glucose. The charged amino acids, lysine and arginine, cross the  $\beta$ -cell plasma membrane via a transport system specific for cationic amino acids. It is generally believed that the accumulation of these positively charged molecules directly depolarizes the  $\beta$ -cell membrane leading to calcium influx.

#### **Regulation of insulin secretion by non-nutrients**

The complex mechanisms that have evolved to enable changes in extracellular nutrients to initiate an exocytotic secretory response are confined to pancreatic  $\beta$ -cells, and perhaps to a subset of hypothalamic neurons [74]. However, the mechanisms that  $\beta$ -cells use to recognize and respond to non-nutrient potentiators of secretion are ubiquitous in mammalian cells, and so are covered only briefly in this section, followed by a review of the physiologically relevant non-nutrient regulators of  $\beta$ -cell function.

Most, if not all, non-nutrient modulators of insulin secretion influence the  $\beta$ -cell by binding to and activating specific receptors on the extracellular surface. Because of its central role in coordinating whole body fuel homeostasis the  $\beta$ -cell expresses receptors for a wide range of biologically active peptides, glycoproteins and neurotransmitters (Table 6.1). However, receptor occupancy generally results in the activation of a limited number of intracellular effector systems, which were introduced in the section on nutrient-induced insulin secretion (Figures 6.9 and 6.10).

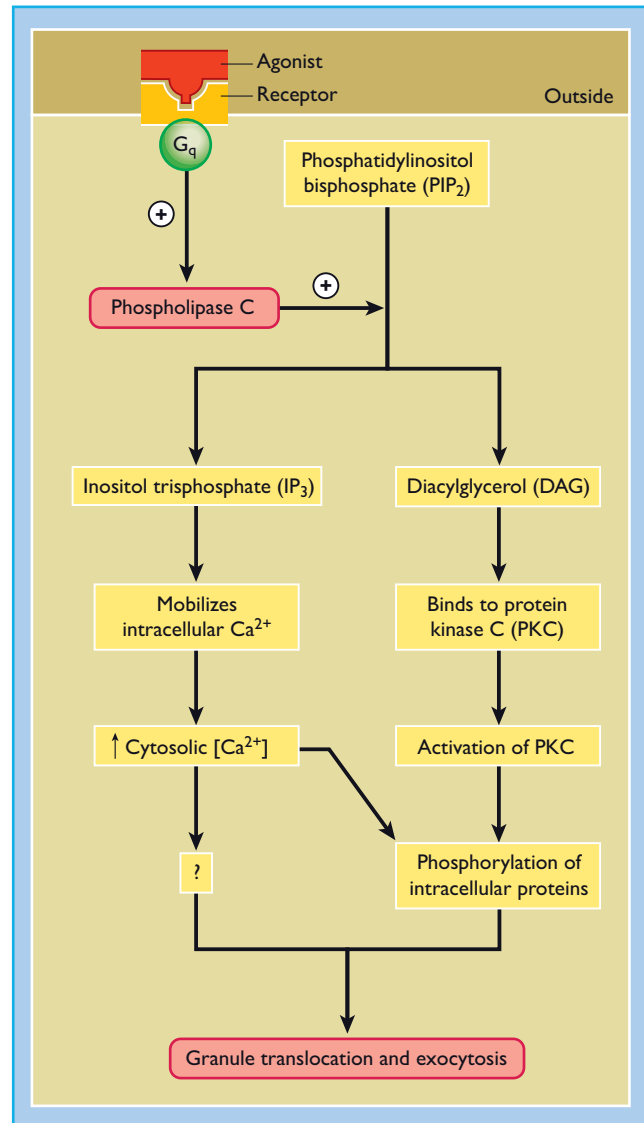

**Figure 6.9** Adenylate cyclase and the regulation of insulin secretion. Some receptor agonists (e.g. glucagon, glucagon-like peptide 1, pituitary adenylate cyclase activating polypeptide) bind to cell-surface receptors that are coupled to adenylate cyclase (AC) via the heterotrimeric GTP-binding protein G<sub>s</sub>. Adenylate cyclase hydrolyses ATP to generate adenosine 5' cyclic monophosphate (cyclic AMP), which activates protein kinase A (PKA) and exchange proteins activated by cyclic AMP (EPACs). Both of these pathways potentiate glucose-stimulated insulin secretion. Glucose also activates adenylate cyclase, but increases in intracellular cyclic AMP levels in response to glucose are generally smaller than those obtained with receptor agonists. Some inhibitory agonists (e.g. norepinephrine, somatostatin) bind to receptors that are coupled to adenylate cyclase via the inhibitory GTP-binding protein G<sub>i</sub>, resulting in reduced adenylate cyclase activity and a decrease in intracellular cyclic AMP.

**Islet hormones**

There is convincing evidence for complex intra-islet interactions via molecules released from islet endocrine cells (Figure 6.2). The physiologic relevance of some of these interactions is still uncertain, but some of the intra-islet factors that are thought to influence insulin secretion are discussed briefly in this section.

It is now clear that β-cells express insulin receptors and the associated intracellular signaling elements, suggesting the existence of autocrine and/or paracrine feedback regulation of β-cell function [19,75]. Earlier suggestions that secreted insulin regulates insulin secretion [76] have not been confirmed [19,77], and the main feedback function of insulin on β-cells is to regulate β-cell gene expression [75,78] and β-cell mass through effects on proliferation and apoptosis [19,79].

**Figure 6.10** Phospholipase C and the regulation of insulin secretion. Some receptor agonists (e.g. acetylcholine, cholecystokinin) bind to cell-surface receptors that are coupled to phospholipase C (PLC) via the heterotrimeric GTP-binding protein G<sub>q</sub>. Phospholipase C hydrolyzes phosphoinositol bisphosphate (PIP<sub>2</sub>), an integral component of the membrane, to generate inositol 1,4,5-trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). IP<sub>3</sub> mobilizes calcium from the endoplasmic reticulum and DAG activates protein kinase C (PKC), both of which enhance insulin secretion. Nutrients also activate PLC in a calcium-dependent manner but the importance of IP<sub>3</sub> and DAG in nutrient-induced insulin secretion is uncertain.

Glucagon is a 29 amino acid peptide secreted by islet α-cells. The precursor, proglucagon, undergoes differential post-translational processing in the gut to produce entirely different peptides with different receptors and biologic activities. These include glucagon-like peptide 1 (GLP-1) (7–36) amide, an “incretin” hormone that is discussed below, and GLP-2, which promotes growth of the intestinal mucosa. Glucagon secretion is regulated

by nutrients, islet and gastrointestinal hormones and the autonomic nervous system, with hypoglycemia and sympathetic nervous input being important stimulators of glucagon secretion [80]. Glucagon enhances insulin secretion through the stimulatory G-protein ( $G_s$ ) coupled activation of adenylate cyclase and the consequent increase in intracellular cyclic AMP (Figure 6.9).

Somatostatin (SST) is expressed by islet  $\delta$ -cells and in numerous other sites, including the central nervous system and D cells of the gastrointestinal tract, where it acts predominantly as an inhibitor of endocrine and exocrine secretion [81]. The precursor, prosomatostatin, is processed by alternative pathways: in islets and the CNS SST-14 is generated, and SST-28, the major circulating form of SST in humans, is produced in the gastrointestinal tract [82]. SST secretion is regulated by a variety of nutrients, endocrine and neural factors [17,81,83]. Islets express five different somatostatin receptor (SSTR) subtypes, and SST-14 released from islet  $\delta$ -cells has a tonic inhibitory effect on insulin and glucagon secretion [17], via activation of SSTR5 and SSTR2, respectively [84,85]. SST receptors are coupled via an inhibitory G-protein(s) to the inhibition of adenylate cyclase and decreased formation of cyclic AMP [86], and to ion channels that cause hyperpolarization of the  $\beta$ -cell membrane and reductions in intracellular calcium [87].

Pancreatic polypeptide (PP) is a 36 amino acid peptide produced by PP cells that are found in the mantle of islets, predominantly those located in the head of the pancreas. PP secretion is mainly regulated via cholinergic parasympathetic stimulation [81], but the physiologic function of PP as a circulating hormone, or as an intra-islet signal, remains uncertain [88].

Ghrelin is a 23 amino acid peptide first identified in the gastrointestinal system, but now known to also be expressed in islet  $\epsilon$ -cells, which are localized to the islet mantle in rodents, and which appear to be developmentally distinct from the classic islet endocrine cells [89,90]. The physiologic function of  $\epsilon$ -cell-derived ghrelin has not been established, but most experimental evidence suggests an inhibitory role in the regulation of insulin secretion [91], analogous to that of  $\delta$ -cell SST [17].

### Neural control of insulin secretion

The association of nerve fibers with islets was shown over 100 years ago by silver staining techniques [92], and since that time it has become well established that islets are innervated by cholinergic, adrenergic and peptidergic autonomic nerves. Parasympathetic (cholinergic) fibers originating in the dorsal motor nucleus of the vagus, and sympathetic (adrenergic) fibers from the greater and middle splanchnic nerves penetrate the pancreas and terminate close to the islet cells. The autonomic innervation of the islets is important in regulating insulin secretion, with enhanced insulin output following activation of parasympathetic nerves and decreased insulin secretion in response to increased sympathetic activity. The autonomic nervous regulation of islet hormone secretion is thought to be involved in the cephalic phase of insulin secretion during feeding, in synchroniz-

ing islets to generate oscillations of hormone secretion, and in regulating islet secretory responses to metabolic stress [5].

### Neurotransmitters: acetylcholine and norepinephrine

The numerous parasympathetic nerve fibers that innervate islets are postganglionic and originate from the intra-pancreatic ganglia, which are controlled by preganglionic fibers originating in the dorsal vagal nucleus [5]. Acetylcholine is the major postganglionic parasympathetic neurotransmitter, and it stimulates the release of insulin and glucagon in a variety of mammalian species [5,93,94]. In  $\beta$ -cells, acetylcholine acts predominantly via M3 receptors [93,95] to activate PLC (Figure 6.10), generating  $IP_3$  and DAG, which act to amplify the effects of glucose by elevating cytosolic calcium and activating PKC [61]. Activation of  $\beta$ -cell muscarinic receptors can also lead to the activation of  $PLA_2$ , with the subsequent generation of AA and lysophosphatidylcholine, which can further enhance nutrient-induced insulin secretion. Acetylcholine also depolarizes the plasma membrane by affecting  $Na^+$  conductivity, and this additional depolarization induces sustained increases in cytosolic calcium [93].

Islets also receive an extensive sympathetic innervation from postganglionic nerves whose cell bodies are located in the celiac or paravertebral ganglia, while the preganglionic nerves originate from the hypothalamus [5]. The major sympathetic neurotransmitter, norepinephrine (noradrenaline), can exert positive and negative influences on hormone secretion. Thus, norepinephrine can exert direct stimulatory effects on the  $\beta$ -cell via  $\beta_2$ -adrenoreceptors [96], or inhibitory effects via  $\alpha_2$ -adrenoreceptors [97], and the net effect of norepinephrine may depend on the relative levels of expression of these receptor subtypes. Differences between species in the expression levels of adrenoreceptor subtypes probably account for the differential effects of  $\beta$ -adrenergic agonists on human islets, where they are stimulatory, and rodent islets, where they are ineffective [98]. The stimulatory effects mediated by  $\beta_2$ -receptors occur by activation of adenylate cyclase and an increase in intracellular cyclic AMP (Figure 6.9) [99], while the inhibitory effect of  $\alpha_2$ -receptor activation involve reductions in cyclic AMP and of cytosolic calcium [86,100], and an unidentified inhibitory action at a more distal point in the stimulus–secretion coupling mechanism [101]. In contrast, norepinephrine has direct stimulatory effects on glucagon secretion from  $\alpha$ -cells mediated by both  $\beta_2$  and  $\alpha_2$ -receptor subtypes [5]. Circulating catecholamines secreted by the adrenal medulla (mainly epinephrine) also have the potential to influence islet hormone secretion through interactions with the adrenoreceptors expressed on the  $\alpha$  and  $\beta$ -cells.

### Neuropeptides

Parasympathetic nerve fibers in islets contain a number of biologically active neuropeptides, including VIP, PACAP and gastrin-releasing polypeptide (GRP), all of which are released by vagal activation and all of which stimulate the release of insulin and glucagon.

VIP (28 amino acids) and PACAP (27 or 38 amino acids) are abundantly expressed neuropeptides that are widely distributed in parasympathetic nerves that supply the islets and gastrointestinal tract [6,102]. VIP and PACAP have similar structures, and VIP1 and VIP2 receptors also have an affinity for PACAP. The stimulatory effects of VIP and PACAP on insulin secretion *in vitro* and *in vivo* are through  $\beta$ -cell VIP2 and PAC1 receptors, respectively, and are thought to involve increases in intracellular cyclic AMP (Figure 6.9) and cytosolic calcium [6,103,104]. GRP is a 27 amino acid peptide that also stimulates the secretion of insulin, glucagon, SST and PP [5,94]. These effects of GRP are mediated through specific receptors, and involve the activation of PLC and the generation of IP<sub>3</sub> and DAG (Figure 6.10) [102,105].

Sympathetic nerves contain different neuropeptides to parasympathetic nerves, and these include NPY and galanin, both of which have inhibitory actions within islets. NPY (36 amino acids) and galanin (29 amino acids) are expressed in fibers innervating both the endocrine and exocrine pancreas [5,106]. Both neuropeptides inhibit basal and glucose-stimulated insulin secretion [86,106,107], although differences between species have been reported. Both NPY and galanin act through specific G<sub>i</sub>-coupled receptors to inhibit adenylate cyclase [108,109], and galanin may have additional inhibitory effects at an undefined late stage of exocytosis [86].

### Incretin and adipokine regulation of insulin secretion

It has been known for over 40 years that insulin secretion from islets is greater following oral rather than intravenous administration of glucose [110], and it is now known that this enhanced insulin secretory output is a consequence of the release of gastrointestinal-derived “incretin” hormones [111]. The main incretins that have been implicated in an elevated insulin response to absorbed nutrients after food intake are glucagon-like peptide 1 (GLP-1), glucose-dependent insulinotropic peptide (GIP) and cholecystokinin (CCK), all of which are hormones secreted by specialized endocrine cells in the gastrointestinal tract in response to the absorption of nutrients [111,112]. These hormones are carried to the islets in the blood and they interact with specific receptors on the  $\beta$ -cell surface to stimulate insulin secretion.

#### Glucagon-like peptide 1

After food intake, intestinal L-cells secrete GLP-1 in response to elevated levels of nutrients derived from carbohydrates, lipids and protein in the intestinal lumen [112,113]. GLP-1 is generated by prohormone convertase 1–3 cleavage of proglucagon in the L-cells and it is highly conserved in mammals, with identical amino acid sequences in humans and mice [82,113]. GLP-1 is degraded by dipeptidyl protease 4 (DPP-4), which cleaves two amino acids from its N-terminus. Full length GLP-1 (1–37) does not show biologic activity, but the truncated peptides GLP-1 (7–36) amide and GLP-1 (7–37) are potent stimulators of insulin secretion *in vitro* and *in vivo* [114]. Observations that infusion of the peptide into individuals with type 2 diabetes before food intake improved insulin output and reduced the post-prandial

increase in circulating glucose led to studies to determine whether GLP-1 or related peptides may be useful as therapies for type 2 diabetes. Reports of other beneficial effects of GLP-1, including its capacity to inhibit glucagon secretion, delay gastric emptying and decrease food intake indicated its positive effects on normalizing post-prandial glycemia, but its half-life of less than 2 minutes precludes its use as a diabetes therapy. Nonetheless, exenatide, a synthetic version of a GLP-1 analogue present in the saliva of the Gila monster lizard, has been developed for clinical use for type 2 diabetes [115]. It has approximately 50% amino acid homology with GLP-1 thus allowing it to exert the same effects on islets as native GLP-1, but its resistance to degradation by DPP-4 increases its half-life to around 2 hours *in vivo*, which ensures effective regulation of blood glucose levels. Another GLP-1 analogue, liraglutide, has a greatly extended half life (>12 hours) as a result of incorporation of the fatty acid palmitate into the GLP-1 sequence, allowing it to bind to plasma albumin and reducing its exposure to DPP-4. Selective DPP-4 inhibitors such as sitagliptin are used clinically to normalize blood glucose levels in type 2 diabetes by extending the half-life of endogenous GLP-1.

GLP-1, exenatide and liraglutide act at specific G-protein coupled receptors [111] that are linked, via G<sub>s</sub>, to adenylate cyclase activation which ultimately increases insulin secretion (Figure 6.9) [114]. Although cyclic AMP has been implicated in the majority of effects of GLP-1 in islets, it may also close rat  $\beta$ -cell K<sub>ATP</sub> channels in a cyclic AMP-independent manner [116].

#### Glucose-dependent insulinotropic peptide

Glucose-dependent insulinotropic peptide (GIP), a 42 amino acid peptide, is released from K-cells in the duodenum and jejunum in response to the absorption of glucose, other actively transported sugars, amino acids and long-chain fatty acids [112]. It was originally called “gastric inhibitory polypeptide” because of its inhibitory effects on acid secretion in the stomach, but its main physiologic effects are now known to be stimulation of insulin secretion in a glucose-dependent manner [102,111]. Like GLP-1, GIP binds to G<sub>s</sub>-coupled receptors on the  $\beta$ -cell plasma membrane, with essentially the same downstream cascades leading to stimulation of insulin secretion (Figure 6.9) [102,111]. GIP is also reported to increase insulin release through generation of AA via phospholipase A<sub>2</sub> activation [117], and closure of K<sub>ATP</sub> channels [111]. Although GLP-1 and GIP both enhance insulin output following their release in response to food intake, it seems unlikely that GIP-related peptides will be developed as therapies for type 2 diabetes because GIP stimulates glucagon secretion and inhibits GLP-1 release, and its infusion in individuals with type 2 diabetes is reported to worsen post-prandial hyperglycemia [118].

#### Cholecystokinin

CCK is another incretin hormone that is released from I-cells in the gastrointestinal tract in response to elevated fat and protein

levels [112]. It was originally isolated from porcine intestine as a 33 amino acid peptide and the truncated CCK-8 form stimulates insulin secretion *in vitro* and *in vivo* [119]. CCK-8 acts at specific  $G_q$ -coupled receptors on  $\beta$ -cells to activate PLC (Figure 6.10) [102], and its potentiation of insulin secretion is completely dependent on PKC activation [120]. However, the physiologic role of CCK as an incretin has not been established because high concentrations are required for its effects on insulin secretion, and it is possible that its major function is in digestion in the duodenum.

### Adipokines

Obesity is a risk factor for diabetes, and hormones (adipokines) released from fat depots have been implicated in insulin resistance associated with obesity and type 2 diabetes [121]. Some adipokines such as leptin, resistin and adiponectin are also reported to influence islet function. Thus,  $\beta$ -cells express Ob-Rb leptin receptors which, when activated by leptin, lead to inhibition of insulin secretion [122], and specific deletion of  $\beta$ -cell Ob-Rb receptors is associated with enhanced insulin secretion [123]. The inhibitory effects of leptin on glucose-stimulated insulin secretion have been attributed to activation of  $\beta$ -cell  $K_{ATP}$  channels [124] or of c-Jun N-terminal kinases (JNKs) [125]. Leptin may also further impair  $\beta$ -cell function through reductions in  $\beta$ -cell mass [123,125]. Resistin, another adipocyte polypeptide, also inhibits glucose-stimulated insulin release [126] and stimulates apoptosis of rat  $\beta$ -cells [127], suggesting that it has similar functions to leptin. However, resistin is not considered to be a true adipokine because although it is secreted at high levels from mouse adipocytes it is not produced by human adipocytes, and high plasma resistin levels do not correlate with reduced insulin sensitivity [128]. However, it is possible that resistin has paracrine effects on  $\beta$ -cell function in humans as it has been identified in human islets [129]. Unlike leptin and resistin, adiponectin has protective effects by improving insulin sensitivity, and decreased plasma adiponectin levels may contribute to the development of type 2 diabetes [130]. The functional effects of adiponectin in  $\beta$ -cells have not been fully established, but human and rat  $\beta$ -cells express adiponectin receptors [131,132], and adiponectin is reported to stimulate insulin secretion [131,132] and protect against  $\beta$ -cell apoptosis [133]. The signaling cascades that couple adiponectin receptors to downstream effects in  $\beta$ -cells are currently unknown.

### Conclusions

Pancreatic islets of Langerhans are complex endocrine organs containing several different types of endocrine cells, with extensive vasculature and autonomic nerve supply. Interactions between the islet cells, the autonomic nervous system and hormones secreted by the gastrointestinal system and adipose tissue enable the appropriate release of islet hormones to regulate metabolic fuel usage and storage.

The insulin-secreting  $\beta$ -cells within islets respond to changes in circulating nutrients by linking changes in nutrient metabolism to  $\beta$ -cell depolarization and the calcium-dependent exocytotic release of stored insulin.  $\beta$ -Cells can also respond to a wide range of hormones and neurotransmitters through conventional cell surface receptors that are linked to a variety of intracellular effectors systems regulating the release of insulin. The ability to detect nutrient, hormonal and neural signals allows  $\beta$ -cells to integrate information about the prevailing metabolic status, and to secrete insulin as required for glucose homeostasis.

This detailed understanding of islet cell biology has informed the development of new treatments for type 2 diabetes, as exemplified by the recent introduction of GLP-1 agonists and DPP-4 inhibitors. Recent studies have suggested associations between type 2 diabetes and polymorphisms in genes associated with  $\beta$ -cell development or function, so current understanding of normal  $\beta$ -cell function may assist in identifying the  $\beta$ -cell pathologies in type 2 diabetes.

## Insulin Action

**Xuxia Wu & W. Timothy Garvey**

Department of Nutrition Sciences, University of Alabama at Birmingham and the Birmingham Veterans Affairs Medical Center, Birmingham, AL, USA

### Keypoints

- Insulin signaling is accurately viewed as involving a matrix of interacting pathways, allowing for extensive modulation and divergence in signal transduction, rather than a linear cascade of sequential reactions.
- Diverse cell types commonly share the proximal steps in insulin signal transduction, including the insulin receptor, insulin receptor substrate molecules (IRS), phosphatidylinositide 3 kinase and Akt/protein kinase B.
- Insulin action is negatively modulated by multiple cellular mechanisms that impair tyrosine phosphorylation of insulin receptors and IRS; foremost among these are serine–threonine kinases and protein tyrosine phosphatases.
- The tissue-specific biologic effects of insulin are explained by effector systems which are uniquely expressed in differentiated target tissues such as the insulin-responsive glucose transport system in skeletal muscle, enzymatic systems mediating antilipolysis in adipose tissue and regulated gene expression leading to suppression of gluconeogenesis in liver.
- Insulin action is highly regulated by three pathways for nutrient sensing: the hexosamine biosynthetic signaling pathway; the mammalian target of rapamycin signaling pathway; and the AMP-activated protein kinase signaling pathway.
- Oxidative stress, inflammation and endoplasmic reticulum stress are associated with insulin resistance, obesity and metabolic syndrome, and impair insulin action via activation of serine–threonine protein kinases.

### General aspects of insulin action

The peptide hormone insulin is exclusively synthesized in and secreted from pancreatic  $\beta$ -cells. Insulin exerts a broad spectrum of anabolic effects in multiple tissues. The regulation of whole body fuel homeostasis primarily involves insulin action in skeletal muscle, adipose tissue, and liver where insulin promotes uptake and storage of carbohydrate, fat, and amino acids, while at the same time antagonizing the catabolism of these fuel reserves. In skeletal muscle, insulin stimulates glucose transport and glucose storage as glycogen, as well as glycolysis and tricarboxylic acid cycle activity. Insulin lowers hepatic glucose output by inhibiting glycogenolysis and gluconeogenesis, and augments glycogen formation. In adipocytes, insulin promotes glucose uptake, glycerol synthesis, and triglyceride formation, while at the same time exerting an antilipolytic effect. During periods of fasting, a fall in circulating insulin combined with increased secretion of counter-regulatory hormones leads to breakdown of stored fuels and increased availability of metabolic substrates for cellular energy.

In this way, alterations in insulin levels in the fed and fasting states have a key role in fuel metabolism and maintain blood glucose levels within a narrowly defined range. Insulin diminishes protein catabolism and increases translation, and also enhances cell growth, differentiation, and survival as a consequence of mitogenic and anti-apoptotic processes. Thus, the action of insulin at the level of cells and tissues affects substrate flux and coordinates the function of multiple organs as whole organisms adapt to the nutritional environment.

In mediating its pleiotropic actions, insulin binds to cell surface receptors, activates multiple signal transduction networks, and engages effector systems responsible for specific biologic functions. Over the last decade it has become clear that the classic perspective of insulin signaling as a linear cascade of sequentially interacting signal transduction molecules is short-sighted. Rather, the promulgation of insulin action is more accurately viewed as alterations in a network of interactions involving a matrix of signal cascades that engage in cross-talk. The final biologic action represents the net synergism of the combined facilitative, inhibitory and complementary signaling pathways that interact with more terminal functional systems in cell biology. While there is relative commonality in signal transduction networks, differentiated insulin target cells express a variety of unique effector systems, which are primarily responsible for mediating the cell-

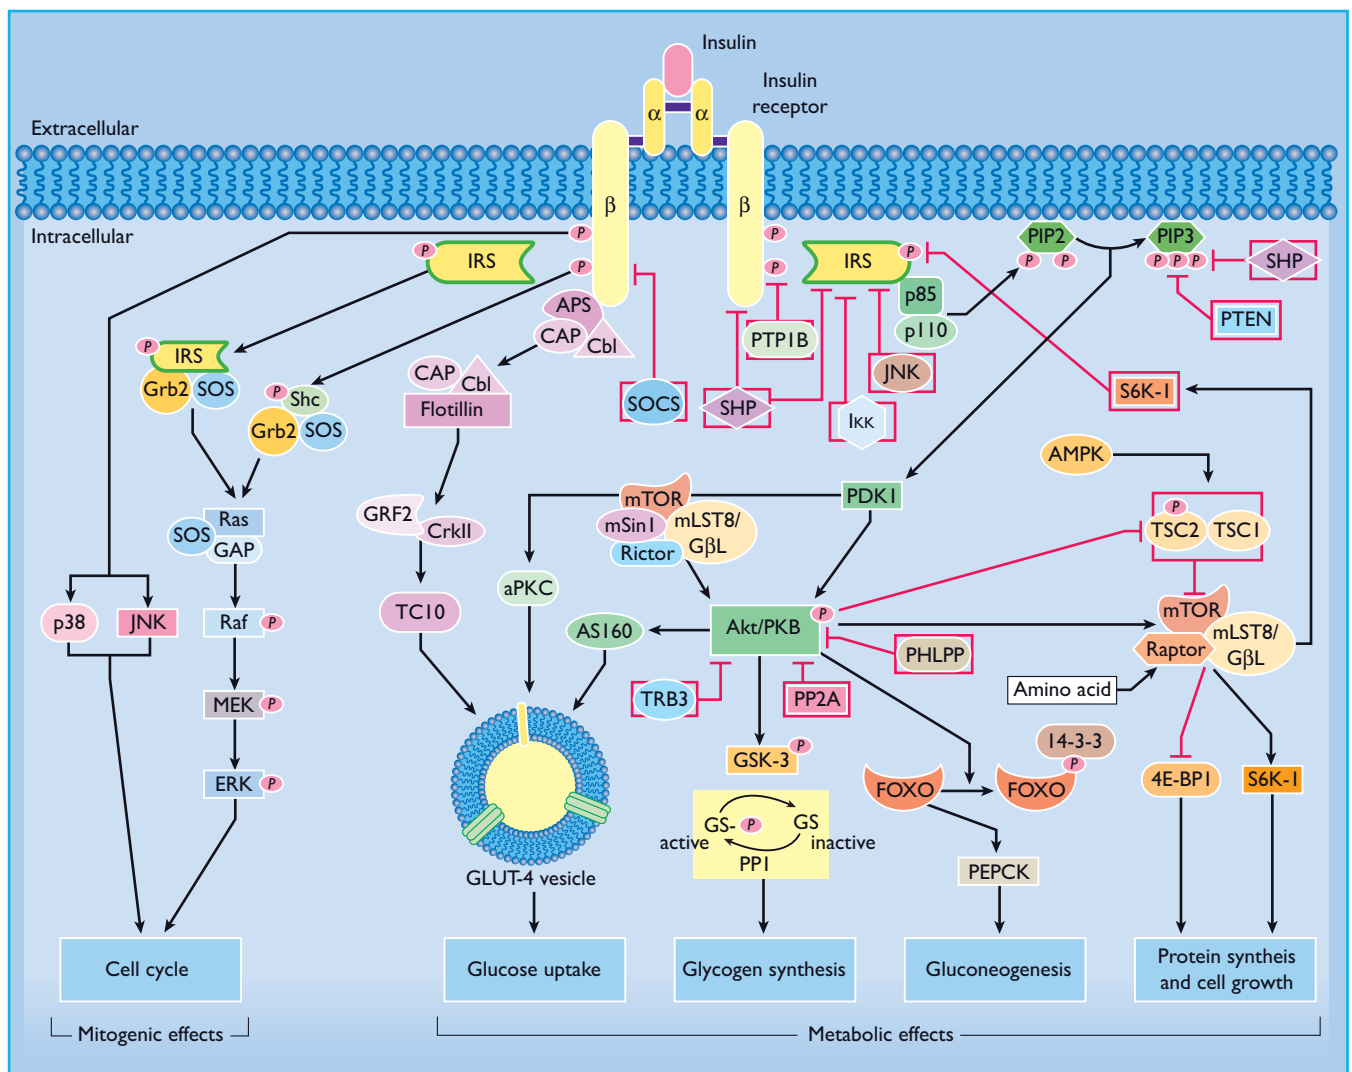

specific and organ-specific biologic functions of insulin. Effector systems include rate-limiting enzymes, enzymatic pathways, membrane transport systems, gene expression, processes regulating the cellular trafficking of proteins and vesicles, and systems governing the translation, post-translational modification and degradation of proteins. Certain aspects of linear insulin signal transduction are evolutionarily conserved; however, complex patterns of interactions between signal and evolved effector systems are more pronounced in mammals and allow for greater plasticity in adaptive responses [1].

This chapter first discusses insulin signaling pathways and networks that are common to multiple target cell types. Recent advances in our understanding of cell processes and pathways that inhibit insulin signaling are delineated. Subsequently, unique aspects of insulin action are described, in particular key effector systems, which are properties of skeletal muscle, adipocytes, and liver, and explain the distinct effects on biologic

functions in these tissues. Finally, nutrient sensing pathways and cell stress responses are discussed in terms of their interaction with insulin signaling and role in the pathogenesis of insulin resistance.

### Insulin action: proximal signaling pathways

Proximal steps in insulin signaling, including the insulin receptor, insulin receptor substrate proteins (IRS), phosphatidylinositol 3 (PI<sub>3</sub>) kinase, Akt/protein kinase B (Akt/PKB), and mitogen activated protein kinase (MAPK) are globally operative in multiple cell types. These proteins also serve as points of divergence or nodes in an expanding matrix of signal transduction pathways, and are highly regulated, both positively and negatively, via crosstalk with other signaling systems and modulatory pathways (Figure 7.1).

**Figure 7.1** A schematic illustration of insulin signaling pathways involved in both metabolic and mitogenic effects. Arrows represent an activation process; blocked arrows represent an inhibition process.

### Insulin receptor molecules

Insulin action is initiated by specific binding to high-affinity receptors on the plasma membrane of its target cells. The insulin receptor is a large transmembrane glycoprotein consisting of two  $\alpha$ - and two  $\beta$ -subunits which form a heterotetramer. The insulin receptor is synthesized from a single gene that consists of 22 exons and 21 introns. Following translation of its mRNA, it is processed into two separate subunits ( $\alpha$  and  $\beta$ ) that assemble as a disulfide-linked holoenzyme of  $(\alpha\beta)_2$  stoichiometry [2]. The 135 kDa  $\alpha$ -subunits, derived from the amino-terminal portion of the proreceptor, reside entirely on the outside of the cell, tethered to the membrane via the 95 kDa  $\beta$ -subunits that span the membrane. Insulin binds to the extracellular  $\alpha$ -subunits. This binding results in conformational changes that bring the  $\alpha$ -subunits closer together, and enables ATP to bind to the intracellular domain of the  $\beta$ -subunit leading to autophosphorylation of distinct tyrosine residues on the  $\beta$ -subunit. Autophosphorylation augments the intrinsic activity of the  $\beta$ -subunit as a tyrosine kinase, directed against other tyrosines within the receptor as well as tyrosine phosphorylation of exogenous substrates. Ligand-dependent stimulation of the  $\beta$ -subunit tyrosine kinase activity is critical for promulgation of the insulin signal. At least six tyrosine residues in the  $\beta$ -subunit undergo phosphorylation and have been shown to serve different roles in insulin signaling. They lie within three functional groups. Phosphorylation of Tyr<sup>972</sup> establishes a recognition motif and docking site that provides sufficient stability of the receptor–substrate complex for intracellular substrate phosphorylation. Tyrosine phosphorylation sites at positions Tyr<sup>1158</sup>, Tyr<sup>1162</sup> and Tyr<sup>1163</sup> are essential for mediating an increase in subunit tyrosine kinase activity and signal transduction. Phosphorylation sites Tyr<sup>1328</sup> and Tyr<sup>1334</sup> affect the sensitivity of Ras/MAPK pathway activation, and are thus involved in the receptor's mitogenic responses [3].

The number of cell-surface insulin receptors is downregulated by chronic exposure to high insulin concentrations *in vitro*, and receptor loss is observed in target cells from hyperinsulinemic insulin-resistant humans. Receptor loss per se can impair maximal insulin responsiveness. This is illustrated in the extreme by genetic ablation of the insulin receptor in mice which results in lethality at 4–5 days after birth as a result of severe diabetic ketoacidosis [4]. Insulin-stimulated glucose uptake and activation of glycogen synthase in muscle are severely impaired in muscle-specific insulin receptor knockout mice [5]. These latter animals also have features of the metabolic syndrome including increases in fat mass, serum triglycerides and serum free fatty acids, but retain normal basal and contraction-stimulated glucose transport [6]. Transgenic mice expressing dominant-negative insulin receptors also develop obesity, hyperinsulinemia, glucose intolerance, and hypertriglyceridemia. These phenotypes are analogous to those seen in insulin-resistant humans. Patients with genetic mutations in the insulin receptor gene (type B insulin resistance) or circulating antibodies directed against the insulin receptor that block ligand binding (type A insulin resistance) develop severe insulin resistance, acanthosis nigricans and

glucose intolerance. In addition to receptor downregulation, the intrinsic activity of the insulin receptor tyrosine kinase is impaired in insulin-resistant humans and patients with type 2 diabetes mellitus (T2DM) via a number of regulatory and pathophysiologic processes which are described in this chapter. Clearly, the number and functional activity of insulin receptors is critical for effective insulin action.

The insulin receptor is similar in structure to the insulin-like growth factor 1 receptor (IGF1R) and several other growth factor and cytokine receptors, which have in common an extracellular ligand-binding domain that activates an intracellular tyrosine kinase domain. The mammalian insulin-like signaling system includes three well-defined ligands: insulin, insulin-like growth factor 1 (IGF-1), and insulin-like growth factor 2 (IGF-2), and all three ligands can bind and activate cell-surface insulin receptors [7]. Alternative splicing involving exon 11 of the insulin receptor gene determines the insertion or deletion of 12 amino acids near the COOH-terminus of the  $\alpha$ -subunit. Isoform A lacking the 12 amino acids has high affinity for IGF-2, predominates during fetal development, and promotes growth as a consequence of IGF-2 binding. Isoform B containing the 12 amino acids predominates postnatally and is activated mainly by insulin. Some evidence supports the contention that dysregulated expression towards the fetal pattern could occur in adult tissues and result in insulin resistance [8].

### Insulin receptor substrate molecules

Following insulin binding and receptor autophosphorylation, the next committed step in signal transduction is tyrosine phosphorylation of intracellular proteins. At least 11 intracellular substrates have been identified that are rapidly phosphorylated on tyrosine residues by ligand-bound insulin receptors, including six insulin receptor substrate (IRS) proteins, Grb2-associated binder 1 (Gab1), Cas-Br-M (murine) ecotropic retroviral transforming sequence homolog (Cbl), and the various isoforms of Src-homology-2-containing protein (Shc) [9].

The IRSs are immediate substrates for the insulin receptor tyrosine kinase, and are of predominant importance for insulin action. IRS proteins have an N-terminal pleckstrin-homology (PH) domain, a phosphotyrosine-binding (PTB) domain and a COOH-terminal region of variable length that contains multiple tyrosine and serine phosphorylation sites [10]. The PH domain helps position IRS for coupling with the insulin receptor, possibly by binding to charged headgroups of certain phosphatidylinositides in adjacent membrane structures. PTB domains recognize the phosphotyrosine in the amino acid sequence asparagine-proline-any amino acid-phosphotyrosine (NPXpY), which encompasses Tyr<sup>972</sup> in the juxtamembranous domain of the insulin receptor  $\beta$ -subunit, and facilitates the formation of the IRS–insulin receptor complex. The center and C-terminus of IRS proteins contain up to 20 potential tyrosine phosphorylation sites that, after phosphorylation by the insulin receptor, bind to other intracellular molecules that contain Src-homology-2 domains (SH2 domains). The SH2-containing proteins that bind to phos-

phorylated IRS proteins could be adaptor molecules, such as the regulatory subunit of PI<sub>3</sub> kinase and the adaptor molecule Grb2, or enzymes with kinase or phosphatase activities such as SH2-domain-containing tyrosine phosphatase 2 (SHP2) and the cytoplasmic tyrosine kinase Fyn. Non-covalent attachment of multiple SH2-containing signaling molecules allows IRS to function as a docking protein that physically apposes proteins involved in downstream transduction cascades. Thus, IRS propagates insulin signal transduction via the docking, apposition, interaction, and activation of downstream signal molecules, rather than as a consequence of any intrinsic enzymatic activity per se. Thus, IRSs provide a major point of divergence of insulin signal transduction pathways, for example, leading to activation of mitogenic (Ras/MAP kinase) and metabolic (PI<sub>3</sub> kinase) pathways [11].

Among the family of IRS proteins, IRS1 and IRS2 exhibit a wide range of tissue expression, including muscle, fat, liver, and pancreatic islets. IRS3 is expressed in adipose tissue, fibroblasts, and liver, while IRS4 is detected in brain, thymus, and embryonic kidney. IRS5 is ubiquitously expressed but most abundant in kidney and liver. IRS6 expression is highest in skeletal muscle. Deletion of IRS1 produces small insulin-resistant mice with nearly normal glucose homeostasis because of  $\beta$ -cell expansion and compensatory hyperinsulinemia. Mice lacking IRS2 display nearly normal growth but develop life-threatening diabetes at 8–15 weeks of age because of reduced  $\beta$ -cell mass and insufficient compensatory insulin secretion. IRS3 knockout mice do not have an obvious phenotype, and IRS4 null mice also appear normal with the exception of reduced fertility. Therefore, IRS1 and IRS2 are considered to be the IRS isoforms critically important in glucose homeostasis. IRS1 functions as the principal IRS in skeletal muscle, and IRS2 predominates in liver and  $\beta$ -cell, where insulin action is required for normal  $\beta$ -cell growth and development.

IRS proteins are a key locus for regulation of insulin action. One mechanism occurs at the level of IRS protein expression; for example, IRS1 and IRS2 proteins are decreased by hyperinsulinemia [12]. Cell loss of IRS could occur through accelerated protein degradation by induction of ubiquitin-mediated degradation of IRS1 and IRS2 by suppressor of cytokine signaling (SOCS) proteins [13], or by inhibition of IRS gene transcription. Regardless of the mechanism, decreased levels of IRS proteins in hyperinsulinemic states, coupled with downregulation of the insulin receptor itself, certainly contribute to the insulin resistance in diabetes [14]. The function of IRS proteins can also be negatively regulated by serine–threonine kinases and protein tyrosine phosphatases such as PTP1B and SHP2, as described below [15]. In addition, IRS1 can be post-translationally modified by either O-linked N-acetylglucosamine adducts (O-GlcNAc) on serine–threonine residues under hyperglycemic conditions [16], or S-nitrosylation as a consequence of nitric oxide generation [17]. These modifications induce the proteasomal downregulation of IRS1 and insulin resistance.

### PI<sub>3</sub> kinase

Among several proteins that bind to IRS1/2, PI<sub>3</sub> kinase is critical for signal transduction mediating the metabolic effects of insulin, including stimulation of glucose uptake into skeletal muscle and adipose tissues. PI<sub>3</sub> kinase activity represents a family of related enzymes that are capable of phosphorylating the hydroxyl groups in the inositol ring of membrane-associated phosphatidylinositol (PtdIns) [18]. The generation of PI(3,4,5)P<sub>3</sub> propagates the insulin signal, and therefore the class I subset of PI3K is responsible for the downstream action of receptor tyrosine kinases (including the insulin receptor) and Ras/MAPK [19]. Class I PI<sub>3</sub> kinases are heterodimeric molecules composed of one regulatory and one catalytic subunit. There are currently five known regulatory subunits, designated p85 $\alpha$ , p55 $\alpha$ , p50 $\alpha$ , p85 $\beta$  or p55 $\gamma$  (known collectively as the p85 subunit), and one of these regulatory subunits is conjoined with one of four known p110 catalytic subunits, p110 $\alpha$ , p110 $\beta$ , p110 $\delta$  or p110 $\gamma$  [20]. Under normal conditions, p85 regulatory subunits are present in excess compared with the amount of the p85–p110 complex, and can serve as negative regulators of insulin action. One explanation pertains to the stoichiometry of free p85 and p85–p110 complexes because free p85 may be able to compete with the p85–p110 complex for recruitment to IRS phosphotyrosine docking sites (i.e. the “free p85” model) [21]. Accordingly, increased expression of p85 can worsen insulin sensitivity as demonstrated in patients with gestational diabetes or obesity who have increased levels of p85 in skeletal muscle. The p85 subunit can also exert negative modulatory effects via cross-talk with stress-kinase pathways. Recent studies have shown that p85 is required for the insulin-stimulated activation of c-Jun NH<sub>2</sub>-terminal kinase (JNK) that occurs in states of insulin resistance, including high-fat diet-induced obesity and JNK overexpression [22]. Because the JNK pathway suppresses insulin action, the involvement of p85 in JNK activation provides a mechanism for cross-talk between the PI<sub>3</sub> kinase signaling pathway and JNK-mediated stress or inflammatory responses. Also, p85 is able to suppress insulin action via positive regulation of the phosphatase and tensin homolog (PTEN), a phosphoinositide phosphatase that degrades PI(3,4,5)P<sub>3</sub> and inhibits downstream insulin signaling [23].

### 3-Phosphoinositide-dependent protein kinase 1

Insulin-mediated activation of PI<sub>3</sub> kinase results in phosphorylation of the inositol ring at the 3' position of phosphatidylinositol in membrane glycolipids, generating PI(3,4,5)P<sub>3</sub>. This leads to recruitment of certain signaling proteins with PH domains to the plasma membrane. Binding to membrane-associated phosphoinositides both activates these proteins and positions them for downstream signal transduction. 3-Phosphoinositide-dependent protein kinase 1 (PDK1) can interact with PI(3,4,5)P<sub>3</sub>, and is responsible for downstream activation of Akt/PKB and aPKCs. PDK1 phosphorylates the activation loops of Akt/PKB on Thr<sup>308</sup>, and PKC $\zeta$  on Thr<sup>410</sup>, enhancing the activity of these kinases.

### Akt/protein kinase B

Phosphorylation and activation of Akt/PKB mediates various insulin- and growth factor-induced cellular responses, such as the stimulation of GLUT-4 translocation to the plasma membrane, the inhibition of glycogen synthase kinase 3 (GSK-3), induction of triglyceride synthesis via increasing the expression of sterol regulatory element-binding proteins 1c (SREBP-1c), and the promotion of cell survival by inhibiting apoptosis. Akt/PKB is a serine–threonine kinase with multiple substrates including kinases, signaling proteins, and transcription factors, such as cyclin-dependent kinase inhibitor p21kip, GSK3 $\beta$ , Bcl-2 antagonist of cell death, AS160, endothelial NO synthase, forkhead box class O1 (Foxo 1) and others. There are three isoforms of Akt/PKB in mammals, each encoded by a different gene (Akt1, Akt2 and Akt3). Akt1 and Akt2 are widely distributed; however, Akt2 is predominant in insulin-sensitive tissues such as liver and fat. Akt3 is largely expressed in the nervous system and testis.

Several lines of evidence implicate a role for Akt/PKB activation in the stimulation of glucose transport and other insulin-induced biologic processes. Expression of constitutively active membrane-bound forms of Akt/PKB results in persistent translocation of GLUT-4 to the plasma membrane in muscle and fat cells [24]. Deletion of Akt1 results in growth retardation and reduced lifespan without metabolic abnormalities [25]. In contrast, Akt2-deficient mice display insulin resistance and develop diabetes as a result of the inability of insulin to stimulate glucose utilization and decrease hepatic glucose output [26]. Mechanistic studies have suggested that Akt2 is the key isoform transducing effects on GLUT-4 glucose uptake; however, Akt/PKB activity alone cannot fully explain the ability of insulin to promote GLUT-4 translocation and stimulate glucose transport [27].

Akt/PKB activation is involved in multiple other insulin responses. One of the first substrates identified for Akt/PKB was GSK3 $\beta$ . Phosphorylation of GSK3 $\beta$  decreases its activity towards glycogen synthase, which leads to increased glycogen synthesis [28]. Akt/PKB seems to stimulate glucose transport concomitant with the phosphorylation of Akt substrate of 160 kDa (AS160), a Rab-GTPase-activating protein (GAP) [29]. Under basal conditions, a functional GAP domain within AS160 is necessary to maintain the intracellular localization of GLUT-4 [30]. Following insulin stimulation, phosphorylation of AS160 shuts off its GAP activity, shifting the equilibrium of its target Rab(s) to an active GTP-bound form, and this enables GLUT-4 translocation by releasing GLUT-4 from intracellular retention mechanisms [30]. As expected, this effect is blocked by pre-exposure to the PI<sub>3</sub> kinase inhibitor wortmannin, indicative of signaling through PI<sub>3</sub> kinase. This response involving AS160 is impaired in skeletal muscle collected from insulin-resistant patients.

### Atypical protein kinase C

Protein kinase C isoforms are categorized as conventional ( $\alpha, \beta, \gamma$ ) (cPKC), novel ( $\delta, \theta, \epsilon, \eta, \mu$ ) (nPKC), and atypical ( $\zeta, \lambda$ ) (aPKC) depending on their ability to be activated by calcium and diacylg-

lycerol (DAG). cPKCs and nPKCs serve primarily as negative feedback inhibitors of the insulin receptor and IRS, and are discussed below. The aPKCs participate in signal transduction, and like Akt/PKB, are activated by the PI<sub>3</sub> kinase pathway and help mediate insulin's metabolic effects. The two aPKC isoenzymes  $\zeta$  and  $\lambda$  vary in their tissue-specific expression and among various mammals; for example, PKC $\lambda$  is the main aPKC in the skeletal muscle and adipose tissue of the mouse, whereas PKC $\zeta$  is more prominent in rats, monkeys, and humans. Activation of PKC $\zeta$  and PKC $\lambda$  occurs proximal to Akt/PKB as a result of direct interaction with 3' phosphoinositides and/or through phosphorylation and activation by PDK1. aPKCs have been shown to have a role in insulin-stimulated glucose uptake and GLUT-4 translocation in adipocytes and muscle [31]. Stimulation of glucose transport and translocation of GLUT-4 vesicles by aPKC may be brought about by effects on the actin cytoskeleton, because PKC $\lambda/\zeta$  can impinge on Rac and actin dynamics [32]. Overexpression of constitutively active forms of PKC $\zeta$  and PKC $\lambda$  increases, and expression of dominant negative forms of these aPKCs reduces, both glucose transport activity and GLUT-4 translocation in response to insulin (31). Decreased activation of aPKCs has been reported in the muscle of humans with T2DM and rodents with insulin resistance [33]. Compellingly, a mouse model with a muscle-selective PKC $\lambda$  gene deletion displays whole-body insulin resistance, impaired insulin-stimulated glucose uptake into muscle and reduced GLUT-4 translocation. The mechanism by which aPKC participates in metabolic signaling remains to be fully elucidated.

### CAP/Cbl/TC10 pathway

In parallel to the PI<sub>3</sub> kinase pathway, substantial evidence has confirmed the participation of the CAP/Cbl/TC10 pathway in glucose transport stimulation [34]. This pathway diverges at the level of the insulin receptor kinase, which mediates tyrosine phosphorylation of the Cbl proto-oncogene through a process that does not involve IRSs. This phosphorylation step requires recruitment of the adapter protein APS, which contains SH2 and PH domains, to the insulin receptor  $\beta$ -subunit and the subsequent binding of Cbl to APS [35]. APS interacts via its SH2 domain with phosphotyrosines in the activation loop of the insulin receptor. Upon binding to the receptor, APS is phosphorylated on a C-terminal tyrosine, which permits the recruitment of Cbl to APS via the SH2 domain of Cbl, and subsequent tyrosine phosphorylation of Cbl. The Cbl associated protein (CAP) is also recruited with Cbl to the insulin receptor–APS complex via tandem SH3 domains in the COOH-terminus of CAP that bind to a proline-rich domain in Cbl. CAP also contains a sorbin homology (SoHo) domain in the NH<sub>2</sub>-terminal region. After disengagement of CAP/Cbl from the insulin receptor, the CAP SoHo domain binds to flotillin in caveolin-containing lipid rafts in the plasma membrane. Lipid rafts are plasma membrane domains, enriched in cholesterol, glycolipids, and sphingolipids, that coordinate signaling events by accumulating specific protein constituents.

Once the CAP/Cbl complex is bound to flotillin, tyrosine phosphorylated Cbl presents a recognition site for recruitment of the CrkII–C3G complex to the lipid raft. CrkII binds to specific phosphorylation sites on Cbl via its SH2 domain and is constitutively associated with the nucleotide exchange factor C3G via its SH3 domain. C3G is a guanyl nucleotide exchange factor for TC10 and other small molecular weight GTP-binding proteins. TC10 is a member of the Rho family of GTPases, and can target to lipid raft domains as a result of its capacity to undergo post-translational modification by farnesylation and palmitoylation. The Rab proteins cycle between GTP- and GDP-bound states to affect vesicle budding from donor membranes and fusion with acceptor membranes. TC10 is known to regulate the actin cytoskeleton [36], and downstream effectors of TC10 have been identified which have been proposed to have a role in the translocation of GLUT-4 [37].

### Ras-p38 MAPK pathway

Another component of signal divergence emanating from IRS docking proteins is the engagement of the Ras/MAPK signaling pathway, which has a critical role in cell growth and mitogenesis. Following insulin-mediated tyrosine phosphorylation of IRS, one of the SH2 domain-containing proteins that docks with IRS is Grb-2, a small cytosolic adapter protein. Grb-2 also contains an SH3 binding domain that binds proteins containing proline-rich sequences, and one of these proteins is SOS (mammalian homolog of the *Drosophila* son-of-sevenless protein), a GDP/GTP exchange factor. This interaction positions SOS for activation of the Ras/MAPK pathway. SOS facilitates GTP activation of membrane-bound Ras, the 21 kDa small molecular weight GTPase, and the GTP-bound form of Ras complexes with and activates Raf-1 kinase. Raf-1 kinase then initiates a cascade leading to sequential phosphorylation and activation of the dual-specificity kinase MEK (MAPK/ERK kinase), which in turn phosphorylates extracellular regulated kinases (ERK1 and ERK2) on threonine and tyrosine residues in their activation loops. Activated ERKs phosphorylate multiple targets that mediate the mitogenic actions of the Ras/MAPK pathway and the growth promoting effects of insulin [38]. Insulin receptors can also mediate activation of the Ras/MAPK pathway through another substrate docking molecule, SHC. Independent of IRS, SHC can also activate the Ras/Raf-1/MEK phosphorylation cascade by forming a complex with Grb-2/SOS in response to insulin. Whether activated through IRS or SHC, ERK1/2 translocates into the nucleus and phosphorylates transcription factors, such as ELK-1, thus modulating DNA binding properties and regulation of gene transcription. ERK also phosphorylates p90 ribosomal protein S6 kinase (p90 S6 kinase), which can phosphorylate and regulate the activity of transcription factors such as *c-fos*. In addition, the MAPK cascade is one of the pathways with the potential to stimulate glycogen synthase because p90 S6 kinase is able to activate the glycogen-associated protein phosphatase-1, which in turn dephosphorylates and activates glycogen synthase [39]. In this way, the MAPK pathway has the potential to interact with metabolic signaling pathways.

However, the MAPK pathway is not necessary for stimulation of glucose transport, and is not viewed as being critically related to the metabolic effects of insulin [40].

## Inhibition of insulin signal transduction

The promulgation of insulin signaling pathways does not proceed unabated; rather, there is an extensive array of mechanisms that dampen or inhibit signal transduction. These inhibitory mechanisms can represent normal dynamic functioning of insulin action as organisms adapt to changing physiologic conditions, or, when unbalanced, can lead to pathophysiologic consequences and the development of insulin resistant states. The elucidation of inhibitory processes has provided insight into the extensive network of regulated insulin action pathways, and has also identified potential therapeutic targets because blocking these inhibitory mechanisms could enhance insulin sensitivity.

### Inhibition of the insulin receptor

As the first critical component in the insulin signaling network, there are also multiple mechanisms that can desensitize insulin action at the level of the insulin receptor. For example, it has long been known that persistent insulin stimulation can lead to loss of cell surface insulin receptors and this downregulation event impairs insulin sensitivity. In addition, multiple cellular proteins and processes can negatively regulate the intrinsic tyrosine kinase activity of the insulin receptor. Two mechanisms (serine–threonine phosphorylation and protein tyrosine phosphatases) act to impair both insulin receptors and IRS docking molecules.

### Downregulation of insulin receptor number

Chronic exposure to high insulin concentrations leads to loss of insulin receptors, resulting in a rightward shift in insulin dose–response curves (i.e. impaired insulin sensitivity). This is caused by increased ligand-mediated internalization of insulin receptors followed by lysosomal degradation, as well as diminished gene expression. Insulin stimulation results in phosphorylation of Foxo1, which disrupts its interaction with the insulin receptor promoter, decreasing insulin receptor gene transcription, thus contributing to receptor loss and insulin resistance [41].

### Plasma differentiation factor 1

Plasma differentiation factor 1 (PC-1), also referred to as ectonucleotide pyrophosphatase phosphodiesterase 1, is a membrane glycoprotein with pyrophosphatase activity that appears to act as an intrinsic inhibitor of the insulin receptor tyrosine kinase [42]. PC-1 binds to amino acids 485–599 of the insulin receptor connecting domain, a region required for the conformational change in receptor  $\beta$ -subunits that permit autophosphorylation upon insulin binding. This interaction with PC-1 interferes with the close opposition of the two  $\beta$ -subunits required for transphosphorylation. Muscle expression of PC-1 is elevated in patients with diabetes and in obesity, and it correlates with diminished

insulin receptor tyrosine phosphorylation and muscle glucose uptake. Analysis of PC-1 gene polymorphisms in a variety of individuals and family cohorts suggests that alterations in this gene are associated with the risk for development of childhood and adult obesity as well as T2DM [43].

### Grb proteins

The growth factor receptor-bound proteins (Grb proteins) constitute a family of structurally related multi-domain adapters with diverse cellular functions but lacking intrinsic enzymatic activity. Grb10 and Grb14 can bind to phosphotyrosine residues on the insulin receptor and alter receptor tyrosine kinase activity [44]. Overexpression of Grb10 and Grb14 in cells inhibits insulin-stimulated phosphorylation of IRS1, IRS2 and Shc [45]. However, the physiologic role of Grb proteins is not fully clear, and their actions may be tissue specific with capabilities as an inhibitory factor or a positive mediator in the insulin signaling pathway.

### Inhibition of insulin receptor substrate proteins

#### Protein phosphotyrosine phosphatases

Endogenous protein phosphotyrosine phosphatases (PTPases) are able to dephosphorylate tyrosine residues on the insulin receptor  $\beta$ -subunit and insulin receptor substrate docking molecules, resulting in a dampening of insulin signal transduction. Two PTPases in particular, PTP-1B and leukocyte common antigen-related phosphatase (LAR), contribute to insulin receptor dephosphorylation in insulin target cells [46]. Membrane-associated PTPase activity is increased in skeletal muscle from patients with T2DM [47], principally because of increments in cytosolic PTPase-1B and membrane-associated LAR [48]. The ability of PTPases to modulate insulin signaling has been demonstrated in mice with genetic ablation of PTPase-1B, which exhibit enhanced insulin sensitivity, increased insulin-mediated tyrosine phosphorylation of the receptor and of IRS1, and a failure to develop insulin resistance when fed a high fat diet [46]. Muscle-specific overexpression of PTP-1B in mice induces tissue insulin resistance with decreased capacity for insulin receptor autophosphorylation [49]. Thus, available data consistently demonstrate that PTPase-1B is able to modulate insulin signaling negatively through dephosphorylation of tyrosine residues in the insulin receptor and IRSs. The role of the LAR in insulin receptor function remains less well defined.

#### Serine–threonine phosphorylation

Serine–threonine phosphorylation of insulin receptors and IRS docking proteins is a major mechanism for negative modulation of insulin signal transduction. Serine phosphorylation diminishes insulin receptor tyrosine kinase activity and decreases receptor–IRS coupling by inhibiting insulin-mediated tyrosine phosphorylation of IRS-1, binding and activation of  $PI_3$  kinase, and stimulation of glucose transport. There are consensus sequences in IRS-1 that make it susceptible to a wide variety of serine–threonine kinases including PKC, PKA, Akt/PKB, MAPK, S6 kinase, GSK3, casein kinase II, Cdc2 kinase, JNK and I $\kappa$ B kinase

(IKK $\beta$ ). Several of these kinases have been shown to function as physiologic modulators causing desensitization of insulin signaling pathways under conditions of nutrient excess, inflammation and cell stress responses. For example, JNK and IKK $\beta$  are activated by inflammatory stimuli (e.g. TNF $\alpha$ ) contributing to insulin resistance, and PKC is activated by DAG which accumulates with increased availability of free fatty acids.

#### Protein kinase C

PKCs are serine–threonine kinases with multiple substrates, including IRS docking proteins and the insulin receptor [50]. Serine–threonine phosphorylation of IRS impairs its ability to associate with the insulin receptor and with  $PI_3$  kinase, resulting in desensitization of the  $PI_3$  kinase pathway. Hyperinsulinemia, hyperglycemia and elevated circulating free fatty acids (e.g. nutrient excess) leads to increased intracellular DAG, which in turn activates conventional and novel PKC isoforms principally via recruitment to the plasma membrane. These conditions are associated with increased serine–threonine phosphorylation and diminished function of insulin receptors and IRS proteins. In addition, insulin activates atypical PKCs, such as PKC $\zeta$ , via the  $PI_3$  kinase pathway, which is also capable of phosphorylating and desensitizing IRS [51].

#### Tumor necrosis factor $\alpha$

Tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) is a cytokine produced by immune cells and also by adipocytes and muscle tissue. While having little impact on systemic circulating concentrations, TNF- $\alpha$  expression is increased in adipose and muscle tissues as a function of insulin resistance [52]. In adipose tissue, TNF- $\alpha$  and other proinflammatory cytokines are produced by adipocytes and also by macrophages that infiltrate adipose tissue under conditions of obesity and insulin resistance. This raises the possibility that the cytokine could be inducing cellular insulin resistance via autocrine and/or paracrine effects. TNF- $\alpha$  induces serine phosphorylation of IRS1, thereby decreasing its ability to be phosphorylated by the insulin receptor tyrosine kinase and impairing downstream insulin signal transduction [53]. Several pathways activated by TNF- $\alpha$  are implicated in increased serine phosphorylation of IRS-1, including the stress-induced kinases, JNK and IKK $\beta$ .

#### JNK

Three JNK-encoding genes have been described in mammals; JNK1 and JNK2 are expressed ubiquitously, whereas JNK3 expression is restricted to neuronal tissues. The JNK isoforms belong to the extended family of MAPKs, and control many cellular functions through regulation of activator protein 1 (AP-1). In addition to TNF- $\alpha$  signaling, insulin also activates JNK1 and JNK2 [54], which then display increased serine kinase activity against multiple intracellular substrates including IRS1, IRS2 and Shc. The ability of insulin to activate JNK represents a negative feedback mechanism by which insulin inhibits its own signaling.

JNK activity is also augmented during cellular stress responses, such as endoplasmic reticulum stress, and is increased in insulin-resistant states. Illustrative data include the observation that high-fat diets increase Ser<sup>307</sup> phosphorylation of IRS1 in wild-type mice but not in JNK1<sup>-/-</sup> mice, while the JNK1<sup>-/-</sup> mice are characterized by decreased adiposity, increased insulin receptor signaling and improved insulin sensitivity [55]. Thus, JNK has been implicated in the pathogenesis of insulin resistance in the metabolic syndrome and T2DM.

#### **NF- $\kappa$ B**

Activation of NF- $\kappa$ B-mediated pathways has been shown to inhibit insulin signaling through enhanced serine phosphorylation of IRS1 [56]. NF- $\kappa$ B is a transcription factor that functions as a proinflammatory “master switch” during inflammation, upregulating the transcription of a wide range of inflammatory mediators. NF- $\kappa$ B is normally retained in the cytoplasm by binding to members of the inhibitor of  $\kappa$ B (I $\kappa$ B) protein family. During inflammatory or metabolic stress, NF- $\kappa$ B is activated by the I $\kappa$ B kinase (IKK) complex, which consists of two catalytic subunits, IKK $\alpha$  and IKK $\beta$ , and a regulatory subunit, IKK $\gamma$ . The IKK $\beta$  subunit phosphorylates I $\kappa$ B, resulting in its ubiquitination and subsequent proteasomal degradation and in the release of NF- $\kappa$ B. The free NF- $\kappa$ B is then able to translocate into the nucleus and activate the transcription of at least 125 genes, most of which are proinflammatory [57]. There exists a substantial body of data implicating NF- $\kappa$ B in the pathogenesis of insulin resistance. Activation of NF- $\kappa$ B accompanies insulin resistance following high fat feeding and obesity, and in the metabolic syndrome. Proinflammatory cytokines such as TNF- $\alpha$  and interleukin 6 (IL-6) can also activate NF- $\kappa$ B. Circulating mononuclear cells in the obese display increased transcription of proinflammatory genes regulated by NF- $\kappa$ B with a decrease in I $\kappa$ B. Weight loss, caloric restriction and exercise training can lead to a reduction in transcription of the proinflammatory genes regulated by NF- $\kappa$ B [58]. Drugs with anti-inflammatory properties, such as thiazolidinediones, statins and salicylates, can inhibit proinflammatory cytokine secretion by interfering with the NF- $\kappa$ B pathway.

#### **I $\kappa$ B kinase- $\beta$**

IKK $\beta$  is a serine kinase that has the ability to desensitize insulin signaling through serine phosphorylation of IRS or the insulin receptor. The desensitizing effect of TNF- $\alpha$ , as a consequence of IRS serine phosphorylation, may in part be mediated through IKK $\beta$ . Consistent with this hypothesis, heterozygous ablation of the IKK $\beta$  gene in mice fed a high-fat diet, or in obese leptin-deficient *ob/ob* mice, prevents insulin resistance [59,60]. Mice that selectively express constitutively active IKK $\beta$  in hepatocytes (LIKK mice) exhibit a T2DM phenotype, characterized by hyperglycemia, profound hepatic insulin resistance, and moderate systemic insulin resistance including effects in muscle [56]. The hepatic production of proinflammatory cytokines, including IL-6, IL-1 $\beta$  and TNF- $\alpha$ , is increased in LIKK mice to a similar

extent as induced by high-fat feeding in wild-type mice. However, no difference in obesity-induced insulin resistance is detectable in muscle-specific IKK $\beta$  knockout mice compared with wild type [61], which suggests that IKK $\beta$  may be more directly involved in the development of hepatic insulin resistance rather than in skeletal muscle.

An important biologic effect of salicylates is the inhibition of the IKK $\beta$  [62]. Predictably, salicylates would then enhance insulin sensitivity by causing a subsequent decrease in IKK $\beta$ -mediated serine phosphorylation of IRS. In fact, treatment with high doses of salicylates improves glucose tolerance and enhances insulin sensitivity in humans and rodents [59].

#### **Accelerated catabolism of PI(3,4,5)P<sub>3</sub> by phosphoinositide phosphatases**

Increased production of PI(3,4,5)P<sub>3</sub> as a result of activated PI<sub>3</sub> kinase is key to metabolic insulin signaling, and the downstream activation of PDK1. PTEN can dephosphorylate PI(3,4,5)P<sub>3</sub> on the 3 position, and SH2-containing inositol phosphatases (SHIPs) can dephosphorylate PI(3,4,5)P<sub>3</sub> on the 5 position of the inositol ring; in either instance, the ability of PI(3,4,5)P<sub>3</sub> to stimulate PDK1 is lost. Therefore, PTEN and SHIP can exert negative regulatory influences on insulin signaling, particularly with respect to its metabolic actions [63]. While multiple studies support the view that PTEN can participate as a negative regulator of insulin action in pathophysiologic states, its role in human insulin resistance is yet to be defined.

#### **Inhibition of insulin signaling by protein–protein interactions**

##### ***Suppressor of cytokine signaling 3***

The SOCS family of proteins (CIS and SOCS 1–7) was originally described as a negative feedback loop for cytokine receptors involving Janus kinase (JaK). Following ligand activation of cytokine and growth factor receptors, JaK phosphorylates and activates signal transducer and activator of transcription (STAT), and these phosphorylated STAT family members then form homodimers or heterodimers that translocate to the cell nucleus where they act as transcription activators. In the nucleus, STAT augments SOCS gene expression. SOCS proteins then feedback to inhibit tyrosine-phosphorylated cytokine receptors, via either competitive binding through their SH2 domain preventing phosphorylation of cytokine receptor substrates, or by binding and inhibiting the action of JaK tyrosine kinases. Evidence suggests that a similar mechanism may be operative for the insulin receptor [46]. Studies have indicated that SOCS-1, SOCS-3 and SOCS-6 can bind to the COOH-terminus of the insulin receptor  $\beta$ -subunit, and block interaction between the insulin receptor and IRS [64]. Interestingly, several factors that induce cellular insulin resistance also induce SOCS-3 expression, including TNF- $\alpha$ , growth hormone, and leptin.

##### ***Tribbles***

The Tribbles (TRB) gene family in mammals is comprised of three proteins that have a truncated kinase domain lacking an

ATP binding site. Accordingly, TRBs are “pseudokinases” that lack detectable kinase activity, but can bind to kinase substrates in phosphorylation cascades and inhibit their phosphorylation. TRB proteins, for example, can bind to Akt/PKB and inhibit its phosphorylation and activation in response to insulin [65], while downregulation of TRB3 improves insulin sensitivity [66].

---

## Tissue-specific insulin action: the role of insulin effector systems

Insulin regulates whole-body fuel homeostasis via specific effects in multiple target tissues. The nature of these biologic actions varies dramatically from tissue to tissue, and these variations, for the most part, are not brought about by differences in insulin signal transmission (described above). Rather, tissue-specific insulin effects are principally explained by effector systems that are uniquely expressed in a variety of differentiated target cells. The biochemical basis of these effects is described in skeletal muscle, adipose tissue, and liver, three organs primarily responsible for fuel storage and oxidation as well as counter-regulatory metabolism.

### Skeletal muscle

#### Insulin stimulation of glucose transport

Skeletal muscle accounts for the bulk of insulin-stimulated glucose uptake *in vivo*, and the hallmark of insulin action in this tissue is the ability to stimulate the glucose transport effector system (Figure 7.2). Glucose transport across the plasma membrane is facilitated by glucose transport proteins (GLUT); to date, 13 members of the GLUT/SLC2 family have been identified. All GLUT proteins are intimately embedded in membranes, and the most highly conserved regions are the putative membrane-spanning domains that serve a common function, the creation of a pore for facilitative diffusion of monosaccharides. Each glucose transporter isoform has a specific role in glucose metabolism determined by its pattern of tissue expression, substrate specificity and affinity, transport kinetics, and regulated expression in different physiologic conditions.

The major transporter isoforms that mediate glucose transport in cells with an insulin-responsive glucose transport system are GLUT-1 and GLUT-4. In unstimulated cells, GLUT-1 predominates at the cell surface and facilitates glucose diffusion across the plasma membrane into the cytosol where glucose is rapidly phosphorylated by hexokinase and metabolized. GLUT-4 contributes minimally to glucose transport in unstimulated target cells, because >90% of the cell content of GLUT-4 resides in intracellular membranes in the basal state. The mechanism by which insulin augments glucose transport activity is by recruiting intracellular GLUT-4 to the plasma membrane, a rate-limiting step for insulin-stimulated glucose uptake and metabolism in peripheral target tissues. Upon dissipation of the insulin signal, deactivation of glucose transport activity is the result of a net reverse translocation of GLUT-4 transporters back into the cell interior. Thus,

GLUT-4 is the major transporter mediating insulin-stimulated glucose transport activity in tissues such as skeletal and cardiac muscle and adipose tissue.

In unstimulated muscle or adipose cells, a component of GLUT-4 resides in an inducible tubulo-vesicular storage compartment that includes the trans-Golgi network and endosomal vesicles located near the endofacial surface of the plasma membrane. However, another component of cellular GLUT-4 exists in an active endocytosis–endosomal recycling pathway that cycles GLUT-4 between endosomes and the plasma membrane. The recycling pathway results in the localization of approximately 4–10% of GLUT-4 in the basal plasma membrane, and this steady-state distribution is the balance of rapid endocytosis and slow recycling. Insulin shifts the distribution of GLUT-4 from intracellular pools towards the plasma membrane, both by elevating the exocytotic rate of GLUT-4 in the recycling pathway and by recruiting GLUT-4 from the inducible storage compartment to the cell surface. Deactivation of transport is accomplished via a slowing of the exocytotic rate and an acceleration of the endocytotic rate, as GLUT-4 is retrieved from the plasma membrane through clathrin-dependent and -independent mechanisms [67,68].

GLUT-4 vesicle trafficking involves the actin and microtubule cytoskeletons. Regarding actin, insulin stimulates cytoskeletal rearrangement with the appearance of cortical  $\beta$ -actin fiber projections that subtend the plasma membrane, and this actin remodeling is under the control of small G-proteins in the Rho, Rab and Rac families. Microtubules surround the inducible intracellular depot of GLUT-4 and microtubule proteins such as dynein and kinesin have been co-purified with GLUT-4. Inhibition of actin remodeling or disruption of microtubules using depolymerizing agents inhibits GLUT-4 translocation and glucose transport stimulation. Data suggest that exocytotic movement of GLUT-4 begins with its transfer to actin scaffolds that connect the microtubule cytoskeleton with the plasma membrane, which positions GLUT-4 vesicles for docking and membrane fusion.

The complete pathway linking insulin signal transduction to stimulation of the glucose transport system has not been fully elucidated. Activation of transport is critically dependent on insulin-mediated autophosphorylation of insulin receptors, tyrosine phosphorylation of IRS1 and activation of  $PI_3$  kinase. The production of  $PI(3,4,5)P_3$  by  $PI_3$  kinase activates PDK1. At this point, PDK1 activates two separate kinase pathways that contribute to GLUT-4 translocation and stimulation of glucose transport activity, Akt2 and atypical PKCs (PKC $\zeta$  and PKC $\lambda$ ). Akt2 then phosphorylates and inhibits AS160 (TBC1D4) and TBC1D1 [69], which are Rab-GTPase-activating proteins. The modulation of AS160 activates Rab small GTPases that in turn regulate aspects of GLUT-4 vesicle docking and cytoskeletal organization [70]. At the same time, the ligand-bound insulin receptor activates the CAP/Cbl/TC10 pathway upstream of IRS1 phosphorylation, and activates TC10, a Rho family member that regulates the actin cytoskeleton. Importantly, the factors

**Figure 7.2** An overview of insulin signaling pathways in skeletal muscle. Arrows represent an activation process.

that link TC10, AS160, atypical PKCs, and other relevant factors with the glucose transport effector system, and which impel the complex changes in GLUT-4 vesicle trafficking associated with transporter translocation, are unknown.

### Muscle contraction: stimulation of glucose transport independent of insulin signaling

Muscle contraction results in GLUT-4 translocation and stimulates muscle glucose transport activity [71]. This effect occurs without any change in serum insulin concentration and does not involve activation of insulin receptors, PI<sub>3</sub> kinase or Akt/PKB. The mobilization of GLUT-4 to the cell surface by acute exercise involves a different intracellular pool of GLUT-4 than that recruited by insulin, and the effects of acute exercise and insulin are partially additive. These observations indicate that signaling

systems mediating glucose transport stimulation are different in response to acute exercise versus insulin [72]. This is underscored by the finding that, in muscle from insulin resistant humans and rodents, GLUT-4 translocation is impaired in response to insulin but normal in response to acute exercise.

While signal transduction mechanisms are not fully understood, this response appears to be at least partially dependent on increments in intracellular 5'AMP, and subsequent activation of adenosine 5' monophosphate-activated protein kinase (AMPK) [73]. AMPK is a serine–threonine kinase that responds to fluctuations in cellular energy levels and functions to maintain energy homeostasis. When ATP levels are low and 5'AMP is elevated, AMPK activates pathways for ATP regeneration and limits further ATP utilization by modifying activity of multiple metabolic enzymes, including acetyl-CoA carboxylase (ACC), hydroxymeth-

ylglutaryl-CoA reductase, creatine kinase, and hormone sensitive lipase. Exercise, ischemia, and hypoxia will activate AMPK via increments in AMP:ATP and creatine:phosphocreatine ratios. AMPK can also be activated, however, through allosteric modification and  $\alpha$ -subunit phosphorylation by one or more upstream kinases, including LKB1.

### Adipose tissue

Adipose tissue is the predominant site for fuel storage as triglyceride, and effector systems responsible for the anabolic effects of insulin on lipogenesis and antilipolysis are key aspects of adipocyte biology (Figure 7.3).

### Lipogenesis

Fat accumulation in adipocytes is determined by the balance between triglyceride synthesis (fatty acid uptake and lipogenesis) and breakdown (lipolysis/fatty acid oxidation). Insulin is a critical stimulator of lipogenesis. Insulin augments availability of both

glycerol and fatty acids for triglyceride synthesis by increasing the uptake of glucose in the adipose cell as well as by activating lipogenic and glycolytic enzymes. These enzymes constitute the effector system for the biologic effects of insulin on lipogenesis, and are modulated by insulin both through post-translational modifications and alteration of gene expression. Regarding post-translational effects, insulin activates Akt/PKB via phosphorylation, and its role in lipogenesis as illustrated by the observation that constitutively active Akt results in high levels of lipogenesis in 3T3-L1 adipocytes. Substrates for activated Akt/PKB include the phosphorylation and inhibition of GSK3, and this in turn abrogates GSK3 inhibition of ATP citrate lyase; the resulting increase in ATP citrate lyase activity enhances conversion of citrate to acetyl-CoA in the cytosol. Acetyl-CoA is then available as the “building block” for fatty acid synthesis.

Insulin also induces gene expression of two key lipogenic proteins: fatty acid synthase (FAS) and SREBP-1. FAS is the central enzyme participating in *de novo* lipogenesis and catalyzes the

**Figure 7.3** Summary of insulin function involved in lipogenesis and lipolysis in adipose tissue. Arrows represent an activation process; blocked arrows represent an inhibition process.

conversion of malonyl-CoA and acetyl-CoA to long-chain fatty acids. Regulation of FAS activity by insulin occurs mainly at the level of gene transcription. SREBP-1 belongs to the class C bHLH (helix-loop-helix) transcription factor family based on its ability to bind to the sterol regulatory element (SRE) of the low-density lipoprotein receptor gene promoter. It activates a battery of genes involved in the uptake and synthesis of fatty acids and triacylglycerides. SREBP-1c is under transcriptional control by insulin [74], and overexpression of SREBP-1c mimics the effect of insulin on the expression of FAS. SREBP-1 also regulates FAS expression as evidenced by the failure of FAS and other lipogenic enzyme genes to be induced by fasting/refeeding in SREBP-1c<sup>-/-</sup> mice [75].

### Lipolysis and antilipolysis

Lipolysis in adipose tissue is tightly regulated to assure that partitioning of metabolic fuels, glucose and free fatty acids (FFA), is adapted to energy needs. During fasting, lipolysis is enhanced to make available FFAs that are the main oxidative fuel for the liver, the heart and skeletal muscle, and are metabolized by the liver to ketones that replace glucose as the principal fuel for nervous tissue. Upon feeding, lipolysis is abated and adipocytes convert to triglyceride storage. The rise (after a meal) and fall (with fasting) of insulin has a central role in this regulatory process as a result of its antilipolytic action in adipocytes. Lipolysis in normal subjects is exquisitely sensitive to inhibition by insulin, such that half-maximal suppression of lipolysis occurs at insulin concentrations well below those needed for significant stimulation of glucose uptake by skeletal muscle. Higher concentrations of insulin can reduce adipocyte release of FFA to nearly zero, although at high insulin concentrations there will still be some appearance of glycerol and FFA from the stimulatory effect of insulin on lipoprotein lipase which acts on triglycerides in circulating lipoproteins.

Hormones regulate lipolysis in adipocytes via coordinated action involving two major effector systems: hormone sensitive lipase (HSL) and perilipins localized to the surface of lipid droplets. Lipolytic and antilipolytic (i.e. insulin) hormones exert opposite effects on HSL and perilipins by determining cAMP availability and protein kinase A (PKA) activity. By way of illustration, catecholamines induce lipolysis and release FFAs from adipocytes by binding to  $\beta$ -adrenergic receptors coupled by heterotrimeric G-proteins to adenylate cyclase, which increases production of cAMP and activates PKA. The two main targets for PKA phosphorylation are HSL and the perilipins [76]. The ability of insulin to antagonize hormone-induced lipolysis is to a large extent accounted for by its ability to lower cAMP levels and thereby reduce PKA activity. The decrease in cAMP is mainly the result of an insulin-mediated phosphorylation and activation of phosphodiesterase 3B (PDE3B) via Akt/PKB. HSL is a key enzyme for the mobilization of triglycerides deposited in adipose tissue following its activation by cAMP/PKA-dependant phosphorylation [77]. HSL is an enzyme with three isoforms ranging from 84 to 130kDa, yet all isoforms have three domains, a catalytic

domain, a regulatory domain with several serine phosphorylation sites required for activation, and an N-terminal variable domain involved in protein-protein and protein-lipid interactions [78]. HSL in muscle can also be stimulated by adrenaline via  $\beta$ -adrenergic activation of PKA, or by muscle contraction via phosphorylation by PKC at least partly activated through the ERK pathway.

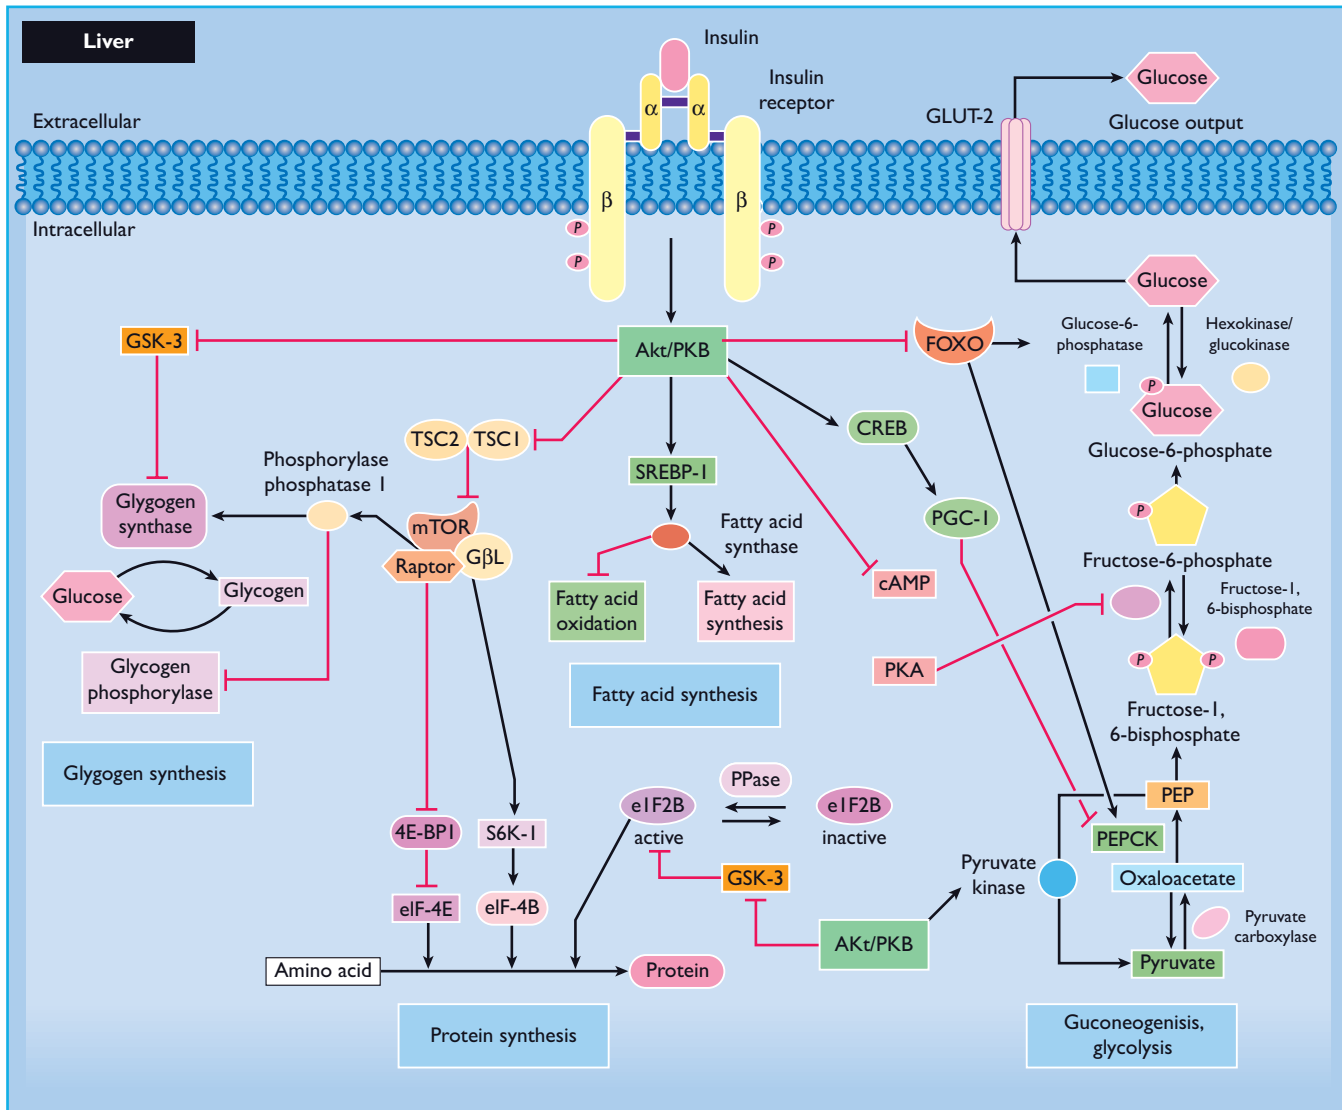

Perilipins are localized at the surface of the lipid droplet in adipocytes [79], and are essential in the regulation of triglyceride deposition and mobilization. In the absence of lipolytic stimulation, perilipin inhibits lipolysis by acting as a barrier against hydrolysis of the triacylglycerol by lipases. When PKA is activated, perilipin becomes phosphorylated and translocates away from the lipid droplet, which allows HSL to hydrolyze the lipid droplet triglyceride core [80]. Insulin blocks lipolysis by inhibiting PKA-mediated phosphorylation of HSL and perilipin, thus reducing both HSL activity and its access to triglycerides in the lipid droplet. In adipocytes there are two forms of perilipin, perilipin A and perilipin B, with perilipin A present at a higher concentration. Adipocyte perilipin content has an inverse correlation with lipolytic rates and a positive correlation with plasma glycerol in humans, and is reduced in obese women. Perilipin knockout mice are lean with increased basal lipolysis and are resistant to diet-induced obesity; however, these mice develop glucose intolerance and insulin resistance more readily, probably because of elevated levels of serum FFAs [81]. In addition, perilipin has a peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) responsive element in its promoter region and is induced by thiazolidinedione agonists of PPAR $\gamma$  [82].

### Liver

Insulin regulates hepatic metabolism through acute post-translational modifications of enzymes, such as phosphorylation, and through changes in gene expression. The stimulation of glycogen formation and regulation of gluconeogenesis by insulin are the critical determinants of hepatic glucose output. In addition, because regulation of gene transcription is critical for the biologic effects of insulin on hepatic metabolism, mechanisms pertinent to transcriptional regulation are discussed (Figure 7.4).

### Glycogenesis/glycogenolysis

Insulin exerts dramatic effects on pathways of intracellular glucose metabolism. Under conditions of insulin stimulation, the major portion of glucose uptake is stored as glycogen in humans. Insulin promotes glycogen synthesis in muscle, adipocytes, and liver by activating glycogen synthase, which adds activated glucosyl groups to growing polysaccharide chains and thus catalyzes the final step in glycogen synthesis. The regulation of glycogen synthase is complex. It involves allosteric activators, translocation of glycogen synthase to the plasma membrane in the presence of glucose metabolites and insulin [83], inhibition by phosphorylation on serine residues by different kinases, and activation by dephosphorylation by serine-threonine phosphatases such as

**Figure 7.4** Summary of insulin signaling pathways in the liver that are involved in glycogen synthesis, gluconeogenesis and glycolysis, and protein synthesis, respectively. Arrows represent an activation process; blocked arrows represent an inhibition process.

protein phosphatase 1 (PP1). The ability of insulin to stimulate glycogen synthase requires proximal signaling through activation of PI<sub>3</sub> kinase and Akt/PKB. One downstream pathway that activates glycogen synthase involves Akt/PKB-mediated phosphorylation and inactivation of GSK3, which results in a reduction in net phosphorylation of glycogen synthase. The reduction in glycogen synthase phosphorylation augments its activity. GSK3β inhibition is not insulin’s only mechanism for stimulating glycogen accumulation. In 3T3-L1 adipocytes, insulin is capable of stimulating glycogen synthase even under experimental conditions when GSK3β is either not detectable or present in very low amounts. Moreover, lithium, a GSK3β inhibitor, is additive with insulin in activating glycogen synthase and glycogen synthase activity [84]. These studies indicate the existence of additional pathways for glycogen synthase activation.

**Inhibition of gluconeogenesis and hepatic glucose output**

Hepatic glucose production is stimulated under fasting conditions by the counter-regulatory hormones glucagon, catecholamines, and glucocorticoids, which augment glucose output by promoting glycogenolysis and gluconeogenesis. During feeding and in response to exogenous insulin injections, hepatic glucose output is potently suppressed by insulin as a result of inhibition of glycogenolysis and gluconeogenesis. Gluconeogenesis is predominantly regulated through changes in gene expression for two key enzymes: phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G-6-Pase). PEPCK catalyzes one of the rate-limiting steps of gluconeogenesis, whereas G-6-Pase catalyzes the final step producing free glucose for transport out of liver via GLUT-2 glucose transporters. Gene transcription of PEPCK is tightly regulated by cAMP; counter-regulatory hor-

mones increase cAMP and induce PEPCK, whereas both are suppressed by insulin. In addition to direct hormonal effects on hepatocytes, hepatic glucose output is modulated by the delivery of gluconeogenic substrates to the liver such as lactate, amino acids, and FFA. For example, a reduction in FFA availability contributes to suppression of hepatic glucose output by insulin through its antilipolytic action in adipocytes, and insulin minimizes counter-regulatory effects of glucagon by inhibiting its secretion from the pancreatic  $\alpha$  cell. Increased hepatic glucose production is an important determinant of fasting hyperglycemia in diabetes, and has been given greater focus because of the potential importance of regulatory pathways controlling hepatic glucose output as targets of drug therapy.

#### **General considerations pertaining to gene regulation by insulin**

Suppression of hepatic glucose output by insulin relies heavily on induced changes in gene transcription. The ability of insulin to regulate gluconeogenesis via effects on gene transcription was first reported in 1963, with the observation that PEPCK expression is under negative regulation by insulin [85]. Over the ensuing five decades, it has become clear that insulin influences the expression of more than 800 genes in both positive and negative manners. Regulation of gene transcription can be brought about by effects on transcription factors that are directly modified via insulin signaling mechanisms, or that are indirect as the result of effects of substrate metabolism. The promoter elements (*cis*-acting sequences) that mediate changes in gene transcription are referred to as insulin response elements (IRE), of which multiple distinct consensus sequences have been defined. These include the serum response element, the activator protein 1 (AP-1) motif, the Ets motif, the E-box motif, and the thyroid transcription factor 2 (TTF-2) motif. All of these IREs mediate stimulatory effects of insulin on gene transcription. In contrast, an element with the consensus sequence T(G/A)TTT(T/G)(G/T), which can be referred to as the PEPCK-like motif, mediates the inhibitory effect of insulin on transcription of genes such as PEPCK, insulin-like growth factor binding protein 1 (IGFBP-1), tyrosine aminotransferase, and the G-6-Pase catalytic subunit. In addition, multiple insulin-responsive genes harbor an IRE containing GC-rich region, which binds the ubiquitous transcription factor Sp1, and this IRE is similarly considered to be an important mediator of insulin action [86].

Together with the *cis*-acting promoter sequences, it is also important to consider the identity of the transcription factors (*trans*-acting factors) activated by insulin that bind to the IREs and alter gene transcription rates. Inhibition of gluconeogenesis by insulin follows receptor-mediated tyrosine phosphorylation of IRS2, the IRS isoform that predominates in transducing the insulin signal in liver. Subsequent activation of PI<sub>3</sub> kinase and Akt/PKB are also required, and activation of Akt2 is critical because Akt2 knockout mice [26], but not Akt1 null mice [25], display hepatic insulin resistance, increased hepatic glucose output, and hyperglycemia. Activated Akt2 then phosphorylates

and inhibits GSK-3, resulting in hepatic glycogen synthesis, and also suppresses PEPCK and G-6-Pase gene expression through a complex process involving multiple transcription factors including Foxo, SREBP-1c, liver X-activated receptor (LXR), Sp1, and others. The interplay of *cis*- and *trans*-acting factors in the regulation of hepatic metabolism is complex and remains to be fully elucidated.

#### **Foxo transcription factors**

The Foxo family in mammals is composed of three expressed genes: Foxo1, Foxo3 and Foxo4, although Foxo1 is the most highly expressed isoform in insulin-responsive tissues such as liver, adipose tissue, and pancreatic  $\beta$ -cells. Foxo proteins, contain a winged-helix motif, comprising the DNA binding domain. Under basal conditions, Foxo proteins reside within the nucleus and actively regulate gene transcription. Upon stimulation by insulin, Akt/PKB phosphorylates Foxo family members at three different conserved serine and threonine residues (Thr<sup>24</sup>, Ser<sup>253</sup> and Ser<sup>319</sup> in Foxo1), which is followed by the dissociation of Foxo proteins from their DNA binding sites and exclusion from the nucleus [87]. Nuclear exclusion appears to involve the binding of protein 14-3-3 to the phosphorylated Akt/PKB sites of Foxo, thus masking the nuclear localization signal [88]. The relocation of Foxo out of the nucleus represents an effective mechanism by which insulin can suppress transcriptional activity. The dependence on Akt/PKB phosphorylation for this effect is highlighted by the observation that replacement of Thr<sup>24</sup> or Ser<sup>253</sup> by alanine results in loss of phosphorylation, lack of Foxo1 nuclear export, and failure of insulin-mediated promoter suppression [89].

The G-6-Pase and PEPCK promoters contain IREs which mediate transcriptional activation by Foxo1 and Foxo3 in the liver. Phosphorylation of Foxo by Akt/PKB impairs Foxo binding to this *cis* element, results in nuclear exclusion of Foxo, and suppression of G-6-Pase and PEPCK gene expression. Foxo is not involved in the regulation of all genes suppressed by insulin, however, and cannot account fully for suppression of G-6-Pase and PEPCK. Under physiologic conditions, there is strong evidence that SREBP-1, LXR, and peroxisome proliferator-activated receptor gamma coactivator 1 (PGC-1) all contribute to regulation of gluconeogenic genes by insulin [90].

The importance of Foxo transcription factors in cell differentiation related to whole body metabolic homeostasis is being increasingly recognized. Foxo1 is involved in pancreatic  $\beta$ -cell proliferation and regulation of pancreatic-duodenal homeobox 1 (Pdx1) expression by insulin [91]. Foxo1 appears to contribute to the complex coordination of transcriptional events involved in adipocyte differentiation. Constitutively active Foxo1 prevents the differentiation of pre-adipocytes, while dominant-negative Foxo1 restores adipocyte differentiation of fibroblasts from insulin receptor deficient mice [92]. The binding of Foxo to its co-activator, PGC-1 $\alpha$ , is disrupted by the phosphorylation of Foxo, and the disruption of this complex can in itself suppress effects on gene transcription [93].

### ***Sterol response element binding protein 1c***

The SREBP family of transcription factors is classically viewed as being involved in the regulation of genes in response to cholesterol availability; however, SREBP-1c is regulated primarily by insulin [92]. This protein is also involved in adipocyte differentiation which explains its alternative designation as adipocyte determination and differentiation factor 1 (ADD1). SREBP-1c/ADD1 is most highly expressed in liver, white adipose tissue, muscle, adrenal gland, and brain.

Insulin stimulates the transcription, post-translational processing, and nuclear translocation of SREBP-1c in cell lines and in adipose, liver, and muscle tissues. In the nucleus, SREBP-1c contributes to a positive autoregulation loop where SREBP-1c augments its own transcription in response to insulin involving a coordinated interaction of multiple transcription factors including LXR $\alpha$ , Sp1, and SREBP-1c itself [94]. This insulin effect is mediated through PI<sub>3</sub> kinase and Akt/PKB, although downstream targets and transcription factors mediating induction of SREBP-1c gene transcription have not been fully clarified. In addition, insulin signal transduction via the Ras/MAPK pathway plays a contributory part by increasing SREBP-1c expression independent of changes in its mRNA levels [94].

While multiple mechanisms may contribute to stimulation of SREBP-1 activity, once in the nucleus, SREBP-1c has an important role in the regulation of specific genes in response to insulin. Insulin suppresses gluconeogenesis and PEPCK expression in part through SREBP-1c. In experiments involving overexpression of wild-type, constitutively active and dominant interfering mutants, SREBP-1c has also been shown to be involved in the induction of FAS and leptin in adipose cells, and glucokinase, pyruvate kinase, FAS, and acetyl CoA carboxylase in the liver [95]. While these insulin-regulated genes contain SREs in their promoter regions, multiple additional hormones, metabolic substrates and transcription factors participate in their transcriptional regulation. Thus, SREBP-1c mediates a positive transcriptional effect on genes promoting glycolysis and lipogenesis, while suppressing genes involved in gluconeogenesis, and seems to prepare the liver for carbohydrate availability following a meal. In fact, excessive and persistent SREBP-1c action has been implicated in intrahepatocellular lipid accumulation and hepatic steatosis.

### ***Liver X receptors***

Liver X receptors (LXRs) are ligand-activated nuclear receptors that regulate genes involved in lipid and carbohydrate metabolism. The endogenous agonists are oxidized cholesterol derivatives referred to as oxysterols, and, when activated, LXR receptors stimulate reverse cholesterol transport and excretion of cholesterol as bile acids to protect hepatocytes from cholesterol excess. LXR activators are also known to stimulate lipogenesis through the concerted action of activated LXR and SREBP-1c resulting in intrahepatocellular triglyceride synthesis and storage. Despite this lipogenic effect, LXR agonism or hyperexpression also increases hepatic insulin sensitivity and lowers glycemia in diabetic animals [96], largely through suppression of genes encoding

the key gluconeogenic enzymes PEPCK and G-6-Pase [96]. Insulin augments expression of LXR $\alpha$  primarily through stabilization of LXR $\alpha$  transcripts, consistent with the conclusion that LXR $\alpha$  contributes in part to the reductions in gluconeogenesis and hepatic glucose output in response to insulin [96]. In addition to its modulatory effects in liver metabolism, activation of pancreatic  $\beta$ -cell LXR $\beta$  with a synthetic agonist increased glucose-induced insulin secretion and insulin content, whereas deletion of the nuclear receptor in LXR $\beta$  knockout mice severely blunted insulin secretion [97]. Downregulation of SREBP-1 expression with specific small interfering RNA blocked LXR $\beta$ -induced expression of pancreatic duodenal homeobox 1, insulin, and GLUT-2 genes. Thus, activation of LXR $\beta$  in pancreatic  $\beta$ -cells increases insulin secretion and insulin mRNA expression via a SREBP-1-regulated pathway. These data support the role of LXR and SREBP-1 pathways in both the regulation of gluconeogenesis in liver and insulin secretion in pancreatic  $\beta$ -cells.

### ***PGC-1***

PEPCK and G-6-Pase gene expression is regulated not only by transcription factors, but also by co-activator proteins, such as PGC-1 [98]. PGC-1 was first identified as a factor involved in brown fat adipogenesis [99]; however, it also has an important role in the expression of gluconeogenic enzymes at physiologic concentrations within hepatocytes [98]. PGC-1 is induced in the liver by glucagon and glucocorticoids in the context of fasting, insulin deficiency, and diabetes, and then participates in the induction of the gluconeogenic program. Glucagon increases expression of PGC-1 via a cAMP-dependent process, and PGC-1 participates as a co-activator with Foxo1 to increase the Foxo1-dependent transcriptional activity of G-6-Pase and PEPCK expression. In this role, both Foxo1 and PGC-1 cooperate to promote fully the induction of gluconeogenic genes in liver.

### ***Sp1 transcription factors***

Sp1 also participates in a complex interplay with other nuclear receptors and co-factors to mediate the effects of insulin on hepatic expression of several genes [86]. There are three different known mechanisms by which Sp1 mediates insulin action: Sp1 may act alone in mediating the effects of insulin; Sp1 binding sites may be closely juxtaposed to those of other insulin-responsive transcription factors, effecting a cooperative interaction required for insulin induction; and Sp1 binding to an insulin-responsive promoter may lead to basal activity, but dissociation of Sp1 from this site may permit other factors to modulate gene activity in response to insulin.

---

## **Nutrient sensing and insulin action**

Fuel metabolism can interact with hormone signaling pathways to regulate a broad range of cell functions. With respect to insulin action, states of chronic nutrient excess, including glucose, amino acids, and fatty acids, impair signal transduction via transcrip-

tional and post-transcriptional mechanisms. These processes link nutrient availability with the ability of insulin to regulate metabolism together with cell growth and differentiation. There are three predominant pathways for nutrient sensing that are highly relevant to the regulation of insulin action: the hexosamine biosynthetic signaling pathway; the mammalian target of rapamycin (mTOR) signaling pathway; and the AMPK signaling pathway.

### Hexosamine biosynthetic signaling pathway

Defects in insulin signaling and impaired insulin secretion in T2DM have long been known to be at least partially reversible following a period (approximately 2–3 weeks) of therapeutic normalization of glycemia [100]. These observations, coupled with findings that elevated glucose concentrations can recapitulate these defects in cultured cell systems and rodent models, has given rise to the concept of “glucose toxicity” [101]. Marshall [102] and others have demonstrated that one important mechanism underlying glucose-induced insulin resistance involves glucose metabolism through a minor intracellular pathway, the hexosamine biosynthetic pathway. Glutamine: fructose-6-phosphate amidotransferase (GFA), the rate-limiting enzyme of this pathway transfers the amide group of glutamine to fructose 6-phosphate resulting in the production of glucosamine-6-phosphate. Glucosamine-6-phosphate is then metabolized to UDP-*N*-acetylglucosamine (UDP-GlcNAc). UDP-GlcNAc serves as the substrate for the enzyme *O*-linked *N*-acetylglucosamine transferase (OGT), which catalyzes the attachment of *O*-GlcNAc to proteins. The counterpart of OGT, *O*-GlcNAcase, catalyzes removal of the *O*-linked glycosyl adduct. Thus, increased glucose flux through the hexosamine biosynthetic pathway leads to increased post-translational modification of cytoplasmic and nuclear proteins by *O*-GlcNAc [103], which can modulate their enzyme activities, proteasomal degradation, and interaction with other proteins or DNA. UDP-GlcNAc levels can fluctuate with the availability of non-esterified fatty acids, uridine, glutamine and glucose, and in this way the hexosamine biosynthetic pathway acts as a nutrient sensor and regulator.

Increased glucose flux through the hexosamine biosynthetic pathway results in impaired ability of insulin to stimulate the glucose transport effector system in adipocytes and muscle cells, and represents a biochemical process by which hyperglycemia can induce insulin resistance [104]. In rodents, hyperglycemia induced by streptozotocin or by glucose infusions, and elevations in circulating FFAs induced by lipid infusion or high-fat feeding, lead to an increase in muscle UDP-GlcNAc levels and insulin resistance as demonstrated in hyperinsulinemic glucose clamp studies. In addition, overexpression of GFA in skeletal muscle and adipose tissue of transgenic mice enhanced glucose metabolism by the hexosamine biosynthetic pathway and induced insulin resistance. The mechanisms by which products of the hexosamine biosynthetic pathway induce insulin resistance, however, have not been fully elucidated. Increased metabolic flux through this

pathway results in increased *O*-glycosylation of the insulin receptor, IRS1, Akt/PKB, GLUT-4 and GSK3 $\beta$ , and this can impair the functional capabilities of these proteins or accelerate their proteasomal degradation. For example, increased *O*-glycosylation of the insulin receptor is accompanied by a decrease in insulin-stimulated receptor autophosphorylation [105]. Glycosylation can also affect activities of nuclear transcription factors. *O*-GlcNAc adducts can decrease transcriptional activity of Sp1 but increase DNA binding and transcriptional regulation by Foxo1. *O*-glycosylation can impair phosphorylation and DNA binding of C/EBP $\beta$ , and decrease NK- $\kappa$ B binding with I $\kappa$ B freeing NF- $\kappa$ B for relocation to the nucleus thereby including transcription of proinflammatory genes. Finally, increased intracellular accumulation of glucosamine-6-P inhibits hexokinase and glycogen synthase activity rapidly via an allosteric interaction with these enzymes. Nevertheless, the extent to which these processes contribute to insulin resistance in patients with diabetes requires further study.

### Mammalian target of rapamycin signaling pathway

The mTOR signaling pathway, also known as FK506 binding protein 12-rapamycin associated protein 1 (FRAP1), is an evolutionarily conserved serine–threonine protein kinase and a member of the PI<sub>3</sub> kinase-related kinase (PIKK) family [106]. It is a central signal integrator that receives signals arising from growth factors, nutrients and cellular energy metabolism, and then activates pathways that control cell growth, proliferation and survival. mTOR contains a COOH-terminal region with strong homology to the catalytic domain of PI<sub>3</sub> kinase, functions as a protein kinase [107], and exists in two functionally distinct complexes dubbed mTOR complex 1 (mTORC1) and mTORC2. mTORC1 is a heterotrimeric protein kinase that consists of the mTOR catalytic subunit and two associated proteins, regulatory associated protein of mTOR (raptor) and mammalian LST8/G-protein  $\beta$ -subunit like protein (mLST8/G $\beta$ L). Nutrients modulate the activity of the mTORC1 complex by affecting the interaction and association of the mTOR catalytic subunit with raptor. mTORC1 determines the activity of eukaryotic initiation factor 4E binding protein (4E-BP1) and ribosomal S6 kinase (S6K). The mTORC2 complex is comprised of mTOR, mLST8/G $\beta$ L, rapamycin-independent companion of mTOR (riCTOR) and MAPK-associated protein (mSin1). The rictor-mTOR complex directly phosphorylates Akt/PkB on Ser<sup>473</sup> and facilitates Thr<sup>308</sup> phosphorylation by PDK1 [108]. This phosphorylation of Akt occurs at Ser<sup>473</sup> which is distinct from activation by PDK1 which phosphorylates Thr<sup>308</sup>.

mTORC1 can impair insulin signaling via its ability to activate S6K, which then can phosphorylate serine residues of IRS1 resulting in desensitization of the PI<sub>3</sub> kinase/Akt pathway [109]. Indeed, IRS1 Ser<sup>302</sup>, which is proximal to the IRS1 PTB domain, contains an S6K recognition motif and is able to be phosphorylated by S6K. In this way, an increase in mTOR activity can contribute to insulin resistance. A surfeit of glucose and amino acids, especially leucine, leads to an increase in mTOR activity, while depletion of

these metabolic substrates or mitochondrial (e.g. oligomycin) and glycolytic (e.g. 2-deoxyglucose) inhibitors attenuate mTOR activity [110]. Thus, activation of S6K by mTOR activity serves as a mechanism by which nutrient excess can desensitize insulin action through serine phosphorylation of IRS1. Data in rodent models are consistent with this formulation. S6K1 activity is enhanced in insulin resistant mice fed a high-fat diet and in genetically obese mouse models, while S6K1<sup>-/-</sup> mice maintained on a high-fat diet remained insulin sensitive [111].

Insulin and amino acids can activate the mTOR pathway in a wortmannin-sensitive manner indicative of signaling through PI<sub>3</sub> kinase; however, the wortmannin target is not class I PI<sub>3</sub> kinases. Rather, the wortmannin target is the class III PI<sub>3</sub> kinase, hVps34. This is substantiated by the observation that knockdown of hVps34 blocks amino acid- and insulin-induced S6K1 activation but has no effect on Akt/PKB activation [112]. Rapamycin can inhibit mTOR through association with its intracellular receptor FKBP12. The FKBP12–rapamycin complex binds directly to a FKBP12–rapamycin binding (FRB) domain in mTOR, and this interaction inhibits mTOR activity. A recent study demonstrated that rapamycin enhances insulin-mediated glucose uptake by inhibiting mTOR-mediated S6K phosphorylation and reducing IRS serine phosphorylation [113]. The proximal signaling component immediately responsible for activating the mTOR pathway is the tuberous sclerosis complex (TSC). TSC can integrate information from the insulin signaling cascade and the AMPK signaling pathway. These multiple steps involved in nutrient sensing by the mTOR signaling pathway are attractive targets for treating insulin resistance in metabolic diseases caused by nutrient excess, such as T2DM and obesity.

### AMPK signaling pathway

The AMPK signaling pathway is activated by elevation of the AMP:ATP ratio. The pathway is switched on by nutrient deprivation leading to accumulation of AMP, or by perturbations that interfere with ATP synthesis, such as glucose deprivation, hypoxia, metabolic inhibitors (2-deoxyglucose, arsenite), and disruption of oxidative phosphorylation. Hardie has described AMPK as a “fuel gauge” that regulates responses to extremes of nutrient availability at the levels of cells, tissues and the whole body [114]. Once activated, it switches on fuel metabolism pathways that generate ATP, while inhibiting anabolic processes that consume ATP. AMPK is a heterotrimeric enzyme complex comprised of  $\alpha$ ,  $\beta$  and  $\gamma$ -subunits, and each subunit has two or more isoforms that exhibit tissue-specific expression. The  $\alpha$ -subunit is the catalytic component, and contains the Thr<sup>172</sup> residue that is phosphorylated by activating upstream kinases. The  $\beta$ -subunit has glycogen-binding C-terminal domains that help cement the trimolecular complex, and can also interact with high glycogen stores to exert an inhibitory effect on AMPK activity. The  $\gamma$ -subunit of AMPK allosterically binds one molecule of AMP or ATP in a mutually exclusive manner allowing for regulation of AMPK activity by changing ratios of AMP to ATP.

The upstream cascade leading to phosphorylation of Thr<sup>172</sup> in the AMPK  $\alpha$ -subunit is initiated by the LKB1 complex. LKB1 is apparently not regulated by AMP and is constitutively active. The binding of AMP to the AMPK  $\gamma$ -subunit results in a net augmentation of phospho-Thr<sup>172</sup> by making this site less susceptible to phosphatases, as well as by allosterically activating the phosphorylated form of the kinase. These two mechanisms create a “multiplier effect” for AMPK activity, allowing a small increase in AMP to produce a large effect on kinase activity. Both effects are antagonized by high ATP concentrations, so that the AMP:ATP ratio becomes a sensitive regulator of AMPK. AMPK is also activated in response to cytosolic Ca<sup>2+</sup> levels via phosphorylation of Thr<sup>172</sup> by calmodulin-dependent kinase kinase- $\beta$  (CaMKK $\beta$ ); however, this action of CaMKK $\beta$  is independent of the AMP level.

AMPK switches on catabolic processes that generate ATP such as glucose uptake, glycolysis, fatty acid oxidation, and mitochondrial biogenesis, while switching off anabolic processes that consume ATP such as fatty acid and cholesterol biosynthesis, gluconeogenesis and glycogenesis. To conserve ATP, AMPK activation suppresses protein synthesis by inhibiting the mTOR pathway and initiation of translation, and by inhibiting translational elongation of proteins via activation of elongation factor 2 kinase. To enhance the capacity for ATP generation, AMPK appears to promote mitochondrial biogenesis through concerted action with another metabolic sensor, the NAD<sup>+</sup>-dependent deacetylase SIRT1. Evidence indicates that AMPK can enhance SIRT1 activity by increasing cellular NAD<sup>+</sup> levels. SIRT1 then deacetylates various AMPK substrates and modulates their activity including PGC-1 $\alpha$  and Foxo1. In this way, AMPK, SIRT1 and PGC-1 $\alpha$  can act in an orchestrated way to regulate energy metabolism. In skeletal muscle, AMPK stimulates lipid oxidation, increases insulin sensitivity and mediates contraction-induced increments in glucose uptake during exercise [115]. In liver, AMPK activation suppresses gluconeogenic enzyme expression and leads to decreased blood glucose values, while fatty acid oxidation is stimulated and cholesterol and triglyceride biosynthesis is blocked. These biologic actions are the result of phosphorylation and inactivation of both ACC and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase) by AMPK. The phosphorylation of ACC is central to the ability of AMPK to promote fatty acid oxidation, because this reduces its activity and results in decreased production of malonyl-CoA, an inhibitor of carnitine palmitoyltransferase I (CPT1). The reduction in malonyl-CoA relieves the inhibition of CPT1 and promotes CPT1-mediated transport of fatty acids into the mitochondria for oxidation. At the transcriptional level, AMPK blocks lipogenesis by limiting endogenous LXR ligand production, which inhibits LXR-dependent transcription of SREBP-1 [116]. AICAR is used experimentally to study the effects of AMPK activation on glucose and lipid metabolism and insulin signaling pathways. AICAR is an adenosine analog that is taken up by adenosine transporters and subsequently phosphorylated to ZMP (5-aminoimidazole-4-carboxamide-1- $\beta$ -D-furanosyl

5'-monophosphate) within the cell, which mimics AMP and activates AMPK signaling through direct binding. In adipocytes, AICAR stimulates glucose uptake, increases adiponectin secretion, and inhibits production of cytokines such as TNF- $\alpha$  and IL-6. Two existing classes of antidiabetic drugs, biguanides (e.g. metformin) and the thiazolidinediones (e.g. rosiglitazone), both act (at least in part) by activation of AMPK. Furthermore, AMPK is activated by the insulin sensitizing hormones leptin and adiponectin. These actions are proof-of-principle that pharmacologic activators of AMPK could be used to treat patients with the metabolic syndrome and T2DM.

---

## Cell stress and insulin action

### Oxidative stress

Oxidative stress caused by increased reactive oxygen species (ROS) generation and/or compromised antioxidant systems represents an important factor in the development of insulin resistance and the related diseases of obesity, metabolic syndrome, and T2DM [117]. Nutrient excess, physical inactivity and hyperglycemia can lead to oxidative stress and low-grade inflammation. A considerable portion of total body oxidant stress and ROS production are generated by dysfunctional mitochondria in skeletal muscle. It is not clear, however, whether mitochondrial dysfunction is the consequence or the cause of increased ROS production. Production of excess ROS can occur in response to diverse stimuli including inflammation and proinflammatory cytokines (e.g. TNF- $\alpha$ ). Oxidative stress can also be self-reinforcing, because ROS activates NF- $\kappa$ B and upregulates expression of proinflammatory genes such as TNF- $\alpha$ , IL-6, and C-reactive protein (CRP) [118]. Oxidants are believed to impair insulin signal transduction by inducing serine phosphorylation of IRS which impairs tyrosine phosphorylation and increases IRS protein degradation.

### Inflammation

Human insulin resistance is frequently accompanied by low-grade systemic inflammation, evidenced by elevated circulating markers of inflammation in these disorders such as white blood cell count, sedimentation rate, CRP, adhesion molecules (e.g. e-selectin), cytokines such as IL-6 and IL-8, and serum amyloid A. In adipose tissue, obesity and insulin resistance are associated with an infiltration of activated macrophages and paracrine cross-talk between macrophages and adipocytes involving multiple secreted factors (e.g. cytokines, adipokines). This process can influence secretion patterns of circulating adipokines that can affect other organs and generate aspects of the metabolic syndrome trait cluster. This includes secretion of IL-1 and IL-6 which helps mediate inflammation in metabolic disorders. For example, IL-1 $\alpha$  and IL-1 $\beta$  exert strong proinflammatory functions [119] and the latter is able to reduce IRS-1 expression. Interestingly, in humans with T2DM, treatment with recombinant human IL-1 receptor antagonist improves glycemic

control [120]. Circulating IL-6 levels are highly correlated with insulin resistance, and related studies demonstrate how proinflammatory cytokines can compromise insulin action, by a mechanism involving recruitment and activation of Jak, STAT proteins, and SHP-2 which helps to activate the ERK/MAP kinase pathway. Subsequent steps include increased transcription of SOCS genes, whose protein products induce insulin resistance at a proximal step at the insulin receptor or IRS proteins.

### Endoplasmic reticulum stress

Although endoplasmic reticulum (ER) stress has been recognized as an adaptive cellular response to an accumulation of unfolded or misfolded proteins in its lumen, the ER stress response can also be triggered by other factors, including chronic nutrient excess, high fatty acid concentrations, and oxidative stress, which are found in insulin resistant states. ER stress activates the JNK pathway with subsequent inhibitory serine phosphorylation of IRS-1, and the development of insulin resistance. The mechanism for JNK activation involves transmembrane ER proteins with luminal domains responsive to ER stress signals and cytoplasmic effector domains that influence intracellular pathways. One of these stress transducers, known as IRE1, links ER stress to JNK activation. Obesity and extended periods of high fat feeding can induce the ER stress response in adipose tissue and liver, as indicated by ER stress markers such as PERK, eIF2 $\alpha$  phosphorylation, and JNK activation. Interestingly, small molecular weight "chemical chaperones" such as phenyl butyric acid which attenuate ER stress, can normalize fasting blood glucose, enhance insulin sensitivity and reduce ER stress in *ob/ob* mice [121]. In diabetes, ER stress has also been implicated in pancreatic  $\beta$ -cell failure [122]. Finally, oxidative stress, caused by excess availability of saturated fatty acids for mitochondrial oxidation, is linked to exacerbation of ER stress.

## Control of Weight: How Do We Get Fat?

**George A. Bray**

Pennington Biomedical Research Center, Baton Rouge, LA, USA

### Keypoints

- Positive energy balance is the essential ingredient required to store body fat and become overweight.
- It is what the energy balance concept does not tell us that is important; for example, it does not explain genetic factors, gender differences in fatness, or effects of age or medications.
- An epidemiologic model for developing overweight in response to the environment identified food, reductions in energy expenditure, viruses, toxins, and drugs as contributing mechanisms.
- Cost of food has an important role in food choices.
- A homeostatic model for control of food intake and energy expenditure helps isolate the specific mechanisms that can be targeted for understanding and treating the problem.

### Introduction

Research over the past two decades has provided an unprecedented expansion of our knowledge about the physiologic and molecular mechanisms regulating body weight and body fat [1]. One great step was the cloning of genes corresponding to five types of obesity in experimental animals that were due to single genes – so-called monogenic obesity syndromes – and the ensuing characterization of the human counterparts to these syndromes [2,3]. Subsequent research has added a number of other genes with lesser effects to the list of genes modifying obesity [4]. Extensive molecular and reverse genetic studies (mouse knock-outs) have helped to identify critical pathways regulating body fat and food intake, and have validated or refuted the importance of previously identified pathways [2].

This chapter reviews this rapidly expanding literature from two perspectives. The first is an epidemiologic approach, considering environmental agents that affect the human being. The second views body weight regulation from a “set-point” or homeostatic approach by considering the way in which one part of the metabolic system communicates with another and how this system may be “overridden” by hedonic or pleasure centers.

### Genetic factors

The epidemic of overweight is occurring on a genetic background that does not change as fast as the epidemic has been exploding. It is nonetheless clear that genetic factors have an important role in its development [2,4]. One analogy for the role of genes in overweight is that “genes load the gun and a permissive or toxic environment pulls the trigger.”

Identification of genetic factors involved in the development of obesity increases yearly. From the time of the early twin and adoption studies more than 10 years ago [2], the focus has been on evaluating large groups of individuals for genetic defects related to the development of overweight [3,4]. These genetic factors can be divided into two groups: the rare genes that produce excess body fat and a group of more common genes that underlie susceptibility to becoming overweight – the so-called ‘susceptibility’ genes [2,4]. The field of genetic factors has been given a recent boost from genome-wide association studies, in which variants in large populations of tens of thousands of people are examined [4]. Using this genome-wide association strategy, 17 genes are now known that account for a small fraction of the variance in human body weight [5]. The most important of these is the FTO gene, which accounts for half of this effect. All of these genes are thought to affect the regulation of food intake.

Underlying the following discussion is the reality that genetic responses to the environment differ between individuals and affect the magnitude of the weight changes. Several genes have such potent effects that they produce overweight in almost any

environment where food is available. Leptin deficiency is one of them [3]. Most other genes that affect the way body weight and body fat vary under different environmental influences have only a small effect. That these small differences exist and differ between individuals accounts for much of the variability in the response to diet that we see.

---

## Epigenetic and intrauterine imprinting

Over the past decade it has become clear that infants who are small for their age are at higher risk for metabolic diseases later in life. This idea was originally proposed by Professor David Barker and is often called the Barker or Developmental Origins of Health and Disease hypothesis [6]. Several examples illustrate its role in human obesity. The first was the Dutch winter famine of 1944, in which the calories available to the residents of the city of Amsterdam were severely reduced by the Nazi occupation [7]. During this famine, intrauterine exposure occurred during all parts of the pregnancy; caloric restriction during the first trimester increased the subsequent risk of overweight in the offspring [7].

Two other examples that fall into the category of fetal imprinting are the increased risk of obesity in offspring of mothers with diabetes [8] and in the offspring of mothers who smoked during the individual's intrauterine period [9,10]. In a study of infants born to Pima Indian women before and after the onset of maternal diabetes, Dabelea *et al.* [8] noted that the infants born after diabetes developed were heavier than those born to the same mother before diabetes developed [11,12]. The risk for overweight at age 3 years was predicted by smoking at first prenatal visit with an odds ratio (OR) of 2.16 (95% confidence interval [CI] 1.05–4.47). Despite being smaller at birth, these infants more than caught up by age 3 years [11,12].

Smoking during pregnancy increases the risk of overweight at entry to school from just under 10% to over 15% if smoking continued throughout pregnancy and to nearly 15% if it was discontinued after the first trimester, indicating that most of the effect is in the early part of pregnancy [13,14].

---

## Environmental agents and overweight: an epidemiologic approach

One way to view the etiology of increased body fat is from the epidemiologic or environmental perspective. Food, medications, viruses, toxins and sedentary lifestyle can each act on the host to produce increased fatness. We need to remember, however, that for each of these agents there are genetic components.

### Food is an environmental agent for obesity

We obtain all of our energy from the foods we eat and the beverages we drink. Thus, without food there could be no life, let alone excess stores of fat. The cost of this food is an important deter-

minant of food choices. In addition to cost and total quantity, food styles of eating and specific food components may be important in determining whether or not we become fat.

### Costs of food

Economic factors may have an etiologic role in explaining the basis for the intake of a small number of “excess calories” over time that leads to overweight [1]. What we consume is influenced by the price we have to pay for it. In the recent past, particularly since the beginning of the 1970s, the prices of foods that are high in energy density (fat and sugar-rich) have fallen relative to other items. The Consumer Price Index rose by 3.8% per year from 1980 to 2000 [15] compared with the rise in food prices, which rose by 3.4% per year. In the period 1960–1980, when there was only a small increase in the prevalence of overweight, food prices rose at a rate of 5.5% per year – slightly faster than the Consumer Price Index, which grew at a rate of 5.3% per year. The relative prices of foods high in sugar and fat have decreased since the early 1980s compared with those of fruits and vegetables. By comparison, Finkelstein *et al.* [15] note that between 1985 and 2000, the prices of fresh fruits and vegetables rose 118%, fish 77% and dairy 56%, compared with sugar and sweets, which rose only 46%, fats and oils 35% and carbonated beverages only 20%. Is it any wonder that people with limited income eat more sugar and fat-containing foods?

### Quantity of food eaten

Eating more food energy over time than we need for our daily energy requirements produces extra fat. In the current epidemic the increase in body weight is on average 0.5–1 kg/year. The amount of net energy storage required by an adult to produce 1 kg of added body weight, 75% of which is fat, can be calculated by using a few assumptions. One kilogram of adipose tissue contains about 7000 kcal (29.4 MJ) of energy. If the efficiency of energy storage were 50%, with the other 50% being used by the synthetic and storage processes, we would need to ingest 14 000 kcal (58.8 MJ) of food energy. As there are 365 days in the year this would be an extra 20 kcal/day (40 kcal/day × 365 day/year = 14 600 kcal) [16]. For simplicity we can round this to 50 kcal/day or the equivalent of 10 teaspoons of sugar.

Has the intake of energy increased? The energy intake (kcal/day) was relatively stable during the first 80 years of the 20th century. During the last 20 years, however, there was a clear rise from about 2300 kcal/day to about 2600 kcal/day, or an increase of 300 kcal/day. This is more than enough to account for the 50 kcal/day net (100 kcal gross) required to produce the 1 kg weight gain each year [17].

### Portion size

Portion sizes have dramatically increased in the past 40 years [18] and now need reduction. One consequence of the larger portion sizes is more food and more calories [17]. The US Department of Agriculture (USDA) estimates that between 1984 and 1994 daily calorie intake increased by 340 kcal/day or 14.7%. Refined grains provided 6.2% of this increase, fats and oils 3.4%, but fruits

and vegetables only 1.4% and meats and dairy products only 0.3%. Calorically sweetened beverages that contain 10% high-fructose corn syrup (HFCS) are made from these grain products. These beverages are available in containers of 12, 20 or 32 oz, which provide 150, 250 or 400 kcal if all is consumed. Many foods list the calories per serving, but the package often contains more than one serving. In 1954, the burger served by Burger King weighed 2.8 oz and had 202 kcal. By 2004, the size had grown to 4.3 oz and 310 kcal. In 1955, McDonald's served French fries weighing 2.4 oz and having 210 kcal. By 2004, this had increased to 7 oz and 610 kcal. Popcorn served at movie theaters has grown from 3 cups containing 174 kcal in 1950 to 21 cups with 1700 kcal in 2004 [19]. Nielsen & Popkin [18] have examined the portion sizes consumed by Americans and have shown the increased energy intake associated with the larger portions of essentially all items examined. Guidance for intake of beverages suggests intake of more water, tea, coffee and low-fat dairy products with lesser consumption of beverages that contain primarily water and caloric sweeteners [20]. The importance of drinking water as an alternative to consuming calories is suggested in a recent study. There was an inverse relationship between water intake expressed per unit of food and beverage intake and total energy intake. When the water intake was less than 20 g/gram of food + beverages, energy intake was 2485 kcal/day. At the highest quartile, when water intake was at or above 90 g/gram of food + beverage, energy intake had fallen to 1791 kcal/day. Thus, drinking water may be one strategy for lowering overall energy intake [21].

### Energy density

Energy density interacts with portion size to affect how much is eaten. Energy density refers to the amount of energy in a given weight of food (kcal/g). Energy density of foods is increased by dehydrating them or by adding fat. Conversely, lower energy density is produced by adding water or removing fat. When energy density of meals was varied and all meals were provided for 2 days, the participants ate the same amount of food, but as a result obtained more energy when the foods were higher in energy density. In this experiment, they obtained about 30% less energy when the meals had low rather than high energy density [22,23]. When energy density and portion size were varied, Kral *et al.* [24] showed that both factors influence the amount that is eaten. The meals with low energy density and small portion sizes provided the fewest calories (398 kcal vs 620 kcal) [24].

### Styles of eating

Breastfeeding is a case in which the style of eating can be associated with later weight gain. In infants, breast milk is their first food, and for many infants their sole food for several months. There are now a number of studies showing that breastfeeding for more than 3 months significantly reduces the risk of being overweight at entry into school and in adolescence when compared with infants who are breastfed for less than 3 months [25]. This may be an example of "infant imprinting" [26,27].

### Restaurants and fast-food establishments

Eating outside the home has increased significantly over the past 30 years. There are now more fast-food restaurants (277 208) than churches in the USA [28]. The number of fast-food restaurants has risen since 1980 from 1 per 2000 people to 1 per 1000 Americans. Of the 206 meals per capita eaten out in 2002, fast-food restaurants served 74% of them. Other important figures are that Americans spent \$100 billion on fast food in 2001, compared to \$6 billion in 1970. An average of three orders of French-fried potatoes are ordered per person per week, and French-fried potatoes have become the most widely consumed vegetable. More than 100 000 new food products were introduced between 1990 and 1998. Eating outside the home has become easier over the last four decades as the number of restaurants has increased, and the percent of meals eaten outside the home reflects this. In 1962, less than 10% of meals were eaten outside the home. By 1992 this had risen to nearly 35%, where it has remained. In a telephone survey of body mass index (BMI) in relation to proximity to fast-food restaurants in Minnesota, however, Jeffrey *et al.* [29] found that eating at a fast-food restaurant was associated with having children, with eating a high-fat diet and having a high BMI, but not with proximity to the restaurant.

Eating in a fast-food restaurant also changes the foods consumed [30,31]. Paeratakul *et al.* [30] compared a day in which individuals ate at a fast-food restaurant with a day when they did not. On the day when food was eaten in the fast-food restaurant, less cereal, milk and vegetables were consumed, but more soft drinks and French-fried potatoes were eaten. Similar findings were reported by Bowman *et al.* [31], who reported in addition that on any given day, over 30% of the total sample group consumed fast food. In this national survey, several other features were also associated with eating at fast-food restaurants, including being male, having a higher household income and residing in the US South. Children who ate at fast-food restaurants consumed more energy, more fat and added sugars, and more sweetened beverages than children who did not eat at fast-food restaurants.

### Night-eating syndrome

The original description of the night-eating syndrome was published in a classic paper by Stunkard in 1955 and updated recently [32]. Recent studies have refined this syndrome. It consists of individuals who eat more than 50% of their daily energy intake during the nighttime [1].

### Frequency of food intake

Frequency of eating may increase the risk of obesity. Crawley & Summerbell [33] showed that among males, but not females, the number of meal-eating events per day was inversely related to BMI. Males with a BMI of 20–25 ate just over 6 times per day compared to less than 6 times for those with a BMI >25 kg/m<sup>2</sup>.

Eating breakfast is associated with eating more frequently, and there are data showing that eating breakfast is associated with lower body weight. Eating breakfast cereal has been related to

decreased BMI in adolescent girls. Using longitudinal data on adolescent girls, Barton *et al.* [34] showed that as cereal intake per week increased from 0 to 3 times per week, there was a small, but significant, decrease in BMI.

### Calorically sweetened soft drinks

One of the consequences of the lower farm prices in the 1970s was a drop in the price of corn, which made inexpensive the production of corn starch which is converted to HFCS. With the development of the isomerase technology in the late 1960s which could convert starch into the highly sweet molecule, fructose, manufacture of soft drinks entered a new era [35]. From the early 1970s through the mid-1990s, HFCS gradually replaced sugar in many manufactured products, and almost entirely replaced sugar in soft drinks manufactured in the USA. In addition to being cheap, HFCS is very sweet. We have argued that this “sweetness” in liquid form is one factor driving the consumption of increased calories which are needed to fuel the current epidemic of obesity.

The relationship of soft-drink consumption to calorie intake, to body weight and to the intake of other dietary components has been examined in both cross-sectional and longitudinal studies [36]. Of the 11 cross-sectional studies examining the relation of caloric intake and soft-drink consumption, nine found a moderately positive association. Among the four longitudinal studies, the strength of the association was slightly stronger. The authors conclude that when humans consume soft drinks there is little caloric compensation. That is, the soft drinks are “added” calories and do not lower the intake of energy in other forms. The strengths of these relationships were stronger in women and in adults. Not surprisingly, they found that studies funded by the food industry had weaker associations than those funded by independent sources.

Several studies on the consumption of calorically sweetened beverages in relation to the epidemic of overweight have received significant attention [35]. Ludwig *et al.* [37] reported that the intake of soft drinks was a predictor of initial BMI in children in the Planet Health Study. They went on to show that higher soft-drink consumption also predicted the increase in BMI during nearly 2 years of follow-up. Those with the highest soft-drink consumption at baseline had the highest increase in BMI. In one of the few randomized well-controlled intervention studies, Danish investigators [38] showed that individuals consuming calorically sweetened beverages during 10 weeks gained weight, whereas subjects drinking the same amount of artificially sweetened beverages lost weight. Equally important, drinking sugar-sweetened beverages was associated with a small, but significant, increase in blood pressure. Women in the Nurses’ Health Study [39] also showed that changes in the consumption of soft drinks predicted changes in body weight over several years of follow-up. In children, a study focusing on reducing intake of “fizzy” drinks and replacing them with water showed slower weight gain than for those not advised to reduce the intake of fizzy drinks [40].

Fructose consumption, either in beverages or food, may have an additional detrimental effect. It has been linked to the development of cardiometabolic risk factors and the metabolic syndrome in participants in the Framingham Study [41]. Cross-sectionally, individuals consuming  $\geq 1$  soft drink per day had a higher prevalence of the metabolic syndrome (OR 1.48; 95% CI 1.30–1.69) and an increased risk of developing the metabolic syndrome over 4 years of follow-up. It may also increase the risk of gout [42] and diabetes [43].

### Dietary fat

Dietary fat is another component of the diet that may be important in the current obesity epidemic [44–46]. In epidemiologic studies, dietary fat intake is related to the fraction of the population that is overweight [45]. In an 8-year follow-up of the Nurses’ Health Study, Field *et al.* [47] found a weak overall association of percent fat and a stronger effect of animal fat, saturated fat and *trans* fat on fatness. In experimental animals, high-fat diets generally produce fat storage. In humans, the relationship of dietary fat to the development of overweight is controversial. It is certainly clear that ingesting too many calories is essential for the increase in body fat. Because the storage capacity for carbohydrate is very limited, it must be oxidized first. Thus, when people overeat, they oxidize carbohydrate and store fat. When fat is a large component of a diet, the foods tend to be “energy dense” and thus overconsumption is easy to achieve.

### Low levels of physical activity

Epidemiologic data show that low levels of physical activity and watching more television predict higher body weight [48]. Recent studies suggest that individuals in US cities where they had to walk more than people in other cities tended to weigh less [49]. Low levels of physical activity also increase the risk of early mortality [50]. Using normal weight, physically active women as the comparison group, Hu *et al.* [51] found that the relative risk of mortality increased from 1.00 to 1.55 (55%) in inactive lean women compared with active lean ones, to 1.92 in active overweight women, and to 2.42 in women who are overweight and physically inactive. It is thus better to be thin than fat and to be physically active rather than inactive.

Television has been one culprit blamed for the reduced levels of physical activity, particularly in children. The first suggestion that TV viewing was associated with overweight was published by Gortmaker and Dietz. Using data from the National Health Examination Survey [52] and the National Longitudinal Study of Youth [53], they found a linear gradient from 11–12% overweight in children watching 0–2 hours/day to over 20–30% when watching more than 5 hours/day. Since that time a number of studies have shown that in both children and adults, those who watch TV more are more overweight. By one estimate about 100 kcal of extra food energy is ingested for each hour of TV viewing. In studies focusing on reducing sedentary activity, which largely means decreasing TV viewing, there was a significant decrease in energy intake with increased activity [54]. In the Early

Childhood Longitudinal Study, investigators found that between kindergarten and third grade, children watching more TV (OR 1.02) and eating fewer family meals together (OR 1.08) predicted a modest increase in weight [55].

### Effect of sleep time and environmental light

Sleep time declines from an average of  $14.2 \pm 1.9$  (mean  $\pm$  SD) hours/day in infancy ( $11.0 \pm 1.1$  hours/day by 1 year of age) to  $8.1 \pm 0.8$  hours/day at 16 years of age [56]. Sleep time declined across the cohorts from 1974 to 1993 due largely to later bedtime, but similar arising time. Nine epidemiologic studies have been published that relate shortness of sleep time with overweight. Six of these studies are cross-sectional in design, and three are longitudinal. The earliest of these studies was only published in 1992, but most were published after 2002. They include both children and adults. In a small case-control study involving 327 short-sleepers compared with 704 controls, Locard *et al.* [57] found that short-sleepers were heavier than the controls.

In two large cross-sectional studies in children, Sekine *et al.* [58] and von Kries *et al.* [59] found that there was a dose-dependent relationship between the amount of sleep and the weight of children when they entered school. Von Kries *et al.* [59] studied 6862 children aged 5–6 years whose sleeping time was reported in 1999–2000 by the parent, and followed-up in 2001–2002. Overweight in this study was defined as a weight for height greater than the 97th percentile. Children with reported sleeping time of less than 10 hours had a prevalence of overweight of 5.4% (95% CI 4.1–7.0), those who slept 10.5–11.0 hours per night had a prevalence of 2.8% (95% CI 2.3–3.3) and those who slept more than 11.5 hours had a prevalence of overweight of 2.1% (95% CI 1.5–2.9). Among the 8274 children from the Toyama Birth Cohort in Japan [58], there was a graded increase in the risk of overweight, defined as a BMI above  $25 \text{ kg/m}^2$ , as sleep time decreased. If the children who were reported to sleep more than 10 hours at age 3 had an OR of 1.0, those who slept 9–10 hours had an OR of 1.49, those with 8–9 hours sleep an OR of 1.89, and those children who were reported to sleep less than 8 hours had an OR for overweight of 2.87.

Another setting in which lighting has a role in the development of weight gain is seasonal affective depressive syndrome (SADS). For some people, the shortening of the daylight hours with the onset of winter is associated with depression and weight gain. When the days begin to lengthen in the spring this symptom complex is reversed. Current evidence suggests that it is related to changing activity of the serotonin system and can be treated with exposure to light or by manipulating brain levels of serotonin pharmacologically.

### Medications that produce weight gain

Several drugs can cause weight gain, including a variety of hormones and psychoactive agents [1,60]. The degree of weight gain is generally less than 10 kg and not sufficient to cause substantial overweight. These drugs may also increase the risk of future type 2 diabetes mellitus.

## Toxins

### Smoking

The rise of smoking from 1900 to 1970 and its decline during the last 30 years of the 20th century has been tracked by the Centers for Disease Control. Weight gain after stopping smoking is gender-dependent, with men gaining an average of 3.8 kg and women 2.8 kg [61]. In a more recent analysis, men were found to gain 4.4 kg and women 5.0 kg [62] and it was calculated that this gain could account for about one-quarter to one-sixth of the increased prevalence of overweight. Several factors predict the weight gain, including younger age, lower socioeconomic status, heavier smoking and genetic factors [63]. Economists have calculated that a 10% increase in the price of cigarettes could increase BMI by  $0.0251 \text{ kg/m}^2$  as a result of the decrease in smoking [64]. Snacks are the major component of food intake that rises when people stop smoking.

### Organochlorines

In human beings, we know that body fat stores many “toxic” chemicals and that they are mobilized with weight loss. Backman first showed in 1970s that organochlorines in the body decreased after bariatric surgery. The metabolic rate can be reduced by organochlorine molecules [65], and conceivably prolonged exposure to many chlorinated chemicals in our environment has affected metabolic pathways and energy metabolism. Under these conditions, thyroid hormone synthesis is decreased, plasma T3 and T4 are decreased, thyroid hormone clearance is increased, and mitochondrial oxidation is reduced in skeletal muscle.

### Monosodium glutamate

Food additives are another class of chemicals that are widely distributed and may be involved in the current epidemic of overweight. In experimental animals, exposure during the neonatal period to monosodium glutamate, a common flavoring ingredient in food, produces fatness [66].

### Viruses as environmental agents

Several viruses produce weight gain in animals and the possibility that they do this in human beings needs more study. (This subject is ably reviewed by Atkinson [67].) It has been known for many years that the injection of several viruses into the central nervous system could produce fatness in mice. The list of viruses now includes canine distemper virus, RAV-7 virus, Borna disease virus, scrapie virus, SMAM-1 virus and three adenoviruses (types 5, 24 and 36). These observations were generally assumed to be pathologic in nature and not relevant to overweight humans. However, the recent finding that antibodies to one of the adenoviruses (AM-36) appear in larger amounts in some overweight humans than in controls challenges this view. This viral syndrome, resulting from AM-36, can be replicated in the ferret, a non-human primate. The features of the syndrome are modest increase in weight and a low cholesterol concentration in the circulation. Further studies are needed to establish that a syndrome of weight loss associated with low concentrations of

cholesterol clearly exists in human beings. If so, this would enhance the value of the epidemiologic model.

---

### **Regulation of body fat as a problem of homeostatic energy regulation with a hedonic override**

A defect in the way the body responds to feedback signals is another way to view the problem of overweight. Such a system has four parts. The control center in the brain is analogous to the thermostat in a heating system. It receives information about the state of the animal or human, transduces this information into neurochemical signals, and activates pathways that lead to or inhibit feeding and the search for food. The signals that the brain receives come from the environment through sense organs and from the body through neural, nutrient or hormonal signals. The response the brain makes includes both the activation and inhibition of motor systems and the modulation of the autonomic nervous system or hormonal control system. Outside of the brain is the so-called controlled system and, for the purpose of this discussion, includes the digestive tract, which ingests, digests and absorbs food; the metabolic systems in liver, muscle and kidney, which transform nutrients; and the adipose tissue, which both stores and releases fatty acids and acts as a secretory endocrine organ [1].

#### **Digestion, metabolism and fat storage**

The controlled system consists of the gastrointestinal tract, liver, muscles, fat tissues, cardiovascular–pulmonary–renal system and supporting bone tissue. The ingestion, digestion and absorption of food provide nutrients to the body and also provide signals from these nutrients to the vagus nerve, which provides the major neural control of gastrointestinal function, and from hormones released by the gastrointestinal tract. The nutrients that are absorbed can be metabolized to provide energy, or they can be stored as glycogen in liver, as protein in muscle or as fat in adipose tissue.

The largest part of the energy we expend each day is for “resting” metabolism, which includes the metabolism of food, the transport of sodium, potassium and other ions across cell membranes, repair of DNA, synthesis of protein, the beating of the heart and functioning of the brain, liver and kidneys. Energy expenditure is most strongly associated with fat-free body mass.

We conclude that day-to-day energy balance is either positive or negative. We do not achieve meal-to-meal or day-to-day energy balance. Rather, if we are to avoid weight gain, we must achieve this over a longer time interval.

If we are to maintain a stable body weight, the metabolic mix of carbohydrate, fat and protein that is oxidized by the body must equal the amounts of these nutrients taken in as food. That is, to maintain energy balance requires that the mix of foods we eat be completely metabolized or oxidized. The capacity for storage of carbohydrate as glycogen is very limited and the capacity to store

protein is also restricted. Only the fat stores can readily expand to accommodate increasing levels of energy intake above those required for daily energy needs. Several studies now show that a high rate of carbohydrate oxidation, as measured by a high respiratory quotient, predicts future weight gain [68]. One explanation for this is that when carbohydrate oxidation is higher than the intake of carbohydrate, carbohydrate stores are depleted. To replace this carbohydrate, an individual must eat more carbohydrate or reduce the oxidation of carbohydrate by the body, because the body cannot convert fatty acids to carbohydrate and the conversion of amino acids to carbohydrate mobilizes important body proteins [69]. Obese individuals who have lost weight are less effective in increasing fat oxidation in the presence of a high-fat diet than normal weight individuals, and this may be one reason why they are so susceptible to regaining weight that has been lost.

Physical activity gradually declines with age. If we are to avoid becoming overweight as we age, we must gradually reduce our food intake or we must maintain a regular exercise program. A moderate level of exercise is beneficial in two ways. First, it reduces risk of cardiovascular disease and type 2 diabetes, and second, it facilitates the oxidation of fat in the diet [70]. Maintaining an exercise program, however, is difficult for many people, particularly as they get older.

The concept of “energy wasting” through uncoupling proteins is one of the expanding basic science aspects of obesity. The original uncoupling protein-1 (UCP1) found in brown fat has a well-established role in helping newborn infants maintain body temperature. Increased expression and/or activation of this protein uncouples oxidation from phosphorylation by enhancing a leak of protons from the inner mitochondrial space, resulting in the conversion of energy to heat without storing the energy in ATP molecules. The UCP1 molecule is important in human infants, but its importance in adults, because of the very low levels of brown fat (and hence UCP1 expression) in adult humans, has been questioned until recently [71]. This new evidence for active brown adipose tissue in adult humans comes from the use of sophisticated techniques combining glucose uptake in tissues (using the <sup>18</sup>fluoro-deoxy-glucose) measured by positron emission tomography and computed tomography. Deposits of brown adipose tissue were demonstrated in the supraclavicular region, along the cervical vertebrae and along thoracic vertebrae. This activity can be blocked by propranolol, a broad-based beta-adrenergic-blocking drug, indicating that this glucose uptake is under control of the sympathetic nervous system. Activity can also be modulated by environmental temperature, with higher temperatures eliminating the uptake and lower temperatures increasing the uptake of labeled glucose. Whether the activity of this tissue can be enhanced by continued stimulation remains to be demonstrated.

#### **The fat cell**

The fat cells in adipose tissue serve two major functions. First, they are the cells that store and release fatty acids ingested in the food we eat or synthesized in the liver or fat cell. Second, fat cells

are a major endocrine cell, secreting many important metabolic and hormonal molecules [1].

Before fat cells can undertake these functions, however, they must be converted from precursor mesenchymal cells to mature fat cells. *In vitro* studies have shown a two-stage process – proliferation followed by differentiation. The proliferative phase is initiated by hormonal stimulation with insulin and glucocorticoids. After the cells begin to grow they enter a state of differentiation where they acquire the genetic state of mature fat cells that can store fatty acids, break down triglycerides, and make and release the many hormones that characterize the mature fat cell. Most of the fatty acids that are stored in human fat cells are derived from the diet, although these cells maintain the capacity for *de novo* synthesis of fatty acids [72].

The discovery of leptin catapulted the fat cell into the arena of endocrine cells [73]. The finding of a peptide released from adipose tissue that acts at a distance has refocused interest in the fat cell from primarily a cell that stores fatty acids to a cell with endocrine and paracrine functions. In addition to leptin, the fat cell secretes a variety of peptides, including lipoprotein lipase, adiponectin (complement D), complement C, adiponectin, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-6 (IL-6), plasminogen activator inhibitor-1 (PAI-1), angiotensinogen, bradykinin and resistin, in addition to other metabolites such as lactate, fatty acids, glycerol and prostacyclin formed from arachidonic acid. This important endocrine tissue has thus greatly expanded its role. Adiponectin and resistin are recent additions to the growing list.

### Messages to the brain from the environment and from the body

The brain receives a continuous stream of information from both the external and internal environments that have a role in the control of feeding. The external information provided by sight, sound and smell are all distant signals for identifying food. Taste and texture of foods are proximate signals generated when food enters the mouth. The classic tastes are sweet, sour, bitter and salty as well as “umami,” a fifth taste. In nature most “sweet” foods also have vitamins and minerals, because they come from fruits. Sour and particularly bitter foods often contain unwanted chemical compounds. The extreme example of this is “bait shyness” or “taste aversion,” the property that some items have that produces a permanent rejection of future food with the same taste. This is a “hard-wired” response in the brain that overrides the usual “feedback” signals.

A taste for fats, specifically unsaturated fatty acids, may be a sixth taste. Receptors on the tongue can identify certain fatty acids. The discovery of taste and smell receptors for polyunsaturated fatty acids on the taste bud that involves a potassium rectifier channel offers an opening into modifying taste inputs into the food-intake system [74]. An important advance was showing that the CD-36 receptor, which binds fatty acids, is the receptor for these fatty acids. These receptors are located on the lingual papillae of the tongue. Mice that do not have the CD36 receptor

do not prefer solutions enriched with long-chain fatty acids or a high-fat diet. These receptors are in close proximity to Ebner glands, a source of lingual lipase, which cleaves triglycerides into fatty acids that can activate the CD36 receptor. When this receptor is activated, there is a rise in pancreatic secretions and an increase in their content [75].

Several gastrointestinal peptides have been studied as potential regulators of food intake. Most of these peptides, including cholecystokinin, gastrin-releasing peptide, oxyntomodulin, neuro-medin B and polypeptide YY3-36 [76] reduce food intake. Cholecystokinin (CCK) was the first peptide shown to reduce food intake in animals and humans alike [77]. Investigation of the growth hormone secretagogue receptor has led to the identification of a new gastrointestinal hormone involved with the control of feeding. This peptide, ghrelin, is produced in oxyntic cells of the gastric fundus. It is a 28 amino acid peptide with an n-octanoyl residue on the serine in the 3-position. It is encoded by a gene with the symbol GHRL (OMIM 506353, chromosome 3p26-p25), and is derived from a 117 amino acid precursor. It stimulates food intake and reduces energy expenditure by acting on NPY/AgRP neurons that in turn inhibit anorexigenic neuro-modulators that function through melanocortin and MC4R and works in animals and human beings when given systemically or into the brain. The level is low in overweight people, suggesting that it may have a role in controlling appetite and weight gain [78–80].

Pancreatic peptides, including amylin, glucagon-like peptide-1 (GLP-1), and enterostatin, also modulate feeding. Amylin is produced in the beta cell of the pancreas along with insulin and is co-secreted. In experimental studies, amylin has been shown to reduce food intake by acting on the amylin (calcitonin-like gene product) receptor. The major locations for this receptor are in the hind-brain and hypothalamus [81]. Pramlintide is a commercial analog of amylin which is currently used to treat diabetes. Both glucagon and its 629 amino acid derivative, GLP-1, reduce food intake in animals and humans. GLP-1 works in the brain and after peripheral administration. Exenatide is a GLP-1-like peptide isolated from the salivary glands of the Gila monster. It has been approved for the treatment of diabetes.

Nutrients may also be afferent signals to reduce food intake. A dip in the circulating level of glucose precedes the onset of eating in more than 50% of the meals in animals and human beings [82]. When this dip is blocked, food intake is delayed. The pattern recognized by this dip is independent of the level from which the drop in glucose begins. The small drop in glucose continues even when food is not available. The dip follows a small rise in insulin, suggesting a relationship of these two signals [1,77].

### The brain and food intake

The brain plays the central role as receiver, transducer and transmitter of information from the peripheral organs [83]. This control is accomplished through sensory organs and internal signals that are integrated through central neurotransmitters that in turn activate neural, hormonal and motor efferent pathways.

Function of the right prefrontal cortex (PFC) may be particularly important. Brain diseases that affect the PFC have suggested that this area is involved in cognitive processes relevant for food intake and physical activity, and dysfunction of this area may represent a central event in the etiology of human obesity [84]. Weight gain and overeating were common side effects of frontal leucotomy performed in the mid-1900s for psychosis. Damage to the right frontal lobe can cause the gourmand syndrome, a passion for eating and a specific preference for fine food. Hyperphagia correlates positively with right frontal atrophy and negatively with left frontal atrophy in degenerative dementia. Hypoperfusion of the right frontal lobe using single photon emission computed tomography (SPECT) can be demonstrated in overeating conditions such as Kleine–Levin syndrome. In contrast, hyperactivity of the right PFC can lead to anorexia-like symptoms.

Monoamines, such as norepinephrine, serotonin, dopamine and histamine, as well as certain amino acids and neuropeptides, are involved in the regulation of food intake. The serotonin system has been one of the most extensively studied of the monoamine pathways [1,77]. Its receptors modulate both the quantity of food eaten and macronutrient selection. Stimulation of the serotonin receptors in the paraventricular nucleus reduces fat intake with little or no effect on the intake of protein or carbohydrate. This reduction in fat intake is probably mediated through 5-HT<sub>2C</sub> receptors, because its effect is attenuated in mice that cannot express the 5-HT<sub>2C</sub> receptor.

Stimulation of  $\alpha_1$ -noradrenergic receptors also reduces food intake [1,77]. Phenylpropanolamine is an agonist acting on this receptor that has a modest inhibition of food intake. Some of the antagonists to the  $\alpha_1$  receptors that are used to treat hypertension produce weight gain, indicating that this receptor is also clinically important.

Stimulation of  $\alpha_2$  receptors increases food intake in experimental animals, and a polymorphism in the  $\alpha_{2a}$ -adrenoceptor has been associated with reduced metabolic rate in humans. The activation of  $\beta_2$  receptors in the brain, however, reduces food intake. These receptors can be activated by agonist drugs (beta-blockers), by releasing norepinephrine in the vicinity of these receptors, or by blocking the reuptake of norepinephrine.

Histamine receptors can also modulate feeding. Stimulation of the H<sub>1</sub> receptor in the central nervous system reduces feeding. Experimentally this has been utilized by modulating the H<sub>3</sub> autoreceptor, which controls histamine release. When the autoreceptor is stimulated, histamine secretion is reduced and food intake increases. Blockade of this H<sub>3</sub> autoreceptor decreases food intake. The histamine system is important in control of feeding because drugs that modulate histamine receptors may produce weight gain.

In animals, seasonally variable dopamine transmission in the suprachiasmatic nucleus appears to drive the storage of food at the appropriate time of year in anticipation of hibernation or migration. Loss-of-function mutations in the D<sub>2</sub> receptor gene are associated with overweight in human beings, and dopamine antagonists can induce obesity in humans. One suggestion is that

this is through modulation of nutrient partitioning, with obesity in humans or fat storage in migratory and hibernating species as the results [85].

The opioid receptors were the first group of peptide receptors shown to modulate feeding. They also modulate fat intake [86]. Both the mu and kappa opioid receptors can stimulate feeding. Stimulation of the mu-opioid receptors increases the intake of dietary fat in experimental animals. Corticotropin releasing hormone (CRH) and the closely related urocortin reduce food intake and body weight in experimental animals.

The endocannabinoid system is a most recent addition to the central controllers of feeding [87]. Tetrahydrocannabinol, isolated from the marijuana plant, stimulates food intake. Isolation of the cannabinoid receptor was followed by identification of two fatty acids, anandamide and 2-arachidonoylglycerol, which are endogenous ligands in the brain for this receptor. Infusion of anandamide or 2-arachidonoylglycerol into the brain stimulates food intake. The cannabinoid-1 (CB-1) receptor is a preganglionic receptor, meaning that its activation inhibits synaptic transmission. Antagonists to this receptor have been shown to reduce food intake and lead to weight loss. There is also a peripheral ligand, oleylethanolamide, which inhibits food intake.

The discovery of leptin in 1994 opened a new window on the control of food intake and body weight [1,77,88]. This peptide is produced primarily in adipose tissue, but can also be produced in the placenta and stomach. As a placental hormone it can be used as an indicator of trophoblastic activity in patients with trophoblastic tumors (hydatidiform moles or choriocarcinoma). Leptin is secreted into the circulation and acts on a number of tissues, with the brain being one of its most important targets. The response of leptin-deficient children to leptin indicates the critical role that this peptide has in the control of energy balance.

To act on leptin receptors in the brain, leptin must enter brain tissue, probably by transport across the blood–brain barrier [86]. Leptin acts on receptors in the arcuate nucleus near the base of the brain to regulate, in a reciprocal fashion, the production and release of at least four peptides. Leptin inhibits the production of neuropeptide Y (NPY) and agouti-related peptide (AGRP) while enhancing the production of pro-opiomelanocortin (POMC), the source of  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH) and cocaine and amphetamine-related transcript (CART) [86]. NPY is one of the most potent stimulators of food intake. It produces these effects through interaction with either the Y-1 or the Y-5 receptor. Mice that do not make NPY have no disturbances (phenotype) in food intake or body weight.

AGRP is the second peptide that is co-secreted with NPY into the paraventricular nucleus (PVN). This peptide antagonizes the inhibitory effect of  $\alpha$ -MSH on food intake. Animals that overexpress AGRP overeat because the inhibitory effects of  $\alpha$ -MSH are blocked.

The third peptide of interest in the arcuate nucleus is POMC, which is the precursor for several peptides, including  $\alpha$ -MSH.  $\alpha$ -MSH acts on the melanocortin-3 and melanocortin-4 (MC4) receptors in the medial hypothalamus to reduce feeding. When

these receptors are knocked out by genetic engineering, the mice become grossly overweight. In recent human studies, genetic defects in the melanocortin receptors are associated with significant excess of body weight. Many genetic alterations have been identified in the MC4 receptor, some of which are in the coding region of the gene and others in the regulatory components [89]. Some of these genetic changes profoundly affect feeding, whereas others have little or no effect.

Another important peptide in the arcuate nucleus is CART. This peptide is co-localized with POMC and, like  $\alpha$ -MSH, inhibits feeding. Antagonists to these peptides or drugs that prevent them from being degraded would make sense as potential treatment strategies.

Two other peptide systems with neurons located in the lateral hypothalamus in the brain have also been linked to the control of feeding. The first of these is melanin-concentrating hormone (MCH) [90]. This peptide increases food intake when injected into the ventricular system of the brain. It is found almost exclusively in the lateral hypothalamus. Animals that overexpress this peptide gain weight and animals that cannot produce this peptide are lean. These observations suggest an important physiologic function for MCH.

The second peptide is orexin A (also called hypocretin). This peptide was identified in a search of G-protein linked peptides that affect food intake. It increases food intake, but its effects are less robust than those described above. However, it does seem to have a role in sleep.

Another recent addition to the list of peptides involved in feeding is the arginine-phenylalanine-amide group (RFA). The first of these peptides to be isolated from a mollusk had only four amino acids. The structure of the RFA peptides is highly conserved, with nearly 80% homology between the frog, rat, cow and humans [91]. In mammals there are five genes and five receptors for these peptides. The 26 and 43 amino acid members of the RFA peptide family stimulate feeding in mammals and are the ligands for two orphan G-protein coupled receptors located in the lateral hypothalamus and the ventromedial nucleus. This family of peptides has been involved in feeding from early phylogenetic times including *Caenorhabditis elegans*. Their role in human beings is not yet established.

### Neural and hormonal control of metabolism

The motor system for acquisition of food and the endocrine and autonomic nervous systems provide the major information for control of the major efferent systems involved with acquiring food and regulating body fat stores. Among the endocrine controls are growth hormone, thyroid hormone, gonadal steroids (testosterone and estrogens), glucocorticoids and insulin.

During growth, growth hormone and thyroid hormone work together to increase the growth of the body. At puberty, gonadal steroids enter the picture and lead to shifts in the relationship of body fat to lean body mass in boys and girls. A distinctive role for growth hormone has been suggested from studies with transgenic mice overexpressing growth hormone in the central nervous

system. These mice are hyperphagic and obese, and show increased expression of NPY and agouti-related protein as well as marked hyperinsulinemia and peripheral insulin resistance [92]. Testosterone increases lean mass relative to fat and reduces visceral fat. Estrogen has the opposite effect. Testosterone levels fall as human males grow older, and there is a corresponding increase in visceral and total body fat and a decrease in lean body mass in older men. This may be compounded by the decline in growth hormone that is also associated with an increase in fat relative to lean mass, particularly visceral fat.

One recent finding suggests that the activity of the enzyme 11- $\beta$ -hydroxysteroid dehydrogenase type 1, which reversibly converts cortisone to cortisol, may be important in determining the quantity of visceral adipose tissue. Changes in this enzyme may contribute to the risk of women of developing more visceral fat after menopause. A high level of this enzyme keeps the quantity of cortisol in visceral fat high and provides a fertile ground for developing new fat cells.

The sympathetic nervous system is an important link between the brain and peripheral metabolism. It appears to be involved in the oscillation of fatty acids in visceral fat that accompanies the increased fat as dogs overeat a high-fat diet [93]. Using genetic homologous recombination (knockout) mice lacking the  $\beta$ 1,  $\beta$ 2 and  $\beta$ 3 receptor have been produced. These animals show a normophagic obesity with cold intolerance. They have higher circulating levels of free fatty acids. Thus sympathetic nervous system function is essential to prevent obesity and to resist cold [94–96].

---

## Conclusions

This chapter aims to provide a snapshot of our understanding of the regulatory systems for factors that are etiologic in obesity. Both epidemiologic and metabolic feedback models are reviewed in assembling this information. We have not reached the end of the story. It is clear, however, that we have a much better glimpse into its operation – one that can provide us a better framework for thinking about both the etiology of obesity and its possible treatments.

### Autoimmune type 1 diabetes

*Ahmed J. Delli, Helena Elding Larsson, Sten-A. Ivarsson & Åke Lernmark*

#### Keypoints

- The pathophysiologic mechanisms in type 1 diabetes (T1DM) involve loss of islet  $\beta$ -cell secretory function caused by selective killing of these cells primarily by aggressive autoimmune responses involving both cellular and humoral immune pathways.
- Inflammatory cells heavily infiltrate pancreatic islets leading to insulinitis where CD8<sup>+</sup> T lymphocytes are thought to be responsible for selective and specific killing of  $\beta$ -cells.
- The complex etiology of T1DM involves a strong genetic predisposition, mainly human leukocyte antigen class II genes, and several putative environmental factors, which are thought to trigger autoimmunity or progression to clinical T1DM.
- A preclinical prodrome in T1DM may vary in duration in which one or more islet autoantibodies may precede insulinitis and predict the disease at the early stages of pathologic insult.
- In genetically susceptible individuals with islet autoantibodies, metabolic indicators such as insulin release abnormalities and insulin resistance may best predict T1DM especially near clinical onset.
- Based on the improving understanding of the etiopathogenesis of T1DM, several clinical trials have been launched aiming at halting the autoimmunity responses, retarding disease progression or preserving remaining  $\beta$ -cell function after clinical onset.

---

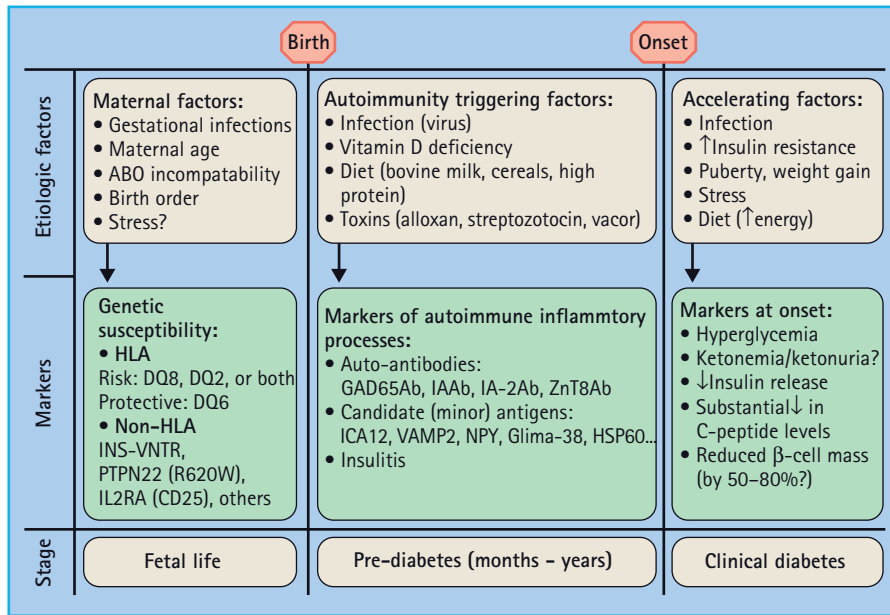

### Introduction

The differentiation between the two main forms of diabetes mellitus – type 1 (previously known as insulin dependent or juvenile onset) and type 2 diabetes (non-insulin dependent or adult onset) – has been possible for almost 50 years. In 1965, insulinitis was

rediscovered [1], supporting the view that autoimmune islet inflammation was associated with the etiopathology in type 1 diabetes mellitus (T1DM), a phenomenon absent in type 2 diabetes mellitus (T2DM) [2]. The evidence for islet autoimmunity was further supported during the last decade by the identification of cellular reactivity with islet antigens [3] and the association between T1DM and other organ-specific autoimmune disorders [4]. More importantly, the long sought after antibodies against islet cells (ICA) were finally detected in sera of patients with concomitant T1DM and autoimmune polyendocrine syndrome [5]. At the same time, T1DM was found to be strongly associated

**Figure 9.1** Schematic presentation of the natural history of type 1 diabetes (T1DM) showing possible etiopathologic factors and disease markers.

with the human leukocyte antigen (HLA) [6]. It was also noted, however, that around 10% of adult patients classified as having T2DM were positive for ICA, a group of patients now commonly known as having latent autoimmune diabetes of adults (LADA) [7]. Several genetic and autoimmune similarities are found between childhood T1DM and LADA; nevertheless, these two entities differ in other genetic and autoimmune processes [8].

T1DM results from an almost complete loss of insulin brought about by selective autoimmune destruction of the pancreatic islets β-cells, which manifests clinically as hyperglycemia-related symptoms and signs. Among non-Hispanic Caucasian populations, more than 90% of T1DM is immune-mediated (also known as T1ADM), in which HLA association is documented and one or more islet cell autoantibodies are detectable at time of diagnosis [2]. The remaining 10%, often termed “idiopathic” (also known as T1BDM as discussed later in this chapter), is highly inheritable but has neither HLA associations nor detectable islet cell autoantibodies [2]. The latter subgroup is found among non-Caucasian ethnic groups such as Asians [9], African-Americans and Hispanic-Americans and is thought to be related to viral infections [2,10]. Clinically, the two forms have similar clinical manifestations and diabetic ketoacidosis may develop in both.

The pathophysiologic mechanisms in T1DM include two distinct stages in genetically susceptible individuals:

- 1 Triggering of autoimmunity resulting in one or multiple islet cell autoantibodies associated with gradual β-cell killing; and
- 2 Loss of β-cell secretory function manifested by the loss of first-phase insulin release (FPIR), reduced C peptide levels, then glucose intolerance and finally hyperglycemia (Figure 9.1).

The autoimmune process with mononuclear infiltration of inflammatory cells (insulinitis) including autoreactive CD8<sup>+</sup> T lymphocytes selectively destroys the β-cells. Both the humoral and

cellular pathways of immunity are involved in the disease process; however, the role of B lymphocytes is evident in laboratory animals such as the non-obese diabetic (NOD) mice but not in humans [11]. Islet autoantibodies, however, may be present before insulinitis [12] and therefore may not be a direct consequence of insulinitis but rather markers of ensuing islet autoimmunity. The induction of islet autoimmunity in genetically susceptible individuals and the appearance of autoantibodies against specific islet cells autoantigens may precede the clinical syndrome by months to several years (Figure 9.2) [13]. During

this autoimmunity period the number of islet autoantibodies may reflect how  $\beta$ -cells are gradually destroyed. It is proposed that clinical manifestations became overt after loss of more than 80% of viable  $\beta$ -cell mass [14], although there may be variable degrees of both cellular regeneration and insulin sensitivity (Figure 9.3) [15].

The continuing progress in the understanding of the natural history of T1DM will be dependent on several longitudinal studies aiming at detecting factors that predict the disease and to implement both prevention and intervention trials.

## Etiology

The etiology of T1DM is multifaceted and may be divided into genetic and environmental etiology and possible gene–environment interactions. Genetic susceptibility increases predisposition for triggering islet autoimmune responses (Figure 9.1). Genetic factors may also help to accelerate the failure of  $\beta$ -cell secretion in response to exogenous environmental factors such as obesity.

## Genetics

The concordance rate of T1DM among monozygotic twins ranges from 30–50% up to 70% [16], depending on follow-up duration, compared to only 10–19% among dizygotic twins [17]. This variability highlights the complexity of etiologic components of T1DM that involves the interaction of multiple genetic factors with a variety of environmental factors. Although more than 85% of T1DM occurs in individuals with no previous first-degree family history, the risk among first-degree relatives is about 15 times higher than the general population [18]. An affected father confers a 6–9% risk of T1DM to his offspring compared to 2–4% if the mother is affected and up to 30% risk if both parents are affected [18,19].

The genetics of T1DM has been studied extensively despite the fact that the mode of inheritance remains uncertain. Recent genome-wide association studies have confirmed the strong associations between T1DM and HLA; however, at least 47 non-HLA genetic factors are thought to contribute. The most prominent genetic factors are listed in Table 9.1.

**Table 9.1** The most important genetic factors associated with the risk of type 1 diabetes mellitus (T1DM).

Genetic factor	Location	Description	Odds ratio
<b>HLA genes*</b>	Chr.6p21	Highest risk <i>Genotype</i>	18.7
HLA class II		Highest risk <i>Haplotypes</i>	2.0–11.4

‡Not *DRB1\*0403*.

The major histocompatibility complex (MHC) of the short arm of chromosome 6 harbors the main loci involved in the genetic susceptibility of T1DM as well as many other autoimmune diseases [20]. The HLA genes represent almost 50% of the familial risk of T1DM. Certain alleles of the HLA region, such as the HLA class II DR and DQ alleles, are mainly present in specific association with each other, a phenomenon known as linkage disequilibrium. The HLA association of T1DM (Table 9.1) is therefore often described by haplotype or genotype of the individual [21].

The genotype that confers the highest risk of T1DM is the heterozygosity of the two high-risk HLA class II haplotypes: DR3-DQ2 (*DRB1\*03-DQA1\*0501-B1\*0201*) and DR4-DQ8 (*DRB1\*04-DQA1\*0301-B1\*0302*) (Table 9.1) [21,22]. One or both of these haplotypes were found in more than 95% of people with T1DM younger than 30 years but also in approximately 40–50% of the general population [23]. The concomitant inheritance of high-risk alleles and haplotypes appears to increase the risk of T1DM significantly through synergistic association of their single risks. For example, in patients with T1DM, DQ8 (*DQA1\*0301-B1\*0302*) is mostly inherited with certain variants of *DRB1\*04* especially *DRB1\*0401*, *DRB1\*0404*, *DRB1\*0402* but not *DRB1\*0403* which has negative association (Table 9.1). DQ2 (*DQA1\*0501-B1\*0201*), however, is mostly inherited with *DRB1\*03* [21,24]. While certain alleles confer higher risk, such as

*DQB1\*0302*, *DRB1\*03* and *DRB1\*0401*, which possesses an independent risk, others confer protection and may “neutralize” high-risk alleles when they are inherited together [25]. The most common protective haplotypes are DQ6 (*DQA1\*0102-B1\*0602* and *DQA1\*0102-B1\*0603*), also *DQA1\*0101-B1\*0503* and *DQA1\*0202-B1\*0303* [21,26]. Furthermore, other HLA class II (such as DPB1) and class I alleles have also been associated with T1DM risk and the search for new associations is continuing (for review see [24]).

Using a candidate gene approach, several other non-HLA genes were found to be associated with increased risk of T1DM, but their contribution is less than the HLA haplotype associations (for references see <http://www.t1dbase.org/page/Welcome/display> or the T1D Genome Consortium website: <https://www.t1dgc.org/home.cfm>). The most important genes are *INS-VNTR* on chromosome 11, *PTPN22 (LYP)* on chromosome 1, *IL2RA (CD25)* on chromosome 10 (Table 9.1) [27].

### Environmental factors

The concordance rate of 50–70% among identical twins [16], the seasonality of diabetes incidence and time of birth [28], the association of diabetes with viral infections [29] and the fact that only 10% of HLA-susceptible individuals develop T1DM [28] are among several observations that indicate a possible etiologic role of environmental factors (Figure 9.1).

**Table 9.2** The main putative environmental risk factors associated with type 1 diabetes mellitus (T1DM).

Factor	Proposed effect mechanisms	Examples
Maternal factors	Triggering autoimmune response	Gestational infections
	Unknown	Higher maternal age
	Unknown	Higher birth order
	Unknown	ABO blood group incompatibility
Virus infections	Direct $\beta$ -cell killing (cytolysis)	Mumps virus
	Mimicry of $\beta$ -cell autoantigens	Rubella virus
	Autoreactive T-cell activation and subsequent $\beta$ -cell killing	Enterovirus/Coxsackie B virus
	Inhibition of insulin production through inducing expression of HLA genes and interferon	Rotavirus Cytomegalovirus Epstein–Barr virus
Dietary factors	Triggering autoimmune response	Bovine milk/short breastfeeding
	Triggering autoimmune response	Cereals
	Unknown	High protein content
	Lack of possible protective effect of vitamin D	Vitamin D deficiency
Factors related to insulin sensitivity and/or resistance	Stressing $\beta$ -cells with excess demands “accelerator hypothesis”	Puberty
	Increase insulin resistance	High energy food
		Weight gain
Psychologic stress	Affect hypothalamic-pituitary-adrenal axis leading to disturbance in autonomic nervous system and autoimmune dysregulation	Stress during pregnancy
		Child–parent separation
		Behavioral deviances
		Difficult adaptation
Toxic substances	Direct damage to $\beta$ -cells	Alloxan
		Streptozocin
		Vacor

The most prominent environmental factors (Table 9.2) include maternal factors [30], viral infections [29], dietary [31,32], high birth weight and growth rate [33], psychologic stress [34] and toxic substances [35]. The concurrent association of islet autoimmunity and factors increasing insulin resistance such as obesity and accelerated growth may boost the autoimmune destruction of  $\beta$ -cells [36]. The hygiene hypothesis proposes that better sanitation created a pathogen-free environment reducing the exposure to pathogens and their products. According to this hypothesis, the immune systems of children tend to be underdeveloped and therefore prone to autoimmune reactions. Additionally, it was also proposed that younger children received low-level antibodies from their mothers and, when exposed to infections such as enterovirus, it increased their T1DM risk [29].

---

## Pathogenesis

Autoimmune T1DM results from loss of immunologic tolerance to  $\beta$ -cells and environmental factors are thought to be involved in initiation or promotion of autoimmunity or both [28]. The selective destruction of  $\beta$ -cells implies specific mechanisms targeting  $\beta$ -cells by autoimmune reactions, which involve infiltration of pancreatic islets by  $CD4^+$  and  $CD8^+$  T lymphocytes and macrophages leading to insulinitis [1]. During the period preceding the clinical onset, autoantibodies targeting specific islet autoantigens such as insulin, glutamic acid decarboxylase (GAD65), islet antigen-2 (IA-2) and zinc transporter (ZnT8) may be detectable for months up to years before hyperglycemia becomes overt [11]. It has been assumed that the occurrence and number of islet autoantibodies such as GAD65Ab and IA-2Ab were associated with insulinitis [37]. A recent study, however, detected islet autoantibodies among 62 (4%) individuals out of 1507 pancreatic donors aged 25–60 years [12]. Although those 62 individuals also had HLA susceptibility, only two of them showed insulinitis, indicating that the presence of islet autoantibodies is not necessarily a marker of insulinitis. The exact role of these autoantibodies is therefore not understood and it needs to be established to what extent they are markers of  $\beta$ -cell destruction by cellular autoimmunity [38].

The intensity and duration of  $\beta$ -cell destruction varies and seems to be related to the presence of high-risk HLA haplotypes especially DR3-DQ2, DR4-DQ8, or both [39]. The HLA class II family molecules are expressed on the surface of antigen-presenting cells (APC) such as dendritic cells and macrophages but also on activated B and T lymphocytes or even activated endothelial cells. High-risk HLA molecules on APC are likely to facilitate activation of  $CD8^+$  T lymphocytes by  $CD4^+$  T lymphocytes. This activation is indirectly exemplified in T1DM siblings who developed the disease by the age of 12 years because T1DM occurred in 55% of siblings sharing the high-risk HLA DR3-DQ2/DR4-DQ8 genotype compared with only 5% of those who shared zero or one haplotype [40].

It has been widely claimed, based on autopsy studies, that around 80–90% of  $\beta$ -cells are already lost at clinical onset [14,41].

Recent reanalysis of patients who died soon after diagnosis, however, revealed that the level of  $\beta$ -cell loss required for hyperglycemia was age-dependent, being about 40% in subjects aged 20 years [42]. Additionally, there are suggestions that  $\beta$ -cell regeneration may have taken place, contributing to the approximately 50% of viable  $\beta$ -cells present at diagnosis [43]. The progressive destruction of  $\beta$ -cells is likely to vary in intensity and duration depending on the age at diagnosis [44]. It is a major drawback, however, that direct and precise assessments of  $\beta$ -cell loss before and after diagnosis are not available in humans. Much of the current knowledge of  $\beta$ -cell function prior to the clinical onset has been derived from laboratory animals such as NOD mice and bio-breeding rats [45]. The  $\beta$ -cell destruction in humans may be estimated indirectly by assessing insulin secretion during intravenous glucose tolerance tests (IVGTT). In particular, FPIR measured by insulin or C peptide is thought to reflect loss of  $\beta$ -cells and to predict T1DM [46]. Data from the Diabetes Prevention Trial Type 1 showed that post-challenge C peptide levels were remarkably reduced 6 months before clinical onset [47].

---

## Cellular autoimmunity

The genetic susceptibility of T1DM predisposing to loss of immunologic tolerance and eventual autoimmune killing of  $\beta$ -cells may be explained by a disordered antigen presenting mechanism [43]. The HLA class II molecules are heterodimers that regulate the immune response and are expressed on the surface of APC such as macrophages. The heterodimer binds peptides generated intracellularly either from self-proteins or from exogenous antigens taken up by phagocytosis. The resulting trimolecular complex represents the ligand for the T-cell receptor (TCR). The interaction between the trimolecular complex and the TCR activates the T lymphocyte. The HLA class II molecules on APC are responsible for antigen presentation to T-helper lymphocytes ( $CD4^+$ ). Upon non-antigenic stimulation, macrophages from people with T1DM and the high-risk HLA DQB1\*0201/\*0302 genotype showed excessive secretion of proinflammatory cytokines and prostaglandin  $E_2$  [48]. Cytokines may damage  $\beta$ -cells directly or indirectly by activating other cells such as T and B lymphocytes [49]. The APC presenting  $\beta$ -cell autoantigens may thus be actively involved in the anti-self autoimmune response that may result from failure to sustain self-recognition or from promoting an anti-self response. APC,  $CD4^+$  and  $CD8^+$  T lymphocytes were all detected in pancreatic autopsies of subjects who died shortly after onset [50], indicating their role in insulinitis. Autoreactive  $CD8^+$  T lymphocytes may have the most significant role in autoimmune destruction of  $\beta$ -cells [51]. Natural killer cells (NK) may also be found with abnormal activity and count [52]. The detection of autoreactive T lymphocytes in insulinitis and in the circulation at the time of diagnosis, in addition to the notion that immunosuppressive drugs such as cyclosporine or anti-CD3 monoclonal antibodies can temporarily abort disease progression, are all considered to support the role of cellular immunity in  $\beta$ -cell destruction [53].

The mechanism involved in  $\beta$ -cell destruction is not yet fully clear. One possible scenario is that  $\beta$ -cells are first destroyed by an environmental factor such as virus. The dying or dead  $\beta$ -cell is next phagocytosed by local dendritic cells (APC), which are then activated and migrate through the lymphatics to a pancreatic draining lymph node. The antigen presentation to and activation of CD4<sup>+</sup> T lymphocytes takes place in the lymph node to include activation of CD8<sup>+</sup> T lymphocytes specific for islet autoantigens. These islet autoantigen-specific CD8<sup>+</sup> T lymphocytes return to the blood circulation, eventually ending up in islets to destroy  $\beta$ -cells. The  $\beta$ -cell killing will generate a new cycle of islet autoantigen presentation known as epitope spreading [49,54]. CD4<sup>+</sup>CD25<sup>+</sup> regulatory T lymphocytes are also thought to have an important role in pathogenesis of T1DM as they may inhibit islet autoantigen specific CD4<sup>+</sup> T lymphocytes [54,55]. These cells express FOXP3 from the X chromosome and are important in development of peripheral tolerance.

The identification of islet autoantigen-specific T lymphocytes has been challenging and the development of standardized assays of T lymphocytes specific to islet autoantigens (insulin, GAD65 and IA-2) is still difficult to achieve [53,55]. Soluble HLA class II tetramer assays to assess autoantigen-specific T lymphocytes [56] and ELISPOT (enzyme-linked immunospot) [57] assays to measure cytokines of each T lymphocytes are tests to assess anti-islet autoantigen T-lymphocyte reactivity. During islet autoimmunity prior to the clinical onset these autoantigen-specific T lymphocytes may not be found in peripheral circulation, rather

they may accumulate in islets and are therefore hard to detect [58].

## Humoral autoimmunity

### Islet cell autoantibodies

The identification in 1974 of ICA was achieved using frozen pancreatic sections and indirect immunofluorescence [5]. Four years later, islet surface antibodies (ICSA) were identified [59] and complement-dependent antibody-mediated islet cell cytotoxicity was described in 1980 [60]. Because ICA assays showed wide variations among ICA-positive sera [61], assays specific to individual autoantigens were later developed to detect autoantibodies against GAD65, IA-2 [62], insulin [63] and recently ZnT8 (Table 9.3) [64]. Islet autoimmunity (single or multiple autoantibodies persistent for 3–6 months) proved to be useful in differentiating T1DM from other forms of diabetes [11]. Multiple islet autoantibodies ( $\geq 2$ ) usually appear within 6–12 months following the appearance of the first autoantibody (Figure 9.2) [65]. Nevertheless, some individuals develop transient islet autoantibodies but they are usually solitary and associated with lower risk [66], possibly because of the presence of protective genes such as HLA DR15–DQ6 [25]. One or more of these autoantibodies can be detected months up to years before clinical onset in more than 95% of newly diagnosed patients with T1DM, even as early as in the perinatal period [67]. Moreover, the detection

**Table 9.3** Characteristics of islet autoantigens and autoantibodies.

	GAD65	IA-2	Insulin	ZnT8
Chromosome	10p11	IA-2: 2q35-36 IA-2 $\beta$ : 7q36	11p15	8q24

Diagnostic sensitivity at 95% diagnostic specificity for insulin autoantibodies (IAA) were from [63].

of the four main autoantibodies may predict the disease by as much as 98% (Figure 9.2) [68].

### Glutamic acid decarboxylase autoantibodies

The enzyme glutamic acid decarboxylase (GAD) is found in neurons and islet  $\beta$ -cells and produces  $\gamma$ -aminobutyric acid (GABA), which is a major inhibitory neurotransmitter. The 64K protein identified as GAD after immunoprecipitation of human islet [69] was found to represent GAD65, not the previously known GAD67 isoform, which shares 65% of the GAD65 amino acid sequence [70]. Unlike GAD67, GAD65, which is encoded by a gene on chromosome 10p11, is expressed mainly in pancreatic islets (Table 9.3) [70].

Autoantibodies against GAD are most commonly to the GAD65 isoform (GAD65Ab), which were found in 70–80% of children with new onset T1DM, 8% of T1DM first-degree relatives but also in about 1% of general population [71]. Unlike ICA, GAD65Ab remain detectable for many years even after considerable loss of  $\beta$ -cell function [72]. Additionally, GAD65Ab detection rate rises with age in new onset T1DM. If the onset was before 10 years of age, some gender differences with female preference is observed. Because GAD65Ab levels are persistent, more prevalent and correlated well with plasma levels of C peptide [38], they are currently considered as good markers for both prediction and follow-up of  $\beta$ -cell dysfunction among individuals at risk.

GAD65Ab were found to be associated with the high-risk HLA haplotypes DR4-DQ8 (*DRB1\*04-DQA1\*0301-B1\*0302*) and DR3-DQ2 (*DRB1\*03-DQA1\*0501-B1\*0201*) [73] but more often with the latter [72]. Recently, anti-idiotypic GAD65Ab were found to be markers that have lower frequency in T1DM and their absence was more predictive than the presence of GAD65Ab [74]. GAD65Ab can be detected with both radiobinding assays and enzyme-linked immunosorbent assay (ELISA) and these assays have been assessed and standardized in the latest Diabetes Antibody Standardization Program (DASP) [62]. The high and improved performance of these assays emphasizes the value of these autoantibodies in prediction and classification of T1DM and also their value as screening tools in individuals at risk (Table 9.3).

### Islet antigen-2 autoantibodies IA-2Ab and IA-2 $\beta$ Ab

This autoantigen is a member of the plasma membrane protein tyrosine phosphatase family [75]. Its composed of two isoforms: IA-2 (formerly known as ICA512) which is a 40K protein encoded on chromosome 2, and IA-2 $\beta$  (phogrin) which is a 37K protein encoded on chromosome 7 (Table 9.3) [76]. The two isoforms share many common epitopes and are present in several neuroendocrine tissues in addition to pancreatic islets with no clear function because they lack enzymatic activity.

The autoantibody reactivity of IA-2Ab is directed to the cytoplasmic portion of the autoantigen and the immuno-reactivity in T1DM is directed against the C-terminal region of IA-2 [77]. IA-2Ab is detected in about 60–70% of patients with new-onset T1DM [78] and in less than 1% of the general population [79].

IA-2Ab are often preceded by IAA, GAD65Ab and ICA, respectively [65], and the frequency decreases with increased age of onset [80]. This indicates that the predictive and screening abilities of IA-2Ab are more useful for younger children especially when combined with GAD65Ab and other markers.

Using radiobinding assays to determine epitope-specific IA-2Ab/IA-2 $\beta$ Ab among healthy siblings of children with T1DM [81], it was found that progression to T1DM was more common with autoantibodies to the juxtamembrane region of IA-2 (IA-2-JM-Ab) while IgE-IA-2Ab conferred protection even when IA-2-JM-Ab were positive. Higher frequencies of IA-2Ab were found in association with *DRB1\*0401* rather than with DQ8 [72]. Furthermore, patients with DQ2 [82] had less association with IA-2Ab indicating a role for additional mechanisms related to the HLA genetic component.

Assays to identify IA-2Ab were developed and standardized using radiobinding tests that can precipitate IA-2Ab, IA-2 $\beta$ Ab along with GAD65Ab. These assays have high levels of sensitivity and specificity and were improved in subsequent DASP workshops [62]. Similarly, ELISA assays combining IA-2Ab and GAD65Ab using biotin-labeled preparations were also standardized and the latest evaluation showed progress in performance of these assays (Table 9.3) [62].

### Insulin autoantibodies

The most highly specific autoantigens of  $\beta$ -cells are insulin and its precursor proinsulin because they are expressed only in  $\beta$ -cells. In 1983, using radioligand-binding assays, insulin autoantibodies (IAA) were first identified in 50% of patients with newly diagnosed diabetes before initiating treatment with exogenous insulin [83]. IAA, which are able to react with both insulin and proinsulin, tend to be the earliest marker of islet autoimmunity [65] but their levels are often fluctuating and present in low titers. The predictive value for T1DM using IAA alone appears to be related to age; it is higher among younger children, possibly related to a higher rate of  $\beta$ -cell destruction. IAA were detectable in 90% of children who progress to T1DM before the age of 5 years compared with only 40–50% of adolescents older than 15 years (Table 9.3) [84].

DR4 is associated with a higher frequency of IAA, which may be related to the linkage disequilibrium with the high-risk DQ8 haplotype [85]. IAA were also associated with the insulin gene on chromosome 11p15 [86] where the number of tandem repeats (VNTR) were found to be associated with T1DM whether IAA were present or not.

Antibodies against exogenous insulin showed no correlation with IAA levels detected at clinical onset of T1DM and appear to be independent of autoimmunity [87]; however, they do share some similar binding features [88]. Unlike IAA, antibodies against exogenous insulin shows higher specificity, therefore they may be detected using the ELISA test, which does not predict T1DM [89]. The IAA fluid-phase radioimmunoassay shows high sensitivity and specificity to detect T1DM and has been modified to use less serum volume (25  $\mu$ L instead of 600  $\mu$ L) in

a new assay known as “micro-IAA” (Table 9.3) [90]. Nevertheless, poor inter-laboratory concordance remains a problem that has delayed standardization of IAA [63].

**ZnT8 Transporter (SLC30A8) autoantibodies ZnT8Ab**

The zinc transporter (ZnT8 isoform-8 transporter) has recently been described as a second novel β-cell-specific autoantigen, in addition to insulin [64]. A polymorphism in the gene encoding this autoantigen, SLC30A8, is also associated with the risk of T2DM [91]. ZnT8 is important for zinc-insulin crystallization and insulin secretion. It facilitates transport and accumulation of cytoplasmic zinc into the secretory vesicles of β-cells. Inside these vesicles, insulin molecules are co-crystallized with two Zn<sup>2+</sup> ions to form solid hexamers.

Nearly 60–80% of patients with new onset T1DM react positively to ZnT8Ab [91], which were detected in around 26% of patients who were negative for the conventional islet autoantibodies (GAD65Ab, IA-2Ab and IAA) [68]. By contrast, ZnT8Ab were detected in only 2% of controls and less than 3% of T2DM [68,91]. Additionally, ZnT8Ab were also detected in 30% of patients with other autoimmune diseases associated with T1DM [64]. Being a target of humoral immunity in T1DM, the high β-cell specificity of ZnT8 is seen as an advantage over other non-specific β-cell autoantigens such as GAD65 and IA-2. This high specificity and independence from other islet autoimmune markers, in addition to the fact that ZnT8Ab titers increase with age, all emphasize the value of ZnT8Ab in predicting T1DM, especially among older children.

The polymorphic *SLC30A8* gene located on chromosome 8 encodes the ZnT8 [91]. This locus and other chromosome 8 loci have not been associated with T1DM risk as such but were associated with the risk of ZnT8Ab [92]. ZnT8Ab were found to react with the C-terminal of the autoantigen and variation at amino acid position 325 determines two important susceptibility markers of ZnT8Ab, which can either be arginine (ZnT8-R) or tryptophan (ZnT8-W) [92]. Immunoprecipitation assays for ZnT8Ab were developed and fluid phase radioassays for the C-terminal of ZnT8Ab were standardized and validated in the DASP workshop (Table 9.3).

**Candidate (minor) autoantigens**

Several studies have reported associations of a group of molecules and substances with T1DM. This group included a wide variety of minor or candidate autoantigens that are thought to be associated with T1DM, autoimmunity or both; examples are, ICA12/SOX13 [93], glima-38 [94], vesicle-associated membrane protein-2 (VAMP2) [95], neuropeptide Y [95], carboxypeptidase H [96], GLUT-2 [97], heat shock protein 60 [98], imogen 38 [99], ICA69 [100] and others (Table 9.4).

**Conclusions**

Considerable progress has been made in the understanding of T1DM pathogenesis as it relates to the appearance of islet autoimmunity prior to the clinical onset of the disease. The development

**Table 9.4** The main candidate (minor) islet autoantigens.

Autoantigen	Molecular weight (kD)	Description	Autoantibody frequency
ICA12 (SOX13)	–	SOX family protein present in pancreas, kidney and placenta. Anti-SOX-13-Ab found more in children	T1DM: 10–30% T2DM: 6–9% Healthy controls: 2–4%
Glima-38	38	Amphiphilic glycosylated β-cell membrane protein. Specific expression on islet and neuron cells	New onset T1DM: 19% Prediabetes phase: 14% Healthy controls: missing
VAMP2	12.6	β-cell secretory vesicles-related protein	T1DM: 21% Healthy controls: 4%
NPY	10.9	β-cell secretory vesicles-related protein	T1DM: 9% Healthy controls: 2%
CPH	43.4	Carboxypeptidase B-like glycoprotein present in islets and brain. Related to cleavage of insulin from proinsulin	ICA* relatives: 20% Healthy controls: missing
GLUT-2	55	Glucose transporter type 2 of β-cells	New onset T1DM: 32–80% Healthy controls: 6.6%
HSP 60	60	A “stress” protein which is thought to be produced and upregulated in response to cellular stress	T1DM: 15% Rheumatoid arthritis: 20% Healthy controls: 1.2%
Imogen 38	38	A protein found in β-cell mitochondria and to a lesser extent in α-cells	No antibodies found
ICA 69	69	A peptide mainly present in islets and neuroendocrine, but also brain, kidney and lung	New onset T1DM: 5–30% Healthy controls: 6% Rheumatoid arthritis 20%

of standardized islet autoantibody tests (GAD65Ab, IA-2Ab, ZnT8Ab) has made it possible to begin screening for subjects at risk to be included in clinical trials aimed at preserving residual  $\beta$ -cell function. Analyses of cell-mediated immunity need further development and standardization to be useful in clinical trials. HLA-DQ on chromosome 6 remains the most important genetic factor for T1DM risk. It is well-established that these HLA class II heterodimeric proteins are necessary but not sufficient for disease. Recent genome-wide association studies have provided a smorgasbord of candidate factors to be explored for T1DM risk. We are still at a loss as to which environmental factor(s) may be responsible for triggering islet autoimmunity and studies such as The Environmental Determinants of Diabetes in the Young (TEDDY) [101] are needed to test fully the multitude of candidate triggers.

## Other Disorders with Type 1 Phenotype

Alice P.S. Kong & Juliana C.N. Chan

### Keypoints

- Patients with type 1 diabetes classically present early, require continuous insulin treatment and carry autoimmune markers such as antibodies to glutamic acid decarboxylase (GAD).
- There are other types of diabetes with type 1 phenotype secondary to heterogeneous etiologies including: maturity-onset diabetes of the young (MODY) and other forms of monogenic diabetes caused by mutations of mitochondria, amylin or pathways implicated in pancreatic  $\beta$ -cell function; latent autoimmune diabetes of adults (LADA); fulminant type 1 diabetes presenting with diabetic ketoacidosis after viral infections and another form which reverts to a clinical course resembling type 2 diabetes after the initial ketotic presentation.
- The correct diagnosis of these disorders with type 1 phenotype is clinically important because of their different clinical course, prognosis and management.

### Introduction

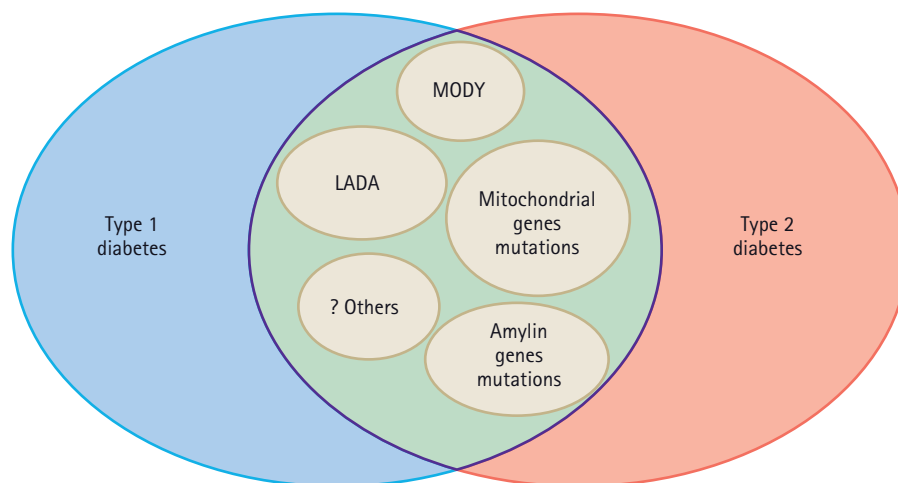

Classic type 1 diabetes mellitus (T1DM) is considered an autoimmune disease with pancreatic  $\beta$ -cell destruction. Affected subjects typically have onset of their disease at a young age with an acute presentation including diabetic ketoacidosis requiring continuous insulin treatment [1]. With a better understanding of the epidemiology and molecular mechanism of diabetes, however, clinical features such as the younger age of onset (e.g. less than 35 years old) or dependence on insulin treatment cannot adequately define the etiology of patients presenting with hyperglycemia.

Furthermore, there are major ethnic differences in disease pattern in terms of presentation and natural progression. In Caucasians, over 90% of patients with diabetes diagnosed before the age of 35 years have type 1 disease [1]. By contrast, autoimmune T1DM is uncommon in non-Caucasian populations [2–5]. Using Hong Kong as an example, which has a relatively homogeneous southern Chinese population leading an affluent lifestyle, less than 10% of adults presenting with diabetic ketoacidosis have autoimmune markers. Similarly, only 10% of Hong Kong Chinese patients with young onset of disease had a type 1 presentation or antibodies to glutamic acid decarboxylase (GAD) [6]. Similar epidemiologic findings have also been reported in other Asian populations from India, Malaysia, Singapore and Mainland

China [7]. In most case series, 60–80% of Caucasian people with T1DM have autoimmune markers such as autoantibodies to GAD and/or islet cell antigens (e.g. ICA-512). Conversely, 5–20% of young Asian patients with a non-ketotic presentation have autoimmune markers with a wide range of insulin reserve. These findings suggest that latent autoimmune diabetes in adults (LADA) is not uncommon in young patients with diabetes, especially those of Asian ethnicity, and there is considerable overlap between type 1 and 2 diabetes phenotypes (Figure 9.4) [6,8].

Our current understanding of the molecular pathways involved in the neogenesis, differentiation and maturation of pancreatic  $\beta$ -cells as well as the intracellular signaling mechanisms leading to insulin secretion are summarized in Figure 9.5. This large body of knowledge has provided the basis for the discovery and description of subtypes of diabetes with predominant  $\beta$ -cell failure from causes other than autoimmunity, such as monogenic diabetes. Patients with monogenic diabetes often have young onset of disease and lean body mass (see Chapter 15). They may also have delayed presentation with complications brought about by the insidious nature of their symptoms [9,10]. With the rising prevalence of young onset diabetes especially in low and middle income countries [11], there is a need for health care providers to be aware of these non-classic presentations of T1DM, because they have important implications on clinical management and family screening.

**Figure 9.4** There are considerable overlaps between the phenotypes of type 1 and type 2 diabetes because of the heterogeneous genetic and autoimmune etiologies. These include maturity-onset diabetes of the young (MODY), latent autoimmune diabetes in adult (LADA) and genetic variants affecting the insulin, amylin and mitochondrial pathways. Other rare causes include fibrocalculous pancreatic diabetes and fulminant type 1 diabetes.

### Atypical diabetes: heterogeneous etiologies of young-onset diabetes

In 1980, Winter *et al.* [12] first described a cohort of 129 African-American youths with acute ketotic presentation, of whom 12 patients subsequently did not require insulin and followed a clinical course resembling type 2 diabetes (T2DM). Since then, a number of reports have shown that there is a poor correlation between the mode of presentation of hyperglycemia, clinical course, need for insulin treatment and autoimmune status in different ethnic groups including Asians [13–15]. Many of these patients did not have HLA genotypes or autoantibodies typical of autoimmune T1DM. Some patients were obese, with insulin resistance and glucotoxicity contributing to the initial ketotic presentation [16].

Monogenic diabetes caused by genetic mutations encoding pathways implicated in insulin synthesis and secretion may lead to young-onset diabetes with atypical presentation. In young Chinese patients with diabetes, there is a higher prevalence of parental history of diabetes (32–47%), particularly maternal history, compared with those having a late onset of disease (12–19%) [10,17,18]. A progressively earlier age of onset of disease in successive generations has also been reported in some of these affected families [19]. These patients may exhibit a mixed phenotype, including young age of diagnosis, insulinopenia and normal body weight (as in type 1), with a non-ketotic state typical of T2DM, despite lack of insulin resistance and metabolic syndrome [20].

### Monogenic diabetes

#### Maturity-onset diabetes of the young

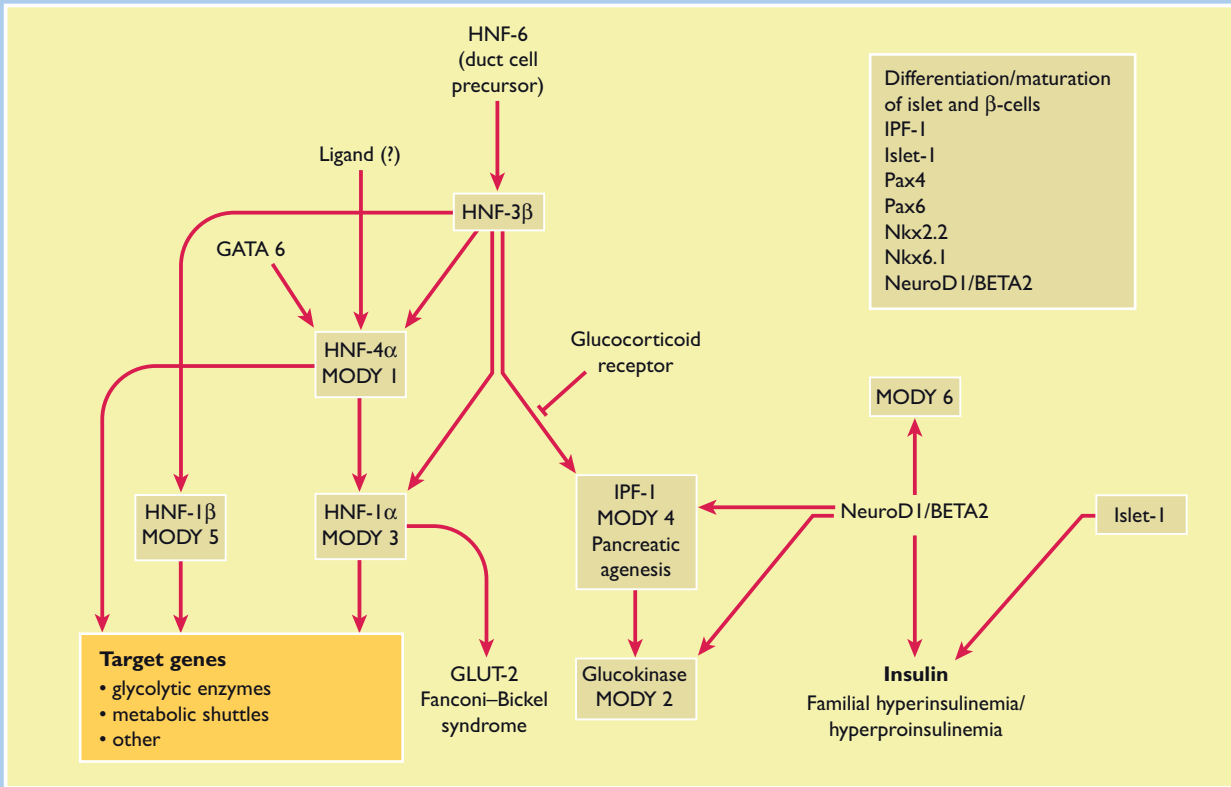

Patients with maturity-onset diabetes of the young (MODY) typically present before the age of 25 years with a strong family history suggestive of autosomal dominant inheritance (see

Chapter 15). Despite a non-ketotic mode of presentation, these patients often have features of abnormal pancreatic  $\beta$ -cell function. Some patients with MODY have a rapid deterioration in glycemic control after initial presentation while others experience mild hyperglycemia and do not require insulin despite having a long duration of disease.

To date, several subtypes of MODY have been reported. These include mutations of transcription factors: *MODY 1*: hepatic nuclear factor 4 $\alpha$  (HNF-4 $\alpha$ ); *MODY 3*: HNF-1 $\alpha$  or transcription factor 1 (TCF1); *MODY 4*: insulin promotion factor 1 (IPF-1); *MODY 5*: HNF-1 $\beta$  or transcription factor 2 (TCF-2); *MODY 6*: neurogenic differentiation 1 (NeuroD1) and *MODY 7*: carboxyl ester lipase (CEL) and glucokinase which is the glucose-sensor of the pancreatic  $\beta$ -cells (*MODY 2*). Transcription factors have key roles in pancreatic development including differentiation and proliferation of  $\beta$ -cells (Figure 9.4b). While genetic mutations in transcription factors typically cause significant insulin insufficiency and hyperglycemia, common polymorphisms of some of these transcription factors (e.g. HNF-1 $\alpha$  [21], HNF-4 $\alpha$  [22] and HNF-1 $\beta$  [23]) have also been shown to be associated with increased risk of diabetes or metabolic traits which may interact with other genetic or environmental and/or lifestyle factors to give rise to overt diabetes.

Over 80% of Caucasian patients with classic MODY (i.e. age of onset less than 25 years with autosomal pattern of inheritance) have been reported to have mutations in HNF-1 $\alpha$  or glucokinase, while other MODY subtypes (HNF-4 $\alpha$ , HNF-1 $\beta$  and IPF-1 mutations) were less common [24]. The frequencies of HNF-1 $\alpha$  mutations ranged 25–50% in French [25], 36% in German [26], 13–18% in British [27], 8% in Japanese [28] and 5% in Chinese patients [9]. In unrelated young Chinese patients with diabetes, 5–10% were found to have glucokinase or HNF-1 $\alpha$  mutations [13,29,30].

Although patients with some forms of MODY (e.g. *MODY 2*) have mild clinical course and rarely develop complications, other forms of MODY may be associated with severe insulin insufficiency and complications often brought about by the late pres-

(a)

(b)

entation and/or delayed use of insulin [10]. In light of the potential long duration of disease, young patients with diabetes are more prone to develop microvascular complications than those with late onset of disease [31], thus emphasizing the importance of family screening.

Furthermore, heterogeneous mutations in these transcription factors can be expressed sequentially in renal tubules with possible roles in various stages of the development of renal tubules [32]. Thus, patients with MODY may have heterogeneous phenotypes with metabolic and renal manifestations. Patients with MODY 3 from mutations in HNF-1 $\alpha$  were found to have a low renal threshold for glucose [33] while patients with MODY 5 from mutations in HNF-1 $\beta$  may have mild diabetes but increased susceptibility to severe renal disease and other urogenital malformations [34]. In a consecutive unrelated cohort consisting of 74 young Chinese patients with T2DM and nephropathy, a novel missense genetic variant in exon 3 (E260D, GAG→GAC) of the HNF-1 $\beta$  gene was identified. Extended family analysis revealed four other siblings carrying this variant with heterogeneity in clinical presentation that included one member with uncomplicated diabetes, one with impaired glucose tolerance and one with microalbuminuria with normal glucose tolerance. A silent polymorphism Q378Q was identified in another unrelated subject in this study. While these findings will need replication in independent and larger cohorts, the phenotypic heterogeneity associated with these genetic variants is noteworthy [35].

### Mitochondrial gene mutations

Mitochondria are important intracellular organelles in the maintenance of glucose homeostasis and energy balance. Mitochondria have their own genome and unlike nuclear DNA which is protected by histones, mitochondrial DNA is more vulnerable to oxidative stress and environmental toxins. Superoxide radicals generated by the mitochondrial respiratory chain are a major source of damage to mitochondrial DNA. Aged patients with a positive family history of diabetes have a high frequency of mitochondrial mutations [36]. Because of its maternal inheritance, mitochondrial DNA is a well-known cause of a subtype of maternally inherited diabetes mellitus [37].

In 1992, an A3243G mutation in the mitochondrial DNA coding for tRNA<sup>Leu(UUR)</sup> (mt3243) was first reported. This form of diabetes was found in patients with both type 1 and type 2 diabetes and was characterized by maternal inheritance and deafness [38]. In a random cohort of Chinese patients with diabetes, 1–3% had this mutation with either type 1 or type 2 clinical course [39–41]. Other point mutations associated with increased risk of diabetes include sites at 3316, 3394 and 14577 as well as deletion and rearrangement in mitochondrial DNA [36].

In keeping with its candidacy as a “thrifty gene,” the frequency of a common polymorphism of the mitochondrial DNA (T16189C) is higher in Chinese subjects with metabolic syndrome than those without (44% vs 33%), after adjustment for age and body mass index (BMI) [42]. In a meta-analysis, Asian subjects without diabetes had a higher frequency of the 16189C variant than their European counterparts (31.0% vs 9.2%) [43]. Despite negative reports in European populations [43], there are consistent data showing the risk association of the 16189C variant with T2DM in Asians [44,45].

### Amylin gene mutations

Amylin, a 37 amino acid polypeptide, is co-secreted with insulin by pancreatic  $\beta$ -cells. It is the principal constituent of the amyloid deposits in the islets of Langerhans in T2DM [46,47]. In autopsy series, pancreatic amyloidosis was associated with  $\beta$ -cell loss in both Caucasian and Chinese subjects [48–50]. It is now evident that formation of intracellular islet amyloid polypeptide (IAPP) oligomers may contribute to pancreatic  $\beta$ -cell loss and progressive hyperglycemia [47]. Changes in metabolic milieu or genetic variants encoding proteins involved in amylin metabolism may lead to structural changes of amylin and increased oligomerization with  $\beta$ -cell death [51].

A S20G variant of the amylin gene has been shown to enhance cytotoxicity in transfected COS-1 cells and amyloidogenicity *in vitro* [52,53]. This genetic variant is found in 2–3% of Japanese, Chinese and Pacific Islanders with diabetes [9,52,54–57]. In Taiwanese Chinese, normoglycemic carriers of the S20G variant had reduced early phase insulin secretion [58]. Co-segregation findings in family studies of S20G variant, however, are incon-

**Figure 9.5** (a) The cascade of transcription factors involved in pancreatic development as well as neogenesis, differentiation and maturation of pancreatic  $\beta$ -cells. Maturity-onset diabetes of the young (MODY) includes subtypes with mutations in transcription factors, namely MODY 1 with mutations of hepatic nuclear factor (HNF-4 $\alpha$ ); MODY 3: HNF-1 $\alpha$ ; MODY 4: insulin promotion factor (IPF-1); MODY 5: HNF-1 $\beta$ ; MODY 6: NeuroD1: neurogenic differentiation 1 and MODY 7: carboxyl ester lipase (CEL) as well as glucokinase (GK) which is the glucose-sensor of the pancreatic  $\beta$ -cells (MODY 2). There are also interactions of glucose transporter 2 (GLUT 2) and endodermal factor, including GATA and various important genes and transcription factors governing the differentiation and maturation of pancreatic islet and beta cells. These include Pax genes family and genes encoding the homeodomain transcription factor Nkx 2.2 and Nkx 6.1. In South Asian Indian population, interaction of the NeuroD1, neurogenin-3 (NEUROG3) and HNF-1 $\alpha$  genes has been observed to have combined effect in controlling islet cell development and insulin secretion, thus contributing to the overall glucose tolerance [93]. (b) The multiple steps involved in regulation of insulin secretion commencing with sensing of ambient blood glucose level by GLUT-2, glycolysis by GK, and ATP production by mitochondria. The generated ATP particles then close the potassium channel leading to membrane depolarization and opening of calcium channels. The intracellular calcium influx is associated with translocation of insulin and amylin containing vesicles to the cellular surface for exocytosis. During these processes, transcription factors are also activated resulting in insulin gene transcription and production to replenish the insulin containing vesicles and maintain continuous insulin secretion. GLUT, glucose transporter; MIDD, maternally inherited diabetes and deafness; MODY, maturity-onset diabetes of the young.

clusive, suggesting that it is likely to be a risk-modifying factor rather than a major diabetes gene [9,52,58].

### Other genetic mutations affecting pancreatic $\beta$ -cell function

Genetic variants of transcription factors implicated in pancreatic  $\beta$ -cell development, structure and function such as Pax6, Nkx2-2, Nkx6-1, NEUROG3 have also been reported in patients with type 1 or type 2 diabetes [59]. The pancreatic  $\beta$ -cell ATP-sensitive  $K^+$  channels ( $K_{ATP}$  channels) comprises of two subunits, the inwardly rectifying potassium channel Kir6.2 and the sulfonylurea receptor SUR1. This transmembrane channel has an important regulatory role in insulin secretion (Figure 9.5b). Genetic variants encoding the  $K_{ATP}$  channels subunits Kir6.2 (KCNJ11) and SUR1 (ABCC8) are associated with reduced insulin secretion and diabetes in different ethnic populations [60–65] including Asians [59]. In the recent genome-wide association studies, polymorphisms encoding components of these  $K_{ATP}$  channels such as KCNJ11 and KCNQ1 have also been found to be associated with 20–30% increased risk of diabetes in Caucasian and Asian populations [66,67].

---

### Autoimmune diabetes in adults

Autoantibodies to GAD are suggested to be sensitive markers of T1DM in Caucasians [13] although they can also be detected in patients with T2DM such as those with autoimmune diabetes in adults (LADA). In the UK Prospective Diabetes Study (UKPDS), approximately 10% of patients with T2DM had anti-GAD antibodies, the majority of whom eventually progressed to insulin dependency [68,69]. Reports from different ethnic groups suggest an estimated 10% prevalence of LADA in diabetic populations [68–70]. In Asians, 10–50% of patients with diabetes and acute or early onset of disease had anti-GAD antibodies depending on selection criteria and assay methodologies [2,6,13,71].

LADA is a slowly progressive form of autoimmune disease causing diabetes and is characterized by the presence of serum autoantibodies to pancreatic antigens [72,73]. Similar to T1DM, patients with LADA often carry other autoantibodies associated with celiac disease, adrenal and thyroid disorders [74,75]. Thus, it is plausible that LADA represents one end of a continuum of autoimmune diabetes with classic T1DM occupying the other end of the spectrum [76].

The nomenclature for this subtype of diabetes have been confusing, including T2DM with islet autoantibodies, slowly progressive insulin-dependent diabetes mellitus [77], type one-and-a-half diabetes [78,79], latent autoimmune diabetes in children (LADC) [80], latent autoimmune diabetes in the young (LADY) [81], autoimmune diabetes [82] and autoimmune diabetes in adults with slowly progressive  $\beta$ -cell failure (ADASP) [70], although LADA remains the most commonly used term. The World Health Organization (WHO) and American Diabetes Association (ADA) acknowledged LADA as a slowly progressive form of T1DM [83,84].

The correct diagnosis of LADA is clinically important because early use of insulin instead of sulphonylurea may prevent or reduce the rate of deterioration of  $\beta$ -cell function in these young patients with diabetes [85]. In patients with LADA, impaired  $\beta$ -cell response is evident at diagnosis and early use of insulin may reduce the adverse effects of glucotoxicity on  $\beta$ -cells [70,82]. Apart from high clinical suspicion, HLA studies may distinguish LADA from classic T1DM. In Caucasian populations, LADA is associated with HLA DQA1-DQB1\*0102(3)-\*0602(3)/X which is uncommon in patients with typical T1DM [86].

---

### Other subtypes of diabetes with type 1 phenotype

In Japan and Korea, uncommon cases of fulminant T1DM presenting with diabetic ketoacidosis (often after a viral infection) have been reported in both young and old patients. These cases were characterized by absence of insulinitis, negative autoantibodies, low C peptide levels, elevated pancreatic enzyme concentrations and association with HLA haplotypes [87,88].

In India, T2DM in youth often overlaps with monogenic forms of diabetes, fibrocalculous pancreatic diabetes and diabetes associated with malnourishment, all of which are ketosis-resistant forms of youth-onset diabetes [89]. In Indian patients with tropical calcific pancreatitis, the loss of endocrine function accompanying the exocrine damage may be an additional factor contributing to the clinical manifestation of diabetes in the presence of other stressors [90]. Using pancreatic specimens, Asian researchers have reported significant correlations between BMI and relatively low volume of  $\beta$ -cells [91] with amyloidosis, inflammation and fibrosis as common pathologic features [92].

---

### Conclusions

Until recently, autoimmune T1DM was considered to be the predominant form of diabetes in children and young adults. With a better understanding of the pathogenesis of diabetes, it is now recognized that genetic or acquired factors that affect the pancreatic  $\beta$ -cell structure and function as well as associated mechanisms such as amylin deposition and mitochondrial damage may give rise to a broad range of clinical manifestations with considerable overlap between type 1 and type 2 phenotypes. Detailed medical history-taking (e.g. family history of diabetes, mode of presentation and exposure to infection), a complete physical examination (e.g. body leanness, microvascular complications, metabolic syndrome and associated cardiovascular risk factors) and the use of appropriate laboratory testing (e.g. autoantibodies against pancreatic antigens and genetic markers) may help clinicians refine the diagnosis. This will help to guide the treatment of these patients who often present at a young age and have a long duration of diabetes ahead of them, this makes them especially at risk for the long-term chronic complications of diabetes.

## Abnormalities of Insulin Secretion and $\beta$ -Cell Defects in Type 2 Diabetes

**Mazen Alsahli & John E. Gerich**

University of Rochester School of Medicine, Rochester, NY, USA

### Keypoints

- Type 2 diabetes mellitus (T2DM) is a heterogeneous disorder caused by a combination of genetic and environmental factors which adversely affect  $\beta$ -cell function and tissue insulin sensitivity.
- About 10% of patients with phenotypic T2DM actually have a late-onset form of autoimmune diabetes while up to another 5% have autosomal dominantly inherited forms such as maturity-onset diabetes of the young and mitochondrial diabetes. The remaining 85% of patients have “garden variety” T2DM which is a polygenic disorder.
- The preponderance of available information indicate that genetic factors primarily affect  $\beta$ -cell function whereas acquired factors (obesity, physical inactivity, glucose and lipid toxicity) are mainly responsible for the insulin resistance seen in this condition. Impaired  $\beta$ -cell function can be detected in genetically predisposed individuals (i.e. the monozygotic twin or first-degree relative of someone who has T2DM) at a time when they have normal glucose tolerance and normal tissue insulin sensitivity.
- T2DM develops because of a progressive deterioration in  $\beta$ -cell function coupled with the addition of acquired insulin resistance for which the  $\beta$ -cell cannot compensate. At time of diagnosis,  $\beta$ -cell function is already reduced about 50% and most of the defects demonstrable in people with T2DM are already present in individuals with impaired glucose tolerance and those genetically predisposed to develop T2DM.
- Commonly found insulin secretion abnormalities include: absent first-phase and diminished second-phase release. Responses to ingestion of mixed meals and to non-glucose stimuli are reduced with a decrease in maximal secretory capacity. The secretory pulses, both rapid and ultradian, are smaller and less regular. The ratio of proinsulin to insulin release is also elevated.
- Normally there is a curvilinear hyperbolic relationship between  $\beta$ -cell function and tissue insulin sensitivity so that as tissue insulin sensitivity decreases (as in obesity and pregnancy),  $\beta$ -cell function increases in a compensatory fashion to maintain normal glucose tolerance. Prospective longitudinal studies have shown that people who have impaired glucose tolerance and progress to T2DM fall off this curve because of an inability of the  $\beta$ -cell to compensate for insulin resistance.
- Acquired factors also adversely affect  $\beta$ -cell function and contribute to the development of T2DM. These include adverse effects of hyperglycemia and increased plasma free fatty acids, respectively termed glucotoxicity and lipotoxicity, alterations in incretins (GLP-1, GIP) and malnutrition *in utero* and in early life which may affect programming of the  $\beta$ -cell with respect to glucose sensing, apoptosis, regeneration and the ability to compensate for insulin resistance. Endoplasmic reticulum stress-induced apoptosis and the effect interleukin-1 $\beta$  has on  $\beta$ -cell function and life cycle are recently receiving more attention for their role in the pathogenesis of T2DM.
- A pathologic feature present in 90% of patients with T2DM is the abnormal extracellular deposits of islet amyloid. It is composed of insoluble fibrils formed from the protein islet amyloid polypeptide (IAPP). Other histologic changes include a 30–50% decrease in islet mass and an alteration in the relative proportion of the islet cell population.
- The IAPP and its amyloid deposits have not been clearly found to be cytotoxic to  $\beta$ -cell and recent evidence from animal studies suggests that the formation of intracellular smaller IAPP oligomers is possibly the cytotoxic form associated with increased  $\beta$ -cell apoptosis.

Type 2 diabetes (T2DM) is a heterogeneous disorder, phenotypically, genotypically and pathogenetically. Approximately 10% of patients have a late-onset form of autoimmune diabetes which may represent a hybrid of type 1 and type 2 diabetes

(see Chapter 9) [1]; up to another 5% of patients have one of the autosomally dominant inherited forms of maturity-onset diabetes of youth (MODY); another 1% may have rare genetic mutations involving insulin receptors and elements of the insulin signaling pathway (see Chapter 15). The remaining 85% of patients have “garden variety” T2DM which is the subject of this chapter.

## Impaired $\beta$ -cell function vs insulin resistance

The common variety of T2DM results from a combination of genetic and acquired factors which adversely affect  $\beta$ -cell function and tissue insulin sensitivity (see Chapter 11) [2,3]. For many years it was controversial whether impaired  $\beta$ -cell function or tissue insulin resistance was the underlying pathogenetic element. Until recently, it was generally thought that insulin resistance preceded  $\beta$ -cell dysfunction and was the primary genetic factor, while  $\beta$ -cell dysfunction was a late phenomenon brought about by exhaustion after years of compensatory hypersecretion [4–6]. During the past several years, however, the accumulation of evidence from sophisticated studies examining  $\beta$ -cell function and tissue insulin sensitivity, both cross-sectionally and longitudinally, have swung the pendulum over to the concept that impaired  $\beta$ -cell function is the primary underlying, probably genetic, defect [2,7–9].

The idea that insulin resistance could be the primary defect can be traced back to the classic studies of Himsworth & Kerr [10] more than 60 years ago, in which it was demonstrated that lean patients with early-onset diabetes were sensitive to exogenous injection of insulin, whereas obese patients with late-onset diabetes were resistant. Twenty-one years later, the first measurement of plasma insulin levels in patients with T2DM [11] found that they had greater than normal values in the fasting and postprandial state, providing further evidence for insulin resistance. Over the following 40 years, numerous studies (summarized in [4,5,12]) reported that patients with T2DM, people with impaired glucose tolerance (IGT), and first-degree relatives of individuals with T2DM who subsequently developed T2DM were hyperinsulinemic and insulin resistant [13,14].

The problem with interpretation of the results of these studies is that they failed to take the following into consideration:

- Importance of the dynamics of insulin secretion.
- Appropriateness of the plasma insulin level for the prevailing stimulus for insulin secretion (i.e. plasma glucose level).
- Relation of  $\beta$ -cell function to insulin resistance.

### Importance of the dynamics of insulin secretion

Although the finding was originally described by Yalow & Berson in 1960, it was not well appreciated until 1967 that, during oral glucose tolerance tests, the elevated 2-hour post-challenge plasma insulin levels in people with T2DM were accompanied by reduced early (30 minute) insulin responses [15]. These decreases in early insulin release are evident even in individuals with mild IGT (Figure 10.1). This reduction in early insulin response has been shown to diminish suppression of endogenous glucose production after glucose ingestion [16]; the resultant hyperglycemia provides a greater stimulus to the  $\beta$ -cell, explaining the late (2 hour) hyperinsulinemia. The latter had often been erroneously interpreted to be the result of insulin resistance [4–6]. Studies in normal volunteers, however, in whom early insulin responses were diminished by infusion of somatostatin so as to simulate the

**Figure 10.1** Relationship between early (30 minutes) and late (2 hour) plasma insulin levels and 2-hour plasma glucose levels during oral glucose tolerance tests ( $n = 294$ , mean  $\pm$  SEM). Reproduced from Gerich [2], with permission from The Endocrine Society.

situation in people with IGT and T2DM produced late hyperinsulinemia [17]. Moreover, restoration of early insulin responses either by insulin or an insulin secretagogue reduces late hyperinsulinemia [18,19].

### Appropriateness of the plasma insulin level for the prevailing glucose level

The major factor acutely regulating insulin is the plasma glucose concentration. In addition to glucose, increases in circulating amino acid, free fatty acid (FFA), gastrointestinal hormones (incretins: glucagon-like peptide [GLP-1], glucose-dependent insulinotropic peptide [GIP]) augment insulin secretion whereas increases in other factors such as catecholamines, cortisol, growth hormone, leptin, and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) can reduce  $\beta$ -cell responses (see Chapter 6).

As glucose is the predominant stimulus for insulin secretion, the prevailing plasma glucose concentration must be taken into consideration in judging whether the plasma insulin concentration is appropriate. For example, the plasma insulin level in an individual with diabetes whose plasma glucose concentration is 180 mg/dL (10 mmol/L) may be twice as great as that of an individual without diabetes with a plasma glucose concentration of 90 mg/dL (5 mmol/L), but is clearly inappropriate because the non-diabetic individual would have a plasma insulin level four times as great at the same hyperglycemia [20]. Such evaluation is difficult with data from oral glucose tolerance tests (OGTT). Although equations exist that relate OGTT responses to those of hyperglycemic clamps [21], the latter are considered to be the gold standard for assessing  $\beta$ -cell function, because with this technique an identical stimulus for insulin release is used and both phases of insulin release can be evaluated.

**Figure 10.2** Curvilinear relationship between  $\beta$ -cell function (represented by the acute insulin response to intravenous arginine) and insulin sensitivity (represented by the glucose infusion rate necessary to maintain euglycemia [M] during a hyperinsulinemic clamp). People who maintained normal glucose tolerance (NGT) stayed on the curvilinear line. People whose glucose tolerance deteriorated to impaired glucose tolerance (IGT) and to type 2 diabetes (DM) fell below the line, demonstrating inadequate  $\beta$ -cell compensation for insulin resistance. Reproduced from Weyer *et al.* [22], with permission from the American Society for Clinical Investigation.

### Relation of $\beta$ -cell function to insulin resistance

Obesity and other acquired factors that cause insulin resistance result in an adaptation of the  $\beta$ -cell so as to maintain normal glucose homeostasis [7,22]. This adaptation, first demonstrated in the case of obesity in 1974, results in an increase in the  $\beta$ -cell sensitivity to glucose [23]. The hyperbolic relationship between  $\beta$ -cell function and tissue insulin sensitivity, first demonstrated by Bergman *et al.* [24] in 1981 and subsequently confirmed in numerous other studies [7,22,25], exists in such a way that as tissue insulin sensitivity decreases,  $\beta$ -cell function increases to maintain normal glucose homeostasis (Figure 10.2). Thus, in addition to the prevailing stimulus for insulin secretion (e.g. plasma glucose concentration) the status of an individual's insulin sensitivity must be taken into consideration in order to assess the appropriateness of  $\beta$ -cell function [7,8].

### Role of $\beta$ -cell defects in the natural history of type 2 diabetes

Longitudinal and cross-sectional studies indicate that most individuals destined to develop T2DM pass through five stages (Figure 10.3) [7,8,26]. The first stage begins at birth, when glucose homeostasis is normal but individuals are at risk for T2DM because of genetic polymorphisms (diabetogenic genes) or an *in utero* environment predisposing them to become obese and limit-

**Figure 10.3** The stages of glucose tolerance and associated  $\beta$ -cell function and insulin sensitivity, from normal glucose tolerance (NGT) through impaired glucose tolerance (IGT), with or without impaired fasting glucose (IFG), and finally type 2 diabetes mellitus (DM).

ing the ability of their pancreatic  $\beta$ -cells to compensate for insulin resistance. In genetically predisposed individuals with normal glucose tolerance, impaired  $\beta$ -cell function is demonstrable even when no insulin resistance is apparent [27–29]. During stage 2, decreases in insulin sensitivity emerge usually as a result of unhealthy lifestyles (environmental), and these, at least initially, are compensated for by an increase in  $\beta$ -cell secretion so that glucose tolerance remains normal. Nevertheless, despite this increase in insulin secretion, a reduction in  $\beta$ -cell function can be demonstrated even when individuals' plasma glucose levels are in the normal range [27–31]. During stage 3,  $\beta$ -cell function deteriorates further to the point that when challenged, as during a glucose tolerance test or a standardized meal, postprandial glucose tolerance becomes abnormal. At this point,  $\beta$ -cell function is clearly abnormal but sufficient to maintain normal fasting plasma glucose concentrations. In stage 4, there is further deterioration in  $\beta$ -cell function noted at least in part from glucose toxicity as a result of postprandial hyperglycemia. This also can reduce insulin sensitivity. Fasting plasma glucose concentrations increase in this stage because of an increase in basal endogenous glucose production. Finally, in stage 5, as a result of further deterioration

in  $\beta$ -cell function, both fasting and postprandial glucose levels reach levels diagnostic of diabetes.

Insulin secretion normally decreases with age. The decline rate has been shown to be about 0.7–1% per year for basal and glucose-stimulated insulin secretion during adult human life in individuals with normal glucose tolerance [32–36]. The rate of decline is about twofold greater in people with IGT [33] and reaches approximately 6% per year in patients with T2DM [37,38]. Insulin sensitivity does not decrease per se with aging and decreases in insulin sensitivity when observed are most likely related to other factors such as changes in body composition and physical fitness.

### Insulin secretion in type 2 diabetes, in IGT and in genetically predisposed individuals with normal glucose tolerance

#### Overview of insulin secretion in healthy individuals

Proinsulin, the insulin precursor, is converted to insulin and C peptide within the  $\beta$ -cell secretory granule. The conversion process requires the sequential action of three peptidase enzymes (prohormone convertases 2 and 3, and carboxypeptidase H) and produces four proinsulin conversion intermediates (32,33-split, 65,66-split, des-31,32-split, and des-64,65-split proinsulins) before ultimately yielding insulin and C peptide (see Figure 6.5). Normally, a small amount of intact proinsulin and its conversion intermediates, mostly the des-31,32-split proinsulin, are released into the circulation along with insulin and C peptide. They are estimated to constitute 10–20% of total immunoreactive insulin measured in the circulation during the basal state [39,40].

The events that lead to release of insulin from  $\beta$ -cells are complex (see Chapter 6). In response to an acute square wave of hyperglycemia such as that used in hyperglycemic clamp experiments in humans or in studies of perfused rat pancreas, insulin release is biphasic (Figure 10.4). It is characterized by an acute increase in insulin release lasting approximately 10 minutes, termed first-phase release, followed by a slowly increasing second phase of insulin release that is more sustained and typically persists as long as glucose is elevated. The first-phase release has been related to insulin-secretory granules located close to the  $\beta$ -cell plasma membrane (immediate releasable pool). In response to an increase in extracellular glucose, islet ATP and cyclic adenosine monophosphate (cAMP) levels increase, causing closure of ATP-sensitive potassium channels; this causes depolarization of the  $\beta$ -cell membrane and an influx of calcium through voltage-sensitive calcium channels; the resultant increase in intracellular calcium leads to movement of insulin-containing granules toward the  $\beta$ -cell membrane, where they merge/incorporate/melt into the membrane with release of the granules' contents. The second-phase insulin release involves synthesis of new insulin molecules as well as ATP-dependent mobilization of granules from a storage pool into the rapidly releasable pool (see Chapter 6). Thus, the normal  $\beta$ -cell response to an increase in glucose concentration is

**Figure 10.4** Biphasic plasma insulin responses during a square wave hyperglycemic clamp in normal volunteers with and without a first-degree relative with type 2 diabetes. Reproduced from Pimenta *et al.* [29], with permission from the American Medical Association.

dependent upon glucose entry in the  $\beta$ -cell and its metabolism, synthesis of insulin and insulin granules, cytochemical structures (microfilaments/microtubules) and other proteins necessary for moving granules toward the  $\beta$ -cell membrane and facilitating their melting into the membrane so that their contents can be released.

The insulin secretion pattern throughout the day is more complicated than that seen during acute square wave of hyperglycemia in hyperglycemic clamp experiments. *In vivo* insulin secretion was found to be pulsatile, undergoing short (rapid) and long (ultradian) oscillations. The basis for these is still poorly understood, but there is evidence that the integrity of these responses is necessary for maintenance of normal glucose homeostasis [41]. The rapid oscillations correspond to serial secretory insulin bursts (Figure 10.5). These high frequency bursts occur every 5–15 minutes and account for the majority of insulin secreted in humans [42–44]. Additionally, enhanced insulin secretion following stimulation with GLP-1, sulfonylureas, or oral glucose can be accounted for by increase in the amplitude of these secretory pulses [45–48]. By contrast, inhibition of insulin

**Figure 10.5** Insulin concentration profile in a canine portal vein illustrating the rapid secretory oscillations before and after glucose ingestion. There is a marked increase in pulse amplitude after glucose ingestion (arrow). Reproduced from Porksen *et al.* [47], with permission from the American Diabetes Association.

secretion by somatostatin or insulin-like growth factor 1 (IGF-1) is accomplished by a decrease in the amplitude of these pulses [49,50]. These rapid oscillations are superimposed on slower and larger ultradian oscillations (Figure 10.6) which occur every 80–150 minutes. The ultradian oscillations are present during basal conditions and have clear amplification after meals. They also tend to closely follow similar oscillations of plasma glucose [51,52].

### Abnormalities in type 2 diabetes

Defects in  $\beta$ -cell function are quite obvious by the time T2DM is diagnosed. For example, in the UK Prospective Diabetes Study, evaluation of  $\beta$ -cell function using the homeostasis model assessment (HOMA) indicated that  $\beta$ -cell function was at diagnosis already reduced by 50% and that there was subsequent further deterioration, regardless of therapy (Figure 10.7) [37]. Commonly found abnormalities include absent first-phase and diminished second-phase release in response to hyperglycemia in hyperglycemic clamp experiments [53–55]. Responses to ingestion of mixed meals (Figure 10.8) and to non-glucose stimuli are delayed or blunted with a decrease in maximal secretory capacity [55–58]. Abnormal oscillatory pattern is also observed. The pulses, both rapid and ultradian, are smaller and less regular. The ultradian

pulses are less amplified after meals and less likely to follow plasma glucose oscillations [42,59].

The ratio of proinsulin and its conversion intermediates to insulin in the circulation is at least twice as high in patients with T2DM than population norms. The increased ratio is noted in the basal and stimulated insulin secretion states and indicates less successful proinsulin to insulin conversion within  $\beta$ -cell secretory granules [39,40,60].

### Abnormalities in patients with IGT and in genetically predisposed individuals

Most of the above abnormalities are also found in individuals with IGT, although at a lesser intensity. These include reduced first and second-phase responses to intravenous glucose (Figure 10.9) [61], reduced early insulin response to oral glucose [16], decreased responses to non-glucose stimuli [62], reduced ability of the  $\beta$ -cell to compensate for insulin resistance [7,22], alterations in rapid and ultradian oscillations of insulin secretion [63,64] as well as increased proinsulin:insulin ratio [65].

Perhaps the most convincing evidence that impaired  $\beta$ -cell function is the primary genetic defect comes from studies of first-degree relatives of individuals with T2DM who still have normal glucose tolerance but have reduced insulin responses in the absence of insulin resistance [2,61], especially studies of monozygotic twins [31,66–68].

Other than hyperinsulinemia to compensate for the increased insulin resistance, obese patients have insulin secretion pattern similar to non-obese subjects, and most of the above abnormalities are not present in obesity in the absence of comorbid diabetes or IGT conditions [51,69].

## Possible mechanisms

### Genetic causes

$\beta$ -Cell dysfunction in T2DM results from a combination of genetic and acquired factors. Unlike MODY, “garden variety” T2DM is a polygenic disorder; this means that multiple genes (i.e. polymorphisms), each insufficient in themselves, must be present with or without acquired abnormalities in order to cause diabetes [70,71]. Such genes may affect  $\beta$ -cell apoptosis, regeneration, glucose sensing, glucose metabolism, ion channels, energy transduction, microtubules/microfilaments and other islet proteins necessary for the synthesis, packaging, movement and release of secretory granules [72,73]. To date, only a few polymorphisms have been identified as risk factors with confidence (see Chapter 12): one involves an amino acid polymorphism (Pro12Ala) in the peroxisome proliferator-activated receptor- $\gamma$  (PPAR $\gamma$ ), which is expressed in insulin target tissues and  $\beta$ -cells [74]; this apparently conveys susceptibility to adverse effects of FFA on insulin release. A second involves the gene encoding calpain-10, a cysteine protease that modulates insulin release as well as insulin effects on muscle and adipose tissue [75]. A third is the E23K variant of the *KIR6.2* gene (potassium inwardly-rectifying channel J11 gene),

**Figure 10.6** Twenty-four hour insulin secretory profile showing ultradian oscillations in a normal weight subject. Meals were consumed at 0900, 1300 and 1800. Statistically significant pulses of secretion are shown by the arrows. Reproduced from Polonsky *et al.* [51], with permission from the American Society for Clinical Investigation.

**Figure 10.7**  $\beta$ -Cell function as measured by the homeostasis model assessment (HOMA) method in patients with type 2 diabetes from the UK Prospective Diabetes Study (UKPDS).  $\beta$ -Cell function is already reduced to 50% at diagnosis and declines thereafter, despite therapy. Adapted from UK Prospective Diabetes Study Group [37].

which has been shown in a large association study to increase the risk of T2DM presumably through its effect on  $\beta$ -cells' potassium channel and, in turn, on insulin secretion [76,77].

More recently, variants of the transcription factor 7-like 2 gene (*TCF7L2*) were found to be associated with increased risk of T2DM [78–80]. Insulin secretion is decreased in carriers of the at-risk alleles [78]. This is thought to be a result of impaired expression of GLP-1, a peptide encoded by the human glucagon gene (*GCG*) whose expression in gut endocrine cells is regulated by *TCF7L2* [81].

Use of knockout techniques in mice has identified several elements of the insulin signaling cascade that might be potential sites where genetic polymorphisms may affect  $\beta$ -cell function, but to date none of these has been found to occur in people with T2DM [82].

### Acquired factors

Several acquired and/or environment factors have been identified that may increase the risk for developing T2DM by impairing  $\beta$ -cell function.

**Figure 10.8** Plasma concentrations of glucose and insulin in subjects with type 2 diabetes and non-diabetic control subjects in response to mixed meals. Adapted from Polonsky *et al.* [165].

### Malnutrition *in utero* and early childhood

Animal experiments and retrospective studies in humans have provided evidence that malnutrition *in utero* and early childhood, as well as *in utero* exposure to hyperglycemia, is associated with an increased risk to develop T2DM later in life. Hales *et al.* [83,84] demonstrated an inverse relationship between weight at birth and at 1 year and the development of T2DM in adult life. It was proposed that malnutrition *in utero* and during the first few months of life may damage  $\beta$ -cell development; it is also possible that nutritional deficiency at this stage may program the  $\beta$ -cell so as to limit its subsequent ability to adapt to overnutrition. The latter possibility is supported by the fact that the strongest link was

**Figure 10.9**  $\beta$ -Cell function in individuals with normal glucose tolerance and impaired glucose tolerance (IGT), with or without a family history of diabetes. Data from Van Haefen *et al.* [61].

between those who were born thin and subsequently became obese. Recall that one of the hallmarks of individuals destined to develop T2DM is their failure to increase their insulin release appropriately to compensate for their acquired insulin resistance [85]. Nevertheless, because not all individuals with early life malnutrition subsequently develop T2DM if they become obese, this situation must be viewed as one risk factor among many that influence susceptibility.

### Glucotoxicity

There is abundant evidence that both prolonged [86] and acute hyperglycemia [87] can adversely affect  $\beta$ -cell function. Moreover, improving glycemic control with the use of secretagogues, insulin sensitizers and even insulin will improve  $\beta$ -cell function in patients with T2DM [88–91]. The mechanisms by which hyperglycemia exerts its adverse effects on  $\beta$ -cells are complex and multifactorial. There is evidence that these mechanisms involve increased production of reactive oxygen species (ROS) within  $\beta$ -cells, oxidative stress-induced alteration of genes transcription and proteins expression, and increased  $\beta$ -cell apoptosis [92]. Nevertheless, because impaired  $\beta$ -cell dysfunction is clearly evident in genetically predisposed individuals with normal glucose tolerance [2] and because optimization of glycemic control does not completely reverse impaired  $\beta$ -cell function in T2DM, this so-called glucotoxicity is clearly a secondary phenomenon but one that could accelerate deterioration over time.

### Lipotoxicity

In addition to elevated levels of plasma glucose, individuals with T2DM have increased circulating levels of FFA as do people who are obese [93]. Obese individuals have greater plasma FFA levels primarily because of their greater fat mass [94]. Obese people with T2DM have somewhat greater circulating FFA levels than obese people without T2DM, not because of greater release of FFA into the circulation, but because of decreased FFA clearance

[95]. A number of *in vitro* and animal studies have demonstrated that prolonged elevation of plasma FFA impairs  $\beta$ -cell function [96,97]. Evidence suggests that fatty acids inhibit glucose stimulated insulin secretion, impair insulin gene expression and, more importantly, promote  $\beta$ -cell apoptosis [92]. One proposed mechanism involves the uncoupling protein-2 (UCP-2), a mitochondrial carrier protein that uncouples substrate oxidation from ATP synthesis [98]. FFA increase UCP-2 activity in  $\beta$ -cells. This impairs ATP generation from glucose metabolism and consequently decreases glucose stimulated insulin secretion [99,100]. FFA impair insulin gene expression by increasing ceramide generation which reduces the binding activity of pancreas-duodenum homeobox-1 (Pdx-1) and MafA, two transcription factors essential for regulation of multiple islet-associated genes including insulin gene [101]. In healthy human volunteers, however, it has not been possible to demonstrate consistently a deleterious effect of acute elevation of plasma FFA on  $\beta$ -cell function. Moreover, the effect of chronic elevation of plasma FFA on  $\beta$ -cell function has not been studied in humans [102,103]. Some animal and *in vitro* studies suggest that FFA exert their adverse effects on  $\beta$ -cell function only in the presence of hyperglycemia, hence the suggestion to use the term glucolipotoxicity instead of lipotoxicity [92]. It is clear that increased plasma FFA is not a primary cause of T2DM, but it is possible that a certain genetic background may prevent some individuals from responding to the adverse effects of FFA on  $\beta$ -cell function and thus increase their risk for developing T2DM.

### Obesity

Obesity is associated with insulin resistance and is the most predictive acquired risk factor for development of T2DM (see Chapter 14) [104]. This may be mediated by a variety of factors released from adipose tissue that can adversely affect  $\beta$ -cell function, including elevated levels of FFA, TNF- $\alpha$  [105], resistin [106], leptin [107], adipon [108] and amylin [109], as well as tissue accumulation of lipid [110,111]. Most obese individuals, however, compensate for their insulin resistance with an appropriate increase in insulin release and do not develop diabetes.

### Inadequate stimulation by incretins

Incretins are hormones released by the gut in response to food ingestion, which augment insulin release in what is known as the incretin effect (i.e. more insulin responses after oral than intravenous glucose despite comparable glycemia). Two major incretins are GLP-1 and GIP (see Chapters 6 and 30). In addition to promoting the biosynthesis and secretion of insulin [112], they increase  $\beta$ -cell replication and inhibit its apoptosis *in vitro* and were found, in rodent model, to increase  $\beta$ -cell mass [113–116].

Patients with T2DM have higher plasma GIP levels after meal ingestion when compared with healthy subjects [114,117]. Results are conflicting in regard to GLP-1 and, if found, the differences in levels between patients with T2DM and healthy subjects have been generally modest [118–120]. The incretin effect, neverthe-

less, is impaired in T2DM [121,122]. Insulin responses to both GLP-1 [123] and GIP [124] are reduced. It is not clear whether the defective incretin effect is merely a manifestation of a generalized reduction in  $\beta$ -cell function as is the reduced insulin response to arginine [56,57,121,125]. Antidiabetic drugs, however, that enhance incretins activity or level (GLP-1 analogues and dipeptidyl peptidase-IV inhibitors) have proven to be effective in lowering glucose in T2DM [126].

### Islet amyloid

A characteristic feature present in over 90% of patients with T2DM is the deposition of islet amyloid (see below). Amyloid is composed of insoluble fibrils formed from a protein called amylin or islet amyloid polypeptide (IAPP) [127,128]. Normally, IAPP is co-secreted with insulin from  $\beta$ -cells at the molar ratio of 1:10–50 [129]. Although the mature form of human IAPP has been reported to impair insulin release and to be  $\beta$ -cell cytotoxic [130], it is unlikely to have a primary role in the pathogenesis of T2DM because it is not present in all patients with T2DM and is actually found in up to 20% of islets in elderly individuals with normal glucose tolerance [131]. Moreover, most obese individuals who hypersecrete insulin do not develop T2DM even though IAPP is co-secreted with insulin.

Recent evidence from *in vitro* and animal studies suggests that small membrane permeant oligomers, but not the mature IAPP fibrils, are the cytotoxic form of IAPP. These oligomers form and act inside the  $\beta$ -cell, possibly causing endoplasmic reticulum stress-induced apoptosis [132,133]. In human, there is still no evidence that patients with T2DM have these toxic oligomers present in their pancreatic islets. However, the S20G mutation of the IAPP gene that increases the susceptibility of IAPP to form oligomers is linked to a rare familial form of T2DM [134–136].

### Cytokines

$\beta$ -Cell function and life cycle are known to be influenced by cytokines especially the proinflammatory cytokine interleukin-1 $\beta$  (IL-1 $\beta$ ). IL-1 $\beta$  is known for its cytokine-mediated  $\beta$ -cell destruction in type 1 diabetes [137,138] but, more recently, it has received attention for its role in the pathogenesis of T2DM. *In vitro* studies have shown that  $\beta$ -cells are capable of producing IL-1 $\beta$  in response to high glucose and leptin levels [139,140]. IL-1 $\beta$  expressing  $\beta$ -cells were found in pancreatic sections of patients with T2DM but not in healthy subjects [140]. At low concentrations, IL-1 $\beta$  enhances human  $\beta$ -cell proliferation and decreases its apoptosis, whereas at higher concentration it impairs  $\beta$ -cell insulin release and increases its apoptosis [140–142]. Apoptosis here is thought to be mediated by Fas, a member of the tumor necrosis factor receptor family that triggers apoptotic cell death independent of TNF- $\alpha$ . IL-1 $\beta$  upregulates Fas expression within  $\beta$ -cells, ultimately enabling Fas-induced apoptosis [142,143]. An IL-1 receptor antagonist (IL-1Ra), which protected human  $\beta$ -cell from IL-1 $\beta$  adverse effects *in vitro* [140], improved glycemic control in patients with T2DM through enhanced  $\beta$ -cell secretory function in a preliminary study [144].

Other inflammatory changes and immunologic abnormalities have been reported in patients with IGT and T2DM. In addition to increased systemic cytokines, these abnormalities involve acute-phase proteins and mediators associated with endothelial cell activation [145]. Most of these changes are small and their contribution to  $\beta$ -cell failure is unclear.

### Islet and islet cell changes in type 2 diabetes

Pancreatic islets represent 3–5% of the adult normal pancreas and  $\beta$ -cells comprise 60–80% of the islet cell population (see Chapter 6).

#### Histology of islets in type 2 diabetes

A pathologic feature present in 90% of patients with T2DM is the abnormal extracellular deposits of islet amyloid (Figures 10.10 and 10.11). These deposits are localized in the pancreas and are not part of a systemic amyloidosis disorder. The islet amyloid is formed from IAPP or amylin, a 37 amino acid peptide [127,128]. IAPP is normally produced by the  $\beta$ -cell, stored along with insulin in its secretory granules, and then co-secreted with insulin following  $\beta$ -cell stimulation [129,146]. IAPP has no known physiologic function in human. In patients with T2DM, the soluble IAPP peptides assume a  $\beta$ -sheet structure and oligomerize to form insoluble amyloid deposits [147,148]. It is still not clear what triggers this process and whether this simply reflects islet cell deterioration and destruction. Similar deposits, nevertheless, can be found in a minority of people without diabetes, especially with aging [131]. The IAPP and its amyloid deposits have not been clearly found to be cytotoxic to  $\beta$ -cells and recent evidence suggests that the formation of intracellular smaller IAPP oligom-

ers is possibly the cytotoxic form associated with increased  $\beta$ -cell apoptosis in animal studies [132,133].

Other histologic changes include a decreased islet mass, an alteration in the relative proportion of the islet cell population (see below), and variable degrees of fibrosis of islets and endocrine tissue [131,149–151].

#### $\beta$ -Cell changes

It is generally agreed that  $\beta$ -cell mass in T2DM is reduced by about 30–50% compared with that of weight-matched individuals with normal glucose tolerance [131,150–159].  $\beta$ -Cell mass has also been reported to be decreased in people with impaired fasting glucose [154]. Reduction in  $\beta$ -cell secretory granules amount has also been reported [160]. The decline in  $\beta$ -cell mass is caused by a decrease in the number of cells rather than the volume of individual cells. A several-fold increase in  $\beta$ -cell apoptosis without an adequate compensatory increase in replication or neogenesis rate is responsible for the reduction in cell numbers

**Figure 10.10** Amyloid deposition in islets of a patient with type 2 diabetes. Amyloid formed from islet amyloid polypeptide (IAPP; stained pink with Congo red) occupies more than 50% of the islet mass and is largely in the centre of the islet. Insulin-containing  $\beta$ -cells (labeled brown with immunoperoxidase) are clustered towards the periphery of the islet and are very reduced in number. Original magnification  $\times 400$ .

**Figure 10.11** Electron-micrographic appearances of islet amyloid deposits in type 2 diabetes. In a patient with type 2 diabetes, amyloid (Am) fibrils closely surround the  $\beta$ -cells (B) and deeply invaginate the distorted cell membrane. Scale bar, 1  $\mu$ m.

[154,160]. The reduced  $\beta$ -cell mass is usually insufficient by itself to explain the decrease in insulin secretory capacity in patients with T2DM [55,58], suggesting additional functional, therefore potentially reversible, defects.

### $\alpha$ -Cell and glucagon changes

The  $\alpha$ -cell mass is either unchanged or slightly increased [131,151]; this would result in a relative increase in  $\alpha$ -cells because  $\beta$ -cell mass decreases. Abnormal  $\alpha$ -cell function in people with IGT and T2DM include: impaired suppression by hyperglycemia, excessive responses to amino acid or mixed meals and diminished responses to hypoglycemia [161]. This has been correlated with reduced  $\beta$ -cell function and could therefore be a secondary phenomenon involving glucose toxicity, lipotoxicity and resistance to insulin.

Absolute or relative hyperglucagonemia is a hallmark of both T1DM and T2DM. Although this exacerbates the consequences of impaired insulin release on hepatic glucose production [16], it is likely to be a secondary phenomenon, because it is readily correctable by physiologic insulin replacement [161].

### $\delta$ -Cell and somatostatin changes

$\delta$ -Cells of the islets release somatostatin, an inhibitor of insulin and glucagon secretion. Relatively little is known of alterations in  $\delta$ -cell population and function in people with T2DM. Studies have reported  $\delta$ -cell mass to be either increased [162] or with no significant change [151,152]. Somatostatin secretion is found to be increased in animal models [163,164]. Given the above findings, it is unlikely that alterations in  $\delta$ -cell mass and release of somatostatin to be a primary cause for the reduced insulin secretion and the relatively excessive glucagon release found in T2DM.

---

## Conclusions

Type 2 diabetes is a disorder involving both inheritable and acquired abnormalities that adversely affect  $\beta$ -cell function and mass and tissue responses to insulin. Current evidence favors the concept that the predominant genetic impact involves impaired insulin secretion whereas additional acquired elements, and thus potentially preventable factors, also adversely affect  $\beta$ -cell function and tissue responses to insulin. Much of the research focus in recent years is directed toward understanding the molecular and genetic basis of the disease. Being a polygenic disorder, multiple different polymorphisms that diminish  $\beta$ -cell function are likely to be identified. New therapies that preserve  $\beta$ -cell function and eventually reverse the defects may be developed in the future.

## Insulin Resistance in Type 2 Diabetes

**Hannele Yki-Järvinen**

Department of Medicine, Division of Diabetes, University of Helsinki, Helsinki, Finland

### Keypoints

- Insulin resistance both precedes and predicts type 2 diabetes mellitus (T2DM). The insulin resistance preceding T2DM is commonly referred to as the metabolic syndrome. Development of T2DM (i.e. overt hyperglycemia), however, also requires the presence of a relative defect in insulin secretion (see Chapter 10).
- Although obesity and physical inactivity have precipitated the epidemic of T2DM, these factors are poorer predictors of cardiovascular disease than a combination of risk factors that define the metabolic syndrome. Diagnosis of the metabolic syndrome requires measurement of waist circumference, glucose, triglycerides and high density lipoprotein cholesterol and blood pressure. These features are not observed in all obese people and can occur even in normal weight individuals. Subjects who develop the metabolic syndrome commonly have excess fat deposited in ectopic locations, especially in the liver. Non-alcoholic fatty liver disease (NAFLD) is defined as excess fat in the liver in the absence of excess alcohol abuse or other known causes of liver disease. The amount of fat in the liver is closely correlated with all features of the metabolic syndrome independent of obesity. Thus, NAFLD frequently coexists in subjects with the metabolic syndrome and may indeed be regarded as another defining feature of the metabolic syndrome. As the metabolic syndrome, NAFLD also predicts both T2DM and cardiovascular disease independent of obesity.
- In the liver, insulin resistance of glucose metabolism in patients with T2DM is characterized by an impaired ability of insulin to inhibit hepatic glucose production leading to mild hyperglycemia and stimulation of insulin secretion. Hepatic insulin resistance is also manifested by failure of insulin suppression of very low density lipoprotein production, which leads to hypertriglyceridemia. High density lipoprotein levels decrease because of increased exchange of cholesterol esters for triglyceride, mediated by cholesterol ester transfer protein. Small, dense, low density lipoprotein particles also predominate in insulin-resistant states, and are highly atherogenic. Hepatic insulin resistance is directly proportional to the amount of fat in the liver, although the molecular mechanisms underlying this association in humans are unclear. Liver fat is increased in obesity but the relationship is weak, implying that many other factors regulate liver fat. These include genetic and dietary factors.
- Insulin resistance in adipose tissue is characterized by inflammation, decreased production of the insulin-sensitizing hormone adiponectin and by an impaired ability of insulin to suppress lipolysis. Raised non-esterified fatty acid (NEFA) levels are the most important source of intrahepatocellular triglyceride both under fasting and post-prandial conditions. Adiponectin deficiency may also contribute to fat accumulation in the liver.
- Insulin stimulation of glucose uptake in skeletal muscle is decreased in patients with T2DM compared with subjects without diabetes if measured under similar conditions of hyperinsulinemia and glycemia. At the molecular level, insulin resistance in muscle is associated with by defects at multiple post-receptor sites, including impairment of insulin receptor substrate 1 tyrosine phosphorylation, phosphoinositide 3' (PI<sub>3</sub>) kinase activation and the glucose transporter 4 translocation, which mediates insulin-stimulated glucose uptake; glycogen synthesis is also decreased. Raised NEFA levels also interfere with glucose utilization and uptake by muscle.
- Chronic hyperglycemia per se reduces insulin sensitivity (glucose toxicity) and could at least partly explain why insulin resistance is more severe in patients with established T2DM than in equally obese subjects without diabetes.

### Insulin resistance – definitions and role in the natural history of type 2 diabetes

Insulin resistance can be defined as the inability of insulin to produce its usual biologic actions at circulating concentrations

that are effective in normal subjects. Insulin resistance in the context of glucose metabolism leads to impaired suppression of endogenous glucose production – under basal conditions as well as after eating (when the physiologic rise in insulin in response to glucose entry from the gut normally shuts down glucose production by the liver) – and to reduced peripheral uptake of glucose. Resistance to the ability of insulin to suppress very low density lipoprotein (VLDL) cholesterol production increases circulating serum triglycerides, while resistance in adipose tissue increases the flux of non-esterified fatty acid (NEFA) both to the

liver and skeletal muscle and impairs the action of insulin on glucose metabolism in these tissues (see Chapters 7 and 13). Resistance to other actions of insulin, such as its vasodilator and antiplatelet aggregation effects, also characterize insulin resistance in patients with T2DM. Insulin resistance may also become more severe in patients with T2DM brought about by any factor causing insulin resistance. Such factors are listed in Table 11.1.

There has been much debate as to whether insulin resistance is the primary defect that precedes  $\beta$ -cell failure in the evolution of hyperglycemia in T2DM, or vice versa. There is a linear decrease in both first-phase insulin release and insulin sensitivity

**Table 11.1** Causes of variation in insulin action in patients with type 2 diabetes. Genetic forms of insulin resistance are discussed in Chapters 12 and 15.

\* Aerobic training increases glucose uptake per unit muscle mass; resistive training does not increase glucose uptake per unit muscle but increases muscle bulk.

in individuals who progress from normal to impaired glucose tolerance [1]. Once the plasma glucose concentration 2 hours after an oral glucose challenge (75 g) reaches the upper limit for impaired glucose tolerance (11.1 mmol/L, 200 mg/dL), post-glucose insulin concentrations fall and glucose then rises into the diabetic range (Figure 11.1). A similar picture has been observed in prospective studies. Thus, low insulin sensitivity and impaired first-phase insulin release both predict the onset of T2DM [1]. These data imply that development of overt hyperglycemia requires a relative decrease in insulin secretion as depicted in Figure 11.1.

The following sections describe the pathogenesis and significance of the cluster of clinical features of insulin resistance called the metabolic syndrome, which characterizes most patients with the common form of T2DM [2]. The metabolic syndrome shares

**Figure 11.1** Natural history of type 2 diabetes (T2DM). Upper panel: the relationship between mean glucose and mean insulin concentrations during an oral glucose tolerance test (OGTT), in individuals with normal (NGT), impaired glucose tolerance (IGT) and diabetes (T2DM). There is a linear positive correlation between glucose and insulin concentrations during an OGTT in individuals with NGT and IGT. By contrast, T2DM is characterized by worsening relative insulin deficiency (i.e. insulin concentrations decline with rising glucose concentrations). Bottom panel: the relationship between glucose concentrations during the OGTT and insulin sensitivity (determined by the euglycemic clamp technique). Insulin sensitivity decreases linearly as glucose tolerance worsens and, in patients with T2DM, insulin sensitivity worsens as glucose concentrations increase. This could be caused by effects of chronic hyperglycemia per se on glucose uptake, or of relative insulin deficiency coupled with increases in NEFA concentrations. These data are from cross-sectional studies [173] but longitudinal studies [1] yield similar findings.

many features in common with non-alcoholic fatty liver disease (NAFLD), which is therefore also briefly described [3]. This is followed by a characterization of features of insulin resistance in individual tissues: the liver, adipose tissue, skeletal muscle and additional sites. The underlying causes are also discussed, focusing on acquired factors. Genetics of T2DM is discussed in Chapter 12. This chapter focuses on the sites, causes and consequences of “insulin resistance” in the common form of T2DM. Certain conditions that may resemble T2DM are discussed in detail in other chapters (see Chapters 2, 15, and 19).

## Metabolic syndrome and non-alcoholic fatty liver disease

### Definitions and significance

#### Metabolic syndrome

Insulin resistance in various tissues leads to hyperglycemia, hypertriglyceridemia and low high-density lipoprotein (HDL) cholesterol. Most patients with T2DM have these features of insulin resistance and, in addition, are often hypertensive and abdominally obese. Although each of the causes and consequences of insulin resistance predicts both T2DM and increased cardiovascular risk, identification of a cluster of abnormalities in a given individual confers a substantial additional cardiovascular risk over and above the risk associated with each individual abnormality [2]. A number of expert groups have developed criteria for identification of such a risk cluster called the metabolic syndrome. The most recent is the definition proposed by the International Diabetes Federation (IDF). According to this definition, a person is identified as having the metabolic syndrome if they have central obesity (defined with ethnicity specific values) plus any two of the following: raised triglycerides; reduced HDL cholesterol; raised blood pressure; or raised fasting plasma glucose (Tables 11.2 and 11.3). Using these criteria, 20–25% of the world’s adult population have the metabolic syndrome. This risk of death from cardiovascular disease is increased approximately twofold in subjects with the metabolic syndrome compared with those not meeting these criteria (see Part 8). In addition, subjects with the metabolic syndrome have a fivefold greater risk of developing T2DM [2].

#### Non-alcoholic fatty liver disease

Subjects with metabolic syndrome who are abdominally obese, have an increase in fat accumulation in the liver and hepatic insulin resistance independent of their obesity and body fat distribution [4,5]. This increase in liver fat associated with insulin resistance is called non-alcoholic fatty liver disease (NAFLD). NAFLD is defined as excess fat in the liver (>5–10% fat histologically) which is not brought about by excess alcohol use (over 20 g/day), effects of other toxins, autoimmune, viral or other causes of steatosis [4]. NAFLD has been shown to predict both T2DM and cardiovascular disease in multiple prospective studies independent of obesity [3].

**Table 11.2** The International Diabetes Federation (IDF) definition of the metabolic syndrome.

According to the new IDF definition, for a person to be defined as having the metabolic syndrome they must have:

Central obesity (defined as waist circumference  $\geq 94$  cm for European men and  $\geq 80$  cm for European women, with ethnicity specific values for other groups; see Table 11.3; below) plus any two of the following four factors:

- 1 Raised triglyceride level:  $\geq 150$  mg/dL (1.7 mmol/L), or specific treatment for this lipid abnormality
- 2 Reduced HDL cholesterol:  $< 40$  mg/dL (1.0 mmol/L) in males and  $< 50$  mg/dL (1.3 mmol/L) in females, or specific treatment for this lipid abnormality
- 3 Raised blood pressure: systolic BP  $\geq 130$  or diastolic BP  $\geq 85$  mmHg, or treatment of previously diagnosed hypertension
- 4 Raised fasting plasma glucose  $\geq 100$  mg/dL (5.6 mmol/L), or previously diagnosed type 2 diabetes. If above 5.6 mmol/L (100 mg/dL), an oral glucose tolerance test is strongly recommended but is not necessary to define presence of the syndrome

If BMI is  $> 30$  kg/m<sup>2</sup>, central obesity can be assumed and waist circumference does not need to be measured

**Table 11.3** Ethnic specific values for waist circumference.

Country/ethnic group	Waist circumference (cm)
Europeans	Male $\geq 94$
In the USA, the ATP III values (102 cm male; 88 cm female) are likely to continue to be used for clinical purposes	Female $\geq 80$
South Asians	Male $\geq 90$
Based on a Chinese, Malay and Asian-Indian population	Female $\geq 80$
Chinese	Male $\geq 90$
	Female $\geq 80$
Japanese	Male $\geq 85$
	Female $\geq 90$
Ethnic South and Central Americans	Use South Asian recommendations until more specific data are available
Sub-Saharan Africans and Eastern Mediterranean and Middle East (Arab) populations	Use European data until more specific data are available

NAFLD covers a spectrum of liver disease including not only steatosis but also non-alcoholic steatohepatitis (NASH) and cirrhosis (Figure 11.2) [4]. The reasons why the liver develops inflammatory changes, as in NASH, in some individuals is unclear. In addition to the epidemic of obesity, T2DM and cardiovascular disease, the incidence of serious liver damage brought about by NAFLD is increasing. It has even been predicted that NASH will become the number one cause of orthotopic liver transplantation by the year 2020 [6].

**Figure 11.2** Overview of the relationship between non-alcoholic fatty liver (NAFL), metabolic syndrome (MetS), non-alcoholic steatohepatitis (NASH), type 2 diabetes and cardiovascular disease.

## Insulin resistance in the liver

### Characteristics

#### Insulin action on glucose metabolism in the fasting state

After an overnight fast, insulin restrains endogenous glucose production (see Chapter 7). Isotopic measurements of glucose production under truly steady-state conditions show a significant relationship between endogenous glucose production and fasting plasma glucose concentration in patients with T2DM [7]. This relationship is observed despite hyperglycemia and normoinsulinemia or hyperinsulinemia, and demonstrates that insulin resistance contributes to the increase in basal endogenous glucose production. This hepatic insulin resistance is associated with excess fat accumulation in the liver. After an overnight fast, when glucose uptake is largely insulin-independent and driven by the mass-action effect of hyperglycemia, the absolute rate of glucose utilization is normal or even increased (Figure 11.3). The clinical implications of these findings are that strategies designed to lower fasting glucose should aim at inhibiting overproduction of glucose from the liver rather than further increasing glucose uptake in T2DM [8].

#### Insulin action on glucose metabolism in the post-prandial state

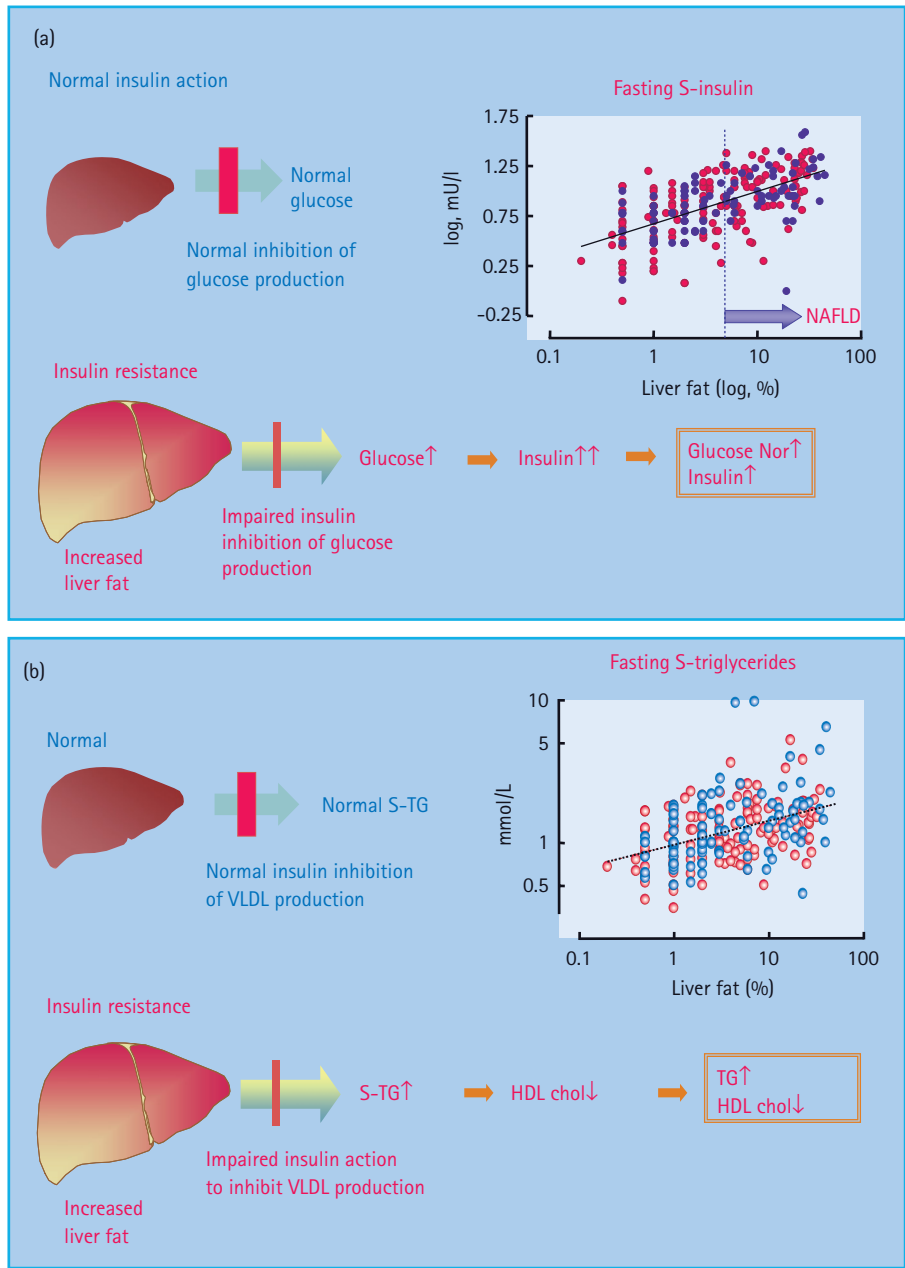

After a meal, increases in insulin and glucose concentrations and a concomitant decrease in glucagon almost completely suppress endogenous glucose production under normal conditions. In patients with T2DM, this suppression is incomplete both because of hepatic insulin resistance, deficient insulin and excessive glucagon secretion [9–11]. Hepatic insulin resistance has been documented by direct measurement of a reduced effect of insulin to decrease hepatic glucose production [11]. This defect correlates closely with liver fat content (Figure 11.4) [12,13]. The pathogenesis and causes of this hepatic insulin resistance are discussed below. Persistent hepatic glucose production after eating is the

main reason for sustained maintenance of post-meal hyperglycemia [9]. Under post-prandial conditions, approximately one-third of glucose is utilized in skeletal muscle, one-third is oxidized in the brain and the remaining third is stored in the liver [14]. In patients with T2DM, the ability of the liver to store glucose during a meal appears intact or is only slightly diminished [9,15]. In absolute terms, the overall rate of glucose utilization is also quantitatively normal, because hyperglycemia per se, via the mass action effect of glucose, acts to compensate for impaired insulin stimulation of glucose uptake into peripheral tissues [16]. Finally, the brain utilizes similar amounts of glucose in both normal subjects and patients with T2DM. Thus, post-prandial hyperglycemia must be caused by the incomplete suppression of endogenous glucose production.

### Lipoprotein metabolism

Evidence from both *in vitro* [17,18] and *in vivo* [19] studies has suggested that insulin normally suppresses the production of VLDL, especially VLDL1 apoB particles from the liver (see Chapter 40). This effect is brought about not only by decreases in NEFA availability following inhibition of lipolysis in fat tissue, but also by a direct hepatic effect of insulin, inhibiting the assembly and production of VLDL particles [19]. In contrast to normal subjects, insulin fails to suppress VLDL apoB production in those with T2DM, even though it profoundly suppresses NEFA concentrations [20]. Overproduction of VLDL [21] and the defect in insulin suppression of VLDL production [22] correlates with the amount of fat in the liver and appears to be one major contributory mechanism underlying the increase in serum triglycerides in patients with insulin-resistant T2DM (Figure 11.3) [23].

HDL levels are reduced in insulin-resistant patients with high serum triglycerides. Under hypertriglyceridemic conditions, there is excessive exchange of cholesterol esters and triglycerides between HDL and the expanded pool of triglyceride-rich lipoproteins, mediated by cholesterol ester transfer protein (CETP) [24]. HDL particles become enriched with triglycerides (predominantly separating in the lighter HDL<sub>3</sub> density range), rendering them as a good substrate for hepatic lipase which removes HDL particles from the circulation at an accelerated rate. Subnormal activity of LPL may further decrease levels of HDL cholesterol by decreasing the conversion of HDL<sub>3</sub> to HDL<sub>2</sub> particles [24]. Elevated concentrations of VLDL particles in the serum of patients with T2DM also increase the CETP-mediated exchange of cholesterol ester and triglyceride between VLDL and low density lipoprotein (LDL) cholesterol particles [25]. This increases the triglyceride content of LDL particles and makes them a better substrate for hepatic lipase [26], which hydrolyzes triglycerides in the LDL particles and increases their density. This sequence of events at least partly explains why patients with T2DM have smaller and more dense LDL particles than individuals without diabetes [27,28]. The small dense LDL particles are known to be highly atherogenic and provide a plausible link between insulin resistance and cardiovascular disease [29–32].

**Figure 11.3** Role of the fatty liver in the pathogenesis of hyperglycemia and (a) hyperinsulinemia and (b) hypertriglyceridemia. (a) Insulin normally restrains hepatic glucose production, which maintains glucose at normal levels. Once the liver is fatty and insulin-resistant, this action of insulin is impaired, leading to hyperglycemia and stimulation of insulin secretion. This results in the combination of near-normal glucose levels and hyperinsulinemia, as long as pancreatic insulin secretion is intact. The insert in (a) denotes the relationship between liver fat and fasting serum insulin. Pink circles, female; blue circles, male. Data from Kotronen *et al.* [5]. If liver fat exceeds 5–10% as a result of non-alcoholic causes, this is defined as non-alcoholic fatty liver disease (NAFLD). (b) Insulin normally inhibits production of very low density lipoprotein (VLDL) cholesterol from the liver. If the liver is fatty and insulin resistant, this ability of insulin is impaired. This results in hypertriglyceridemia and this in turn is the main reason for lowering of high density lipoprotein (HDL) cholesterol. The insert in (b) depicts the relationship between liver fat and fasting serum triglycerides. Pink circles, female; blue circles, male. Data from Kotronen *et al.* [5].

**Pathogenesis of hepatic insulin resistance and the fatty liver**

It is not ethically possible to sample human liver for research purposes, and therefore data on the pathogenesis of hepatic insulin resistance in humans are mainly based on *in vivo* studies using stable isotope and hepatic venous catheterization techniques.

**Sources of intrahepatocellular triglyceride**

The fatty acids in intrahepatocellular triglycerides can be derived from dietary chylomicron remnants, NEFAs released from

adipose tissue, or from post-prandial lipolysis of chylomicrons, which can occur at a rate in excess of what can be taken up by tissues (spillover), and from *de novo* lipogenesis [33]. *In vivo* studies using stable isotope techniques have shown that after an overnight fast, the majority of hepatic fatty acids originate from adipose tissue lipolysis [34]. The contribution of splanchnic lipolysis to hepatic free fatty acid (FFA) delivery averages 5–10% in normal weight subjects and increases to 30% in men and women with visceral obesity [35]. Thus, subcutaneous adipose tissue provides the majority of hepatic FFA delivery. In the post-prandial state, the contribution of the spillover pathway and uptake of

**Figure 11.4** Relationship between hepatic insulin sensitivity (measured by the ability of insulin to suppress hepatic glucose production by insulin) and liver fat in normal subjects (open circles) and in patients with type 2 diabetes (closed circles). Data from Kotronen *et al.* [174].

**Figure 11.5** The relationship between body mass index and insulin sensitivity of glucose metabolism as determined by the euglycemic clamp technique in subjects without diabetes. Data from the European Group for the Study of Insulin Resistance (EGIR) (kindly provided by Professor Eleuterio Ferrannini).

chylomicron remnants increase and can account for up to half of the fatty acids secreted as VLDL triglyceride. *De novo* lipogenesis accounts for less than 5% in normal subjects post-prandially [36]; however, in subjects with fatty liver, rates of *de novo* lipogenesis appear to be significantly elevated [34,37]. This may result from excess carbohydrate intake [38]. An impaired ability of insulin-resistant subjects to store carbohydrate as glycogen in muscle could also contribute to excess *de novo* lipogenesis in the liver [39].

The fatty acid composition of intrahepatocellular triglyceride changes as a function of the amount of liver fat present. The fatty liver contains increased amounts of saturated fatty acids and decreased amounts of polyunsaturated fatty acids [40]. Whether the increase in saturated fatty acids is caused by *de novo* lipogenesis, which produces saturated fatty acids [41], or other sources is unclear.

#### Cellular mechanism of hepatic insulin resistance

Triglycerides themselves are inert and cannot explain hepatic insulin resistance. Data from animal studies suggest at least two lipid mediators, ceramides and diacylglycerols, which could cause insulin resistance. Ceramides are sphingolipids, with a sphingoid backbone that relies on the availability of saturated fatty acids [42]. Ceramides appear to be required for insulin resistance induced by saturated, but not unsaturated, fatty acids in rat soleus muscle [43]. Ceramides accumulate in the liver during tristearin (18:0)–but not triolein (18:1 n-9) enriched diets [44]. Ceramides are upregulated in skeletal muscle [45] and adipose tissue [46] of insulin-resistant subjects, but data are sparse on the ceramide content of human fatty liver [40]. Diacylglycerols, which are immediate precursors of triacylglycerols, activate protein kinase C $\epsilon$  (PKC $\epsilon$ ) in the liver, which binds to and inactivates the insulin

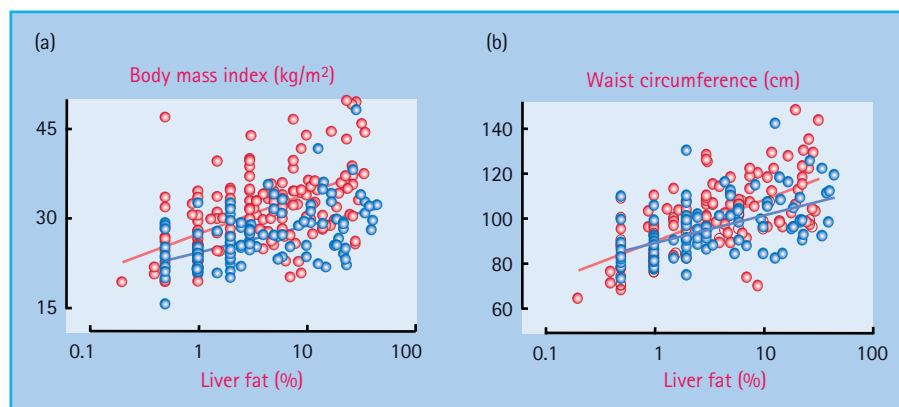

receptor tyrosine kinase and decreases insulin receptor substrate 2 (IRS-2) tyrosine phosphorylation. In downstream signaling, this leads to reduced insulin activation of PI<sub>3</sub>-kinase, AKT2, glycogen synthase kinase 3 (GSK-3) and FOXO phosphorylation, which decreases hepatic glycogen synthesis and reduces inhibition of hepatic gluconeogenesis [47]. In the human liver, diacylglycerol concentrations are increased in proportion to increases in intrahepatocellular triglyceride [40]. PKC $\epsilon$  activity has been shown to be increased in the liver of patients with T2DM [48].

#### Acquired causes of variation in hepatic insulin sensitivity and liver fat content

##### Body weight

Obesity is related to insulin resistance, although at any given body mass index (BMI), insulin sensitivity, measured as the amount of glucose required to maintain normoglycemia during hyperinsulinemia (a measure of whole body insulin resistance, which could be both hepatic and peripheral), varies considerably (Figure 11.5). Obesity impairs both insulin stimulation of glucose uptake and insulin inhibition of endogenous glucose production [11,49]. Liver fat content and hepatic insulin resistance are related to BMI and waist circumference; however, the variation at any given BMI is large (Figure 11.6).

Weight loss induces rapid and substantial changes in liver fat content and hepatic insulin sensitivity [50,51]. In a study where obese women lost 8% of their body weight over 18 weeks, liver fat content and total body fat mass decreased by 39% and 14%, respectively [52]. In another study, 7% weight loss decreased liver fat content by approximately 40% over 7 weeks [53]. In this study, a 30% decrease in liver fat was observed as early as after 2 days of a low carbohydrate diet (~1000 kcal, approximately 10% carbohydrate). In both of these studies, there was a marked

**Figure 11.6** The relationship between liver fat and body mass index (a), and liver fat and waist circumference (b) in 271 non-diabetic subjects (red circles denote women and blue circles men). Data from Kotronen *et al.* [5].

improvement in directly measured hepatic insulin sensitivity [52,53]. Weight gain increases liver fat. In an overfeeding study of healthy volunteers, 9.5% weight gain over 4 weeks was associated with a 2.5-fold increase in liver fat content, hyperinsulinemia and a 4.4-fold increase in serum alanine aminotransferase (ALT) activity [54].

#### Fat distribution

Over 50 years ago, Vague [55] classified obese subjects according to the degree of “masculine differentiation” into those with “gynoid” and those with “android” obesity. Gynoid obesity was characterized by lower body deposition of fat (around the thighs and buttocks) and relative underdevelopment of the musculature, while android obesity defined upper body (truncal) adiposity, greater overall muscular development and a tendency to develop hypertension, diabetes, atherosclerosis and gout. These phenotypic observations have subsequently been confirmed in prospective studies [56–58].

The mechanisms linking upper body obesity to features of insulin resistance are poorly understood. Regarding hepatic insulin resistance and liver fat, it has been suggested that truncal obesity is harmful because it is accompanied by visceral fat accumulation within the abdomen, and because this fat depot is more metabolically active than subcutaneous adipose tissue. Omental and mesenteric adipocytes have a higher rate of lipolysis than subcutaneous, and could liberate excessive amounts of NEFA into the portal vein, thus causing the liver to become insulin resistant. This “portal theory”, however, lacks firm supporting evidence from *in vivo* studies [59]. Limited data suggest that concentrations of NEFA and glycerol in the portal vein are close to those in arterial plasma, and tracer studies have shown that NEFA released within the splanchnic (visceral) bed contribute only about 10% of total NEFA delivery to the liver [60]. Furthermore, although the turnover rate of NEFA is higher in women with upper, compared to those with lower body obesity, the excess NEFA have been found to originate from subcutaneous fat in the upper body rather than from the splanchnic bed [61].

Visceral fat also has been proposed to release more inflammatory cytokines such as interleukin 6 (IL-6) than subcutaneous adipose tissue, but such data do not prove cause and effect [62,63]. Thus, visceral fat could be an innocent bystander as well as a culprit [59].

#### Diet composition

Very few human data are available regarding the effects of changes in diet composition on hepatic insulin sensitivity and liver fat content. Cross-sectional data have suggested that the relative amount of fat, especially saturated fat in the diet, is directly correlated with liver fat [52,64] and that the percentage of dietary saturated fat intake is increased in NAFLD compared with controls [65]. A small intervention study suggested that a high fat (56% of kcal) low carbohydrate diet may increase liver fat compared to a low fat (16% of kcal) high carbohydrate diet [66]. The dietary carbohydrate content, however, may also be important. A cross-sectional study in 247 healthy subjects showed that a high glycemic index diet is associated with high liver fat independent of carbohydrate, fiber, protein and fat intake [67], but there are no intervention studies to confirm this finding.

#### Genetic causes regulating liver fat and hepatic insulin sensitivity

Twin studies suggest that 35–60% of the variation in the levels of circulating liver enzymes in serum of subjects not using excess alcohol and who have no known liver disease is genetically determined [68,69]. Recently, a genome-wide association scan of non-synonymous sequence variations in a population comprising Hispanic, African-American and European-American individuals identified an allele in the *PNPLA3* (adiponutrin) gene to be strongly associated with increased liver fat [70]. The finding that hepatic fat content is more than twofold higher in *PNPLA3* rs738409[G] homozygotes than in non-carriers has been confirmed in multiple studies [70,71]. The missense mutation I148M in adiponectin promotes triglyceride accumulation by inhibiting triglyceride hydrolysis [72].

---

## Insulin resistance in adipose tissue

Adipose tissue is not merely a depot for excess energy but an active endocrine organ, which releases hormones such as adiponectin and leptin to the circulation (see Chapter 8). In addition, it has recently been shown that in obese subjects [73] and in subjects with a fatty liver independent of obesity [46], adipose tissue is inflamed. This inflammation is characterized by macrophage infiltration and increased expression of proinflammatory molecules such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) and IL-6, and of chemokines such as MCP-1 [73–76]. The initial trigger of the inflammatory changes is unknown.

Cinti *et al.* [77] showed that in both obese (db/db) mice and humans >90% of the macrophages surround dead adipocytes, and the number of macrophages correlated positively with adipocyte size [73,77]. An increased number of macrophages surrounding dead adipocytes also characterized subjects with a fatty liver compared to equally obese subjects with normal liver fat content [46]. The inflammation in adipose tissue may cause insulin resistance, not only in adipose tissue, but possibly also in other tissues such as the liver. Although it is in general difficult to prove cause and effect in human studies, it is likely that increases in NEFA from the insulin resistance of antilipolysis and the decrease in the concentration of adiponectin are likely mediators of systemic, mainly hepatic, insulin resistance as a consequence of changes occurring in adipose tissue. Macrophage accumulation in human adipose tissue is at least in part reversible as weight loss can reduce both macrophage infiltration and expression of genes involved in macrophage recruitment [78].

### Resistance to the antilipolytic action of insulin

Lipolysis in adipose tissue is exquisitely insulin sensitive: in normal subjects, rates of glycerol production are half-maximally suppressed at a plasma insulin concentration of 13 mU/L [79,80]. Triglyceride breakdown is increased and plasma NEFA concentrations are higher in patients with T2DM than in normal subjects studied at comparable insulin levels, suggesting that adipose tissue is also affected by insulin resistance [81,82]. Unrestrained lipolysis to a degree that could lead to ketoacidosis, however, does not occur spontaneously in T2DM, because insulin deficiency is not sufficiently profound.

Increased NEFA concentrations may contribute to worsening of hyperglycemia because of multiple interactions between NEFA and glucose metabolism. A large increase in plasma NEFA concentrations can decrease insulin-stimulated glucose uptake [83] and NEFA may be deposited as triglycerides in skeletal muscle [84,85]. Second, the increased concentration of NEFA reflects increased NEFA turnover, which increases delivery to the liver, where NEFA can be deposited as triglycerides. In the liver, NEFA also stimulate glucose production, especially via gluconeogenesis. The biochemical mechanisms through which NEFA might interfere with insulin action are discussed in Chapter 13.

### Adiponectin deficiency

Adiponectin is a hormone produced in adipose tissue. Based on animal studies, its main target is the liver, where it has both anti-inflammatory and insulin-sensitizing effects and decreases liver fat content [86]. The marked increase in serum adiponectin observed during treatment with peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ) agonists and the close correlation between changes in liver fat and serum adiponectin concentrations [87] support the possibility that adiponectin regulates liver fat content in humans. Serum adiponectin levels are decreased in obese compared to non-obese subjects and in subjects with the metabolic syndrome compared to those without the syndrome.

---

## Insulin resistance in skeletal muscle

There is abundant evidence that the ability of insulin to stimulate *in vivo* glucose disposal is decreased in skeletal muscle of patients with T2DM when measured under similar conditions in age, gender and weight-matched subjects without diabetes [88–90]. Under real-life conditions, however, hyperglycemia compensates for the defect in insulin-stimulated glucose uptake, and maintains the rate of absolute glucose utilization at a normal level in patients with T2DM compared with subjects without diabetes [16].

### Mechanisms of insulin resistance in muscle

Multiple defects in the insulin signaling cascade have been identified. There do not appear to be any major disturbances in insulin-receptor binding, and the minor decreases in the tyrosine kinase activity of the receptor  $\beta$ -subunit appear to be secondary to the metabolic disturbances, because they are reversible with weight loss [91].

The abnormality must therefore lie at a post-receptor level. Defects in insulin signaling in human skeletal muscle have been demonstrated in early signaling events such as activation by tyrosine phosphorylation of IRS-1 – a substrate of the insulin receptor's tyrosine kinase – and in the activation of PI<sub>3</sub> kinase [92], which is required for insulin's stimulation of glucose transport and glycogen synthesis (see Chapter 7). Insulin-enhanced glucose uptake, mediated by translocation of the glucose transporter 4 (GLUT-4) protein to the cell surface, and stimulation of glucose phosphorylation via hexokinase II are also diminished [93,94].

The defects in insulin action in skeletal muscle are generally more severe than in equally obese, non-diabetic subjects of the same age, gender and body fat distribution. This suggests that there is an additional genetic defect (see Chapter 12) or that metabolic disturbances such as chronic hyperglycemia (glucose toxicity), or extracellular NEFA or lipid accumulation within the myocytes (lipotoxicity) could be responsible. Indeed, intramyocellular lipid content is higher in patients with T2DM than in

equally obese non-diabetic subjects [95] or in lean subjects without diabetes [96].

### Causes of insulin resistance in muscle

#### Obesity

Obesity decreases insulin-stimulated glucose uptake in skeletal muscle independently of changes in physical fitness (see Chapter 14). This decrease could be partly caused by increased NEFA produced by adipose tissue and fat accumulation in myocytes [84,85].

#### Abdominal obesity

Insulin resistance in skeletal muscle is more severe in subjects with android than those with gynoid obesity [97]. Histologically, abdominally obese subjects have a decreased capillary density and an insulin-resistant fiber type in their skeletal muscles [98,99].

#### Physical inactivity

The sedentary lifestyle that characterizes Westernized societies is an important contributor to obesity and to T2DM (see Chapters 4 and 23). Data from several prospective epidemiologic studies such the Nurse's Health Study [100] have shown an inverse association between physical activity and the incidence of T2DM [101–103].

Insulin sensitivity of glucose uptake by skeletal muscle is directly proportional to physical fitness measured by maximal oxygen consumption ( $\dot{V}O_{2max}$ ) [104]. Decreased physical fitness (maximal aerobic power) in muscle in patients with T2DM is characterized by decreased capillary density and impaired mitochondrial oxidative phosphorylation [105]. Glucose tolerance and insulin-stimulated glucose uptake are also enhanced by resistive training, which increases total muscle mass without influencing glucose uptake per unit muscle mass [104].

Insulin and exercise stimulate glucose uptake through independent mechanisms. While insulin enhances glucose uptake in skeletal muscle via the classic insulin signaling pathway (see Chapter 7), exercise has no effect on tyrosine phosphorylation of the insulin receptor or of IRS-1 [106]. The mechanism of contraction-stimulated glucose uptake involves adenosine 5' monophosphate-activated protein kinase (AMPK) [107]. AMPK, especially its  $\alpha 2$  isoform, is activated by muscle contraction in human skeletal muscle, and this results in GLUT-4 translocation to the cell membrane and an increase in inward glucose transport [107].

In insulin-resistant patients with T2DM, the ability of insulin to stimulate tyrosine phosphorylation of the insulin receptor and of IRS-1, IRS-1 associated PI<sub>3</sub> kinase activity [92] and translocation of GLUT-4 [108] are all subnormal. Aerobic training, however, has been shown to increase the GLUT-4 content in skeletal muscle [109] and the expression and activity of glycogen synthase [110] to a comparable degree to normal subjects. Thus, the signaling pathways through which exercise enhances glucose uptake may be intact in patients with T2DM. This has the practi-

cal implication that the glycemic response to exercise is not blunted by insulin resistance.

#### Chronic hyperglycemia

Hyperglycemia itself, independent of insulin, NEFA or counter-regulatory hormones, can induce insulin resistance in human skeletal muscle [111]. This "glucose toxicity" induced insulin resistance could contribute to the lower rates of insulin-stimulated glucose uptake in patients with T2DM compared with weight, age and gender-matched subjects without diabetes and measured during maintenance of similar levels of glycemia and insulinemia. Although chronic hyperglycemia induces insulin resistance, however, glucose utilization is stimulated acutely via the mass action effects of glucose even in patients with diabetes. This effect explains why hyperglycemic patients with T2DM are able to utilize as much glucose as normal subjects at normoglycemia, in spite of the insulin resistance in the subjects with diabetes [111,112].

The degree of insulin resistance in patients with T2DM is directly proportional to the severity of hyperglycemia [111]. Thus, insulin resistance induced by the hexosamine pathway in hyperglycemic patients with T2DM could be viewed as a compensatory mechanism that protects muscles against excessive uptake of glucose. Consistent with this, in isolated skeletal muscle from patients with T2DM [112], insulin-stimulated glucose transport in muscles of hyperglycemic patients with T2DM was similar to that in normoglycemic subjects but impaired when measured after short-term exposure to normoglycemia. Prolonged exposure to normoglycemia completely normalized the defect in insulin-stimulated glucose transport [112]. Clinically, the ability of hyperglycemia to induce insulin resistance in patients with T2DM may explain why any treatment, such as sulfonylureas, which improves glycemic control may also improve insulin sensitivity even if the primary site of action is not in insulin-sensitive tissues [111].

The hexosamine pathway was discovered in 1991, by Marshall *et al.* [113], who found that it mediated glucose-induced insulin resistance in primary cultured rat adipocytes. Downregulation of the insulin-responsive glucose transport system was observed to require three components: glucose, insulin and glutamine. Inactivation of the glutamine-requiring enzyme, glutamine:fructose-6-amidotransferase (GFA), the rate-limiting enzyme of the hexosamine pathway, by glutamine analogs, prevented glucose-induced desensitization of glucose transport [113]. GFA catalyzes the interconversion of glutamine and fructose-6-phosphate to form glucosamine-6-phosphate (GlcN-6-P) and glutamate [114]. GFA is expressed in insulin target tissues such as skeletal muscle, where its activity is increased in patients with T2DM [115]. The end-product of the pathway, UDP-*N*-acetyl-glucosamine (UDP-NAcGln) is attached to the OH-group of threonine and serine residues of proteins (these same residues can also be phosphorylated), which results in O-glycation of proteins. These include multiple proteins involved in glucose-responsive and insulin-dependent transcription and signaling events [114].

## Resistance to other actions of insulin

### Vascular effects of insulin

At physiologic concentrations and within a physiologic time-frame, insulin decreases the stiffness of large arteries [116]. This effect is blunted in obesity [117]. These data are consistent with epidemiologic data that indicate that insulin resistance and arterial stiffness are independently associated in subjects without diabetes. Patients with T2DM have stiffer arteries than age and weight-matched healthy subjects [118,119].

Another vascular effect of insulin is vasodilatation of peripheral resistance vessels [120], mediated at least in part by enhanced nitric oxide (NO) production by the endothelium [121]. Because this effect requires prolonged or high doses of insulin, its physiologic significance has thus been questioned [120]. In patients with T2DM, defects in insulin action on blood flow have not been observed when tested at insulin concentrations within the physiologic range, but have been observed at grossly supraphysiologic insulin levels (600 mU/L) [120].

Insulin stimulates NO production in endothelial cells [122], and acutely increases endothelium-dependent but not endothelium-independent vasodilatation in normal subjects [121]. Endothelium-dependent vasodilatation is known to be impaired in T2DM and other insulin-resistant states [123,124]. Whether this defect is caused by insulin resistance at the level of endothelial cells [125] or to indirect causes of endothelial dysfunction such as chronic hyperglycemia [126] or dyslipidemia [124] cannot be determined from cross-sectional human data.

### Effects of insulin on autonomic nervous tone

Another of the many actions of insulin is its effect on the autonomic nervous system. Insulin can enter the hypothalamus and other parts of the brain, where insulin receptors are expressed at high levels, and it acts centrally to stimulate the sympathetic nervous system. Manifestations include increases in muscle sympathetic nervous activity [127] and in norepinephrine spillover rate (a measure of norepinephrine release from sympathetic nerve endings in the tissues) [128]. Insulin also regulates the autonomic control of heart rate, decreasing vagal tone and increasing sympathetic drive [129]. In insulin-resistant obese subjects, basal sympathetic tone is increased and the subsequent response to insulin blunted [130]. This defect is also observed in non-obese but insulin-resistant subjects [129], and in patients with T2DM [131]. Enhanced central effects of the associated hyperinsulinemia may contribute.

### Insulin resistance, hemostasis and coagulation

Insulin normally inhibits platelet aggregation [132], and this action is blunted both *in vitro* [132] and *in vivo* [133] in insulin-resistant obese subjects without diabetes and those with T2DM.

Plasminogen activator inhibitor 1 (PAI-1) is an inhibitor of fibrinolysis, and raised plasma levels predict increased risk of a coronary event [134]. Procoagulant changes, such as impaired

fibrinolysis and increased levels of PAI-1, and defects in platelet function are frequently associated with insulin resistance, especially in obese patients with T2DM. These abnormalities predispose to atherothrombotic vascular disease (see Part 8).

### Effects of insulin on uric acid metabolism

In normal subjects, insulin acutely reduces the renal clearance of both sodium and uric acid [135]. These actions are preserved in insulin-resistant states such as obesity, diabetes and essential hypertension, and so provide a potential mechanistic link for the clustering of hyperinsulinemia with hyperuricemia and hypertension [136,137].

### Other effects of insulin

Insulin acutely lowers serum potassium concentrations by stimulating potassium uptake into skeletal muscle and the splanchnic bed [138]. It also attenuates agonist-induced intracellular increases in  $Ca^{2+}$  concentrations in vascular smooth muscle cells [139] and inhibits sodium, potassium and phosphate excretion by the kidney [138]. The hypokalemic antinatriuretic actions of insulin are both preserved in patients with insulin resistance affecting glucose metabolism and essential hypertension [140,141] and in those with T2DM [142].

### Relationship of insulin resistance to hypertension

Of the putative components of the “insulin resistance syndrome,” the association between insulin resistance and hypertension is perhaps the most controversial. Hypertension and insulin resistance have been shown to be linked, independently of confounding factors such as obesity [143], but the relationship appears inconsistent [144–146]. Numerous mechanisms have been postulated to explain this association, but it is currently unclear which – if any – are relevant. In insulin-resistant patients with essential hypertension, basal intracellular  $Ca^{2+}$  levels have been shown to be elevated, and the normal ability of insulin to attenuate angiotensin II induced increases in intracellular  $Ca^{2+}$  is blunted in skin fibroblasts [139]; however, there are no data in patients with T2DM. The renal action of insulin to reabsorb sodium is similar in normotensive and hypertensive insulin-resistant subjects and in patients with T2DM [142], which implies that changes in the antinatriuretic effect of insulin cannot explain the increased prevalence of hypertension in insulin-resistant individuals or those with T2DM. The suggestion that insulin sensitivity influences salt sensitivity is controversial [147–151]. Insulin resistance has consistently been found to correlate with high sodium–lithium counter-transport in erythrocyte membranes; this is thought to parallel increased activity of the  $Na^+ - H^+$  pump in the cell membrane of other tissues, which could raise intracellular  $Na^+$  and  $Ca^{2+}$  concentrations and enhance vascular smooth muscle contractility. Such defects may contribute to the development of hypertension in both insulin-resistant subjects without diabetes and in patients with T2DM (see Chapter 40).

In theory, an increase in peripheral vascular resistance (which would raise diastolic blood pressure) could also be a consequence of impaired insulin-induced vasodilatation. Such defects,

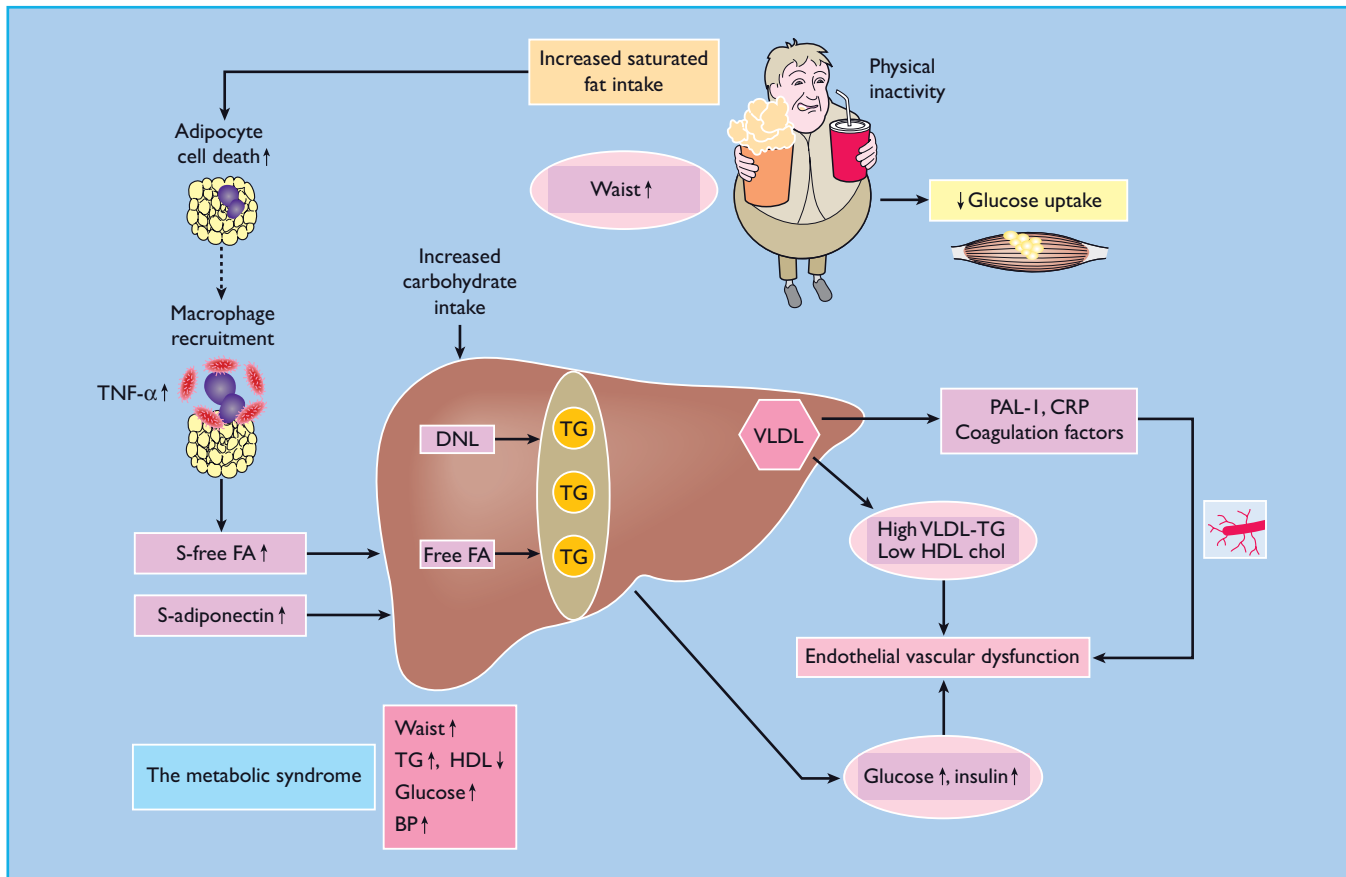

however, have not been documented under physiologic conditions [120]. It is also unclear whether the defects in endothelium-dependent vasorelaxation observed at very high insulin concentrations are specific to insulin or are a consequence of a more generalized defect in endothelial or smooth-muscle function, or of structural changes in arteries secondary to hypertension. Increased systolic blood pressure is, in most hypertensive individuals, a consequence of increased arterial stiffness [152]. Resistance to the normal ability of insulin to decrease stiffness could therefore increase systolic blood pressure [117].

### Conclusions

Insulin resistance, even when present in individuals without diabetes, is characterized not only by abnormalities in glucose homeostasis, but also by defects in insulin regulation of lipid and uric

acid metabolism, vascular function, hemostasis and coagulation. These consequences of insulin resistance (normal or impaired glucose tolerance, hypertriglyceridemia, a low HDL cholesterol concentration, small LDL size, hypertension, increases in uric acid and PAI-1 concentrations) and fasting hyperinsulinemia were called “syndrome X” by Reaven [153] to emphasize that insulin resistance comprises a cluster of abnormalities.

This syndrome, now called the metabolic syndrome (Table 11.2) rather than syndrome X, is important to recognize clinically as it is associated with many components that can potentially be modified to prevent premature atherosclerosis and cardiovascular disease, the main cause of excessive mortality in those with T2DM. Various mechanisms have been proposed to explain how insulin resistance and/or the accompanying hyperinsulinemia could cause these abnormalities. Accumulation of fat in the liver appears to occur in those individuals who develop the metabolic syndrome, independent of obesity. The liver, once fatty, is insulin

**Figure 11.7** Causes and consequences of insulin resistance and pathogenesis of the metabolic syndrome. Overeating and inactivity are common and important causes of obesity. In many obese but also sometimes in non-obese subjects, fat accumulates in the liver. Saturated fat and high refined carbohydrate intake may be particularly harmful. Genetic predisposition also has a role, at least in fat accumulation in the liver. In obese subjects with a fatty liver, adipose tissue is inflamed. This inflammation is characterized by increased expression of cytokines such as tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), and increased macrophage infiltration around dead adipocytes. The cause of the inflammation poorly understood.

Inflamed adipose tissue is insulin-resistant and overproduces free fatty acids (FFA) which contribute to excess triglyceride storage (TG) in the liver. Adiponectin deficiency also characterizes inflamed adipose tissue and decreases insulin sensitivity. Once fatty the liver overproduces glucose and VLDL as depicted in Figure 11.3, and also other factors such as plasminogen activator 1 (PAI-1) and coagulation factors. Excess refined carbohydrate may increase *de novo* lipogenesis in the liver (DNL), thus increasing intrahepatocellular triglyceride. Overeating and inactivity are also characterized by insulin resistance of glucose uptake by skeletal muscle.

resistant and overproduces glucose, VLDL, PAI-1, C-reactive protein and coagulation factors, which could all contribute to increased cardiovascular risk (Figure 11.7). The exact causes of why fat accumulates in the liver of some but not others are unknown but appear to involve genetic factors (adiponutrin polymorphism) and acquired factors (use of refined carbohydrates, high saturated fat intake, weight gain). Insulin resistance and inflammation characterize adipose tissue of those who have a fatty liver. In patients with T2DM, insulin resistance is further worsened by chronic hyperglycemia, which itself causes insulin resistance.

## The Genetics of Type 2 Diabetes: From Candidate Gene Biology to Genome-wide Studies

Martine Vaxillaire<sup>1</sup> & Philippe Froguel<sup>1,2</sup>

<sup>1</sup>CNRS-8090 Unit, Pasteur Institute, Lille, France

<sup>2</sup>Section of Genomic Medicine, Imperial College London, London, UK

### Keypoints

- Type 2 diabetes (T2DM) is a multifactorial heterogeneous disease with a complex interplay of genetic and environmental factors influencing intermediate traits such as  $\beta$ -cell mass and development, insulin secretion and action, and fat distribution.
- Three general approaches to identifying genetic susceptibility factors are used: the study of candidate genes selected as having a plausible role in glucose homeostasis; a genome-wide scan to detect chromosomal regions with linkage in nuclear families; a genome-wide scan for association with common variants (single nucleotide polymorphisms and copy number variant); and the study of spontaneous, bred or transgenic animal models of T2DM.
- Common T2DM shows familial clustering, but does not segregate in a classic Mendelian fashion. It is thought to be polygenic and probably multigenic (many different gene combinations among people with diabetes). Only a small fraction of the genetic risk for common adult T2DM is known.
- Common nucleotide variants within or near the genes implicated in monogenic forms of diabetes (e.g. *GCK*, *HNF4A* or *HNF1B/TCF2* in maturity-onset diabetes of the young [MODY], or *WFS1* in Wolfram syndrome) may contribute to T2DM with modest risk effects.
- Candidate genes identified as having an association with common polygenic T2DM include the insulin promoter, class III alleles of the variable region upstream of the insulin gene, the peroxisome proliferator-activated receptor  $\gamma$  (*PPARG*), *KCNJ11* encoding the pore forming Kir6.2 subunit of the  $\beta$ -cell inwardly rectifying  $K_{ATP}$  channel. Minor susceptibility might operate in some populations from other genes, including insulin receptor substrate 1 (*IRS-1*), adiponectin (*ACDC*) or ectonucleotide pyrophosphatase/phosphodiesterase 1 enzyme (*ENPP1*) in a context of obesity or diabetes.
- In genome scans of diabetic families, loci for T2DM have been found at several sites, including chromosomes 1q, 2q (*NIDDM1*), 2p, 3q, 12q, 11q, 10q and 20. *NIDDM1* has been identified as coding for calpain 10, a non-lysosomal cysteine protease with actions at the mitochondria and plasma membrane, and also in pancreatic  $\beta$ -cell apoptosis.
- In 2007, five large genome-wide association studies in European descent populations have identified new potential T2DM genes, including the Wnt signaling related transcription factors *TCF7L2* and *HHEX*, the zinc transporter ZnT8 (*SLC30A8*), the CDK5 regulatory subunit-associated protein 1-like 1 (*CDKAL1*) and a regulatory protein for IGF2 (*IGF2BP2*). A consensus of close to 20 confirmed T2DM-susceptibility loci to date provided novel insights into the biology of T2DM and glucose homeostasis, but individually with a relatively small genetic effect. Importantly, these genes implicate several pathways involved in  $\beta$ -cell development and function.
- Compared with clinical risk factors alone, the inclusion of common genetic variants (at least those identified to date) associated with the risk of T2DM has a small effect on the ability to predict future development of T2DM. At the individual level, however, a combined genotype score based on 15 risk alleles confers a 5–8 fold increased risk of developing T2DM. Identifying the subgroups of individuals at higher risk is important to target these subjects with more effective preventative measures.

### Genetic architecture of type 2 diabetes: a complex interaction of genetic susceptibility and environmental exposures

Type 2 diabetes mellitus (T2DM) is a heterogeneous metabolic disease resulting from defects of both insulin secretion and action

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

[1,2]. The prevalence of diabetes has been estimated as 12.3% of the population of the USA, and worldwide to affect 285 million people with a projection to increase to 435 million by 2030 [3]; the vast majority of these individuals have T2DM. The disease affects various groups differently; minority racial groups including Hispanics, African-Americans, Native Americans or people living in the Middle East are affected at a higher rate than white individuals.

The etiology of T2DM is multifactorial, including genetic as well as prenatal and postnatal factors that influence several

different defects of glucose homeostasis, primarily in  $\beta$ -cell function and also in muscle and liver. It is generally accepted that T2DM results from a complex interplay of genetic and environmental factors influencing a number of intermediate traits of relevance to the diabetic phenotype ( $\beta$ -cell mass, insulin secretion, insulin action, fat distribution and obesity) [3]. Quantitative phenotypes related to glucose homeostasis are also known to be heritable, with a greater relative impact of genetic components on *in vivo* insulin secretion [4].

Although several monogenic forms of diabetes have been identified (see Chapter 15), such as maturity-onset diabetes of the young (MODY) and maternally inherited diabetes and deafness (MIDD) [5,6], diabetes in adulthood seems to be a polygenic disorder in the majority of cases. T2DM shows a clear familial aggregation, with a risk for people with familial diabetes that is increased by a factor of 2–6 compared with those without familial diabetes; it does not segregate in a classical Mendelian fashion, and appears to result from several combined gene defects, or from the simultaneous action of several susceptibility alleles, or else from combinations of frequent variants at several loci that may have deleterious effects when predisposing environmental factors are present [3,7]. T2DM is probably also multigenic, meaning that many different combinations of gene defects may exist among subgroups of people with diabetes. Whereas the current worldwide epidemic of T2DM is greatly driven by lifestyle and dietary changes, a combination of these environmental factors and susceptible genetic determinants contribute to the development of T2DM [7].

The primary biochemical events leading to common diabetes in adulthood are still largely unknown in most cases, even if new genetic and biologic insights into T2DM etiology have recently arisen from the completion of genome-wide association (GWA) studies in several European descent populations [3,7]. Genetic and environmental factors may affect both insulin secretion and insulin action [1], and a variety of environmental factors can be implicated in the clinical expression of T2DM (see Chapter 4), such as the degree and type of obesity, sedentary lifestyle, malnutrition in fetal and perinatal periods, lifestyle and different kinds of drugs such as steroids, diuretics and antihypertensive agents (see Chapter 16). It is noteworthy that obesity, which is one of the so-called risk factors of T2DM, is also clearly under genetic control. Both disorders are frequently associated and share many metabolic abnormalities, which suggests that they might also share susceptibility genes [8,9]. Moreover, retrospective studies have shown that low birth weight is associated with insulin resistance and T2DM in adulthood [10,11]. It has been proposed that this association results from a metabolic adaptation to poor fetal nutrition [12]. The identification of gene variants that contribute both to variation in fetal growth and to the susceptibility to T2DM, however, suggests that this metabolic “programming” could also be partly genetically determined [13].

These complex interactions between genes and environment complicate the task of identifying any single genetic susceptibility factor for T2DM. Three general approaches have been adopted

**Table 12.1** Genetic and genomic approaches used for the study of type 2 diabetes genes.

<b>Family-based studies</b>
Linkage studies (genome-wide scan with microsatellite markers)
Transmission disequilibrium test (in sibships or nuclear families)
Study of monogenic diabetes (extreme phenotypes, syndromic diseases)
<b>Population-based studies</b>
Survey of candidate genes and targeted genomic regions (~100 SNPs)
Genome-wide association study (HapMap-based SNPs choice, 500K–1M SNPs)
Other types of genetic markers (rare variants, CNVs, insertion/deletion)
Study of general populations and prospective cohorts (epidemiology-based data)
<b>Functional genomic approaches</b>
Gene expression profiling, transcriptomics (microarray gene expression data in human and animal models)
Molecular and cellular analyses ( <i>in vitro</i> and <i>in vivo</i> model systems)
Expressed quantitative trait linkage (in human and animal models)
Epigenetics (in humans, and animal models)
CNV, copy number variant; SNP, single nucleotide polymorphism.

to search for genes underlying complex traits such as T2DM [6], as described in Table 12.1.

The first approach was to focus on candidate genes, that is, genes selected as having a plausible role in the control of glucose homeostasis and/or insulin secretion, on the basis of their known or presumed biologic functions. Although this approach has led to the identification of several susceptibility genes with small effects (see below), no genes with a moderate or major effect on the polygenic forms of diabetes have been found. Possible explanations for this failure to identify genes with a major effect include the possibility that they do not exist, or our incomplete knowledge of the pathophysiologic mechanisms of T2DM and the genes that control them, has obscured the choice of candidates.

The second approach is to perform genome-wide scans for linkage in collections of nuclear families or sib-pairs with T2DM [14], or for GWA in large case–control samples, as was performed in recent years [15]. These “hypothesis-free” approaches require no presumptions as to the function of the susceptibility loci. Although a large number of genomic regions with presumed linkage have been mapped [11–14], identification of the susceptibility genes and causal variants within these regions has proceeded at a very slow pace. In contrast, the recently completed GWA studies from several independent European case–control cohorts have released at least a dozen of confirmed at-risk loci, with unexpected susceptibility genes for T2DM and a number of at-risk variants having been replicated in most of the European populations investigated [6,15,16].

A third approach has used microarray gene expression analysis in attempt to define genetic alterations in T2DM. Through such analysis, a defect in skeletal muscle of people with diabetes was

discovered and characterized by a coordinated decrease in the expression of nuclear-encoded genes involved in mitochondrial oxidative phosphorylation [17]. This defect appears to be secondary to reduced expression of the transcriptional coactivators PGC-1 $\alpha$  and PGC-1 $\beta$ . Similar changes in expression have been observed in some cohorts of first-degree relatives of individuals with diabetes, suggesting that these may be heritable traits [18]. A second potential gene is the transcription factor ARNT/HIF1 $\beta$ , which was identified using islets isolated from individuals with T2DM compared with normal glucose-tolerant controls. Reduced ARNT levels in human diabetic islets were associated with altered  $\beta$ -cell expression of other genes involved in glucose sensing, insulin signaling and transcriptional control [19], suggesting an important role for ARNT in the impaired islet function of human T2DM.

Another complementary approach to identifying diabetes genes is to study spontaneous (such as the Zucker diabetic fatty rats or fat/fat mice, [20]), bred (like the GK rats, [21]) or transgenic (using  $\beta$ -cell-specific gene inactivation, [22–24]) animal models of T2DM. The genes responsible for diabetes in these models may not necessarily be major players in typical T2DM in humans, but such studies provide the most direct way of improving the overall understanding of the molecular circuitry that maintains glucose homeostasis. Nevertheless, despite the evidence of a strong genetic background in T2DM, very little is yet known about the genetic risk factors for T2DM. By far the most striking results in defining etiologic genes have been obtained by studying the highly familial MODY form of young-onset diabetes or other rare forms of monogenic diabetes.

## Genes involved in monogenic diabetes and their relevance to adult-onset T2DM

Some of the most compelling evidence that inherited gene defects can cause glycemic dysregulation comes from the clinical and genetic description of monogenic forms of diabetes, including MODY characterized by an autosomal dominant inheritance of young-onset diabetes, neonatal or early infancy diabetes, or diabetes with extrapancreatic features (see Chapter 15) [4,6]. Although rare, these monogenic forms of diabetes provide a paradigm for understanding and investigating some of the genetic components of more complex forms of diabetes in adults.

The well-defined mode of inheritance of MODY, with a high penetrance and early-onset diabetes, allows the collection of multigenerational pedigrees, making MODY an attractive model for genetic studies. MODY usually develops in thin young adults (usually before 25 years of age; in childhood, adolescence or young adulthood), and is associated with primary insulin-secretion defects [4,5]. The prevalence of MODY is estimated to be less than 1–2% of patients with T2DM, although it could represent as many as 5% of European cases of diabetes [4,25]. MODY is not a single entity, but involves genetic, metabolic and clinical heterogeneity. So far, heterozygous mutations or chromosome rearrangements in seven genes have been identified as responsible for the disease (Table 12.2). These genes encode the enzyme glucokinase (*GCK*, MODY type 2) [26–28], the transcription factors hepatocyte nuclear factor 4 $\alpha$  (*HNF-4 $\alpha$* /*HNF4A*, MODY type 1) [29], hepatocyte nuclear factor 1 $\alpha$  (*HNF-1 $\alpha$* /*HNF1A*,

**Table 12.2** The different subtypes of maturity-onset diabetes of the young (MODY).

MODY type	Gene locus	Gene name	Year of discovery	Distribution	Onset of diabetes	Primary defect	Severity of diabetes	Complications	OMIM
MODY1	20q	<i>HNF4A (TCF14)</i>	1996	Rare (2–3%)	Adolescence/early adulthood	Pancreas/other	Severe	Frequent	600281
MODY2	7p	<i>GCK</i>	1992	20–60%*	Early childhood/life-long	Pancreas/liver	Mild IFG	Rare	138079
MODY3	12q	<i>TCF1 (HNF1A)</i>	1996	15–60%*	Adolescence/early adulthood	Pancreas/kidney/other	Severe	Frequent	142410
MODY4	13q	<i>IPF-1</i>	1997	Rare (<1%)	Early adulthood	Pancreas/other	Severe	Unknown; pancreas agenesis and NDM in homozygote (rare)	600733
MODY5	17q	<i>TCF2 (HNF1B)</i>	1997	Rare (2%)	Early adulthood	Kidney/pancreas	Severe	Kidney disease (RCAD); pancreas agenesis and NDM in homozygote (rare)	189907
MODY6	2q32	<i>NEUROD1</i>	1999	Rare (<1%)	Early adulthood	Pancreas	Severe	Unknown; NDM in homozygote (rare)	601724
MODY7	11p15.5	<i>INS</i>	2008	Rare (<1%)	Early childhood/early adulthood	Pancreas	Mild to severe	Rare	176730

IFG, impaired fasting glycemia; NDM, neonatal diabetes mellitus; RCAD, renal cysts and diabetes syndrome.

\* Different distributions in different populations.

MODY type 3) [30,31], insulin promoter factor 1 (IPF-1, MODY type 4) [32,33], hepatocyte nuclear factor 1 $\beta$  (HNF-1 $\beta$ /TCF2, MODY type 5) [34] and NEUROD1/ $\beta$ 2 (MODY type 6) [35], and the preproinsulin (*INS*) (MODY type 7) [6]. Moreover, additional unknown genes (MODY-X) related to the MODY phenotype remain to be discovered from families in which early-onset diabetes cosegregates with genetic markers outside the known MODY loci [36–38].

The relative prevalence of the different subtypes of MODY has been shown to vary greatly in studies of British, French, German and Spanish family cohorts [39–42]. These contrasting results may be caused by differences in the genetic background of these populations, or else may reflect, at least partly, ascertainment bias in the recruitment of families. Altogether, mutations in *GCK* and *HNF1A* are the cause of the two most prevalent MODY2 and MODY3 subtypes, accounting for around 50–60% of all MODY cases. Mutations in *HNF4A* and *TCF2/Hnf-1 $\beta$*  were identified in many dozens of families and the other defects caused by mutations in *PDX1* and *NEUROD1* are rarer disorders [43,44].

Recent challenging studies have tried to identify a connection between monogenic diabetes genes and common T2DM, that is to test whether common but less severe variants might have a role in the pathogenesis of common multifactorial forms of the disease. Indeed, if major mutations (i.e. causing a substantial functional defect and normally rare or absent in the general population) lead to a highly penetrant form of diabetes, it seems plausible that more subtle genetic changes affecting the structure or expression of the gene product might have a role in determining (minor) susceptibility to T2DM. Our current understanding of genetic variants influencing T2DM supports this hypothesis [3,4,6], but common variants (also referred as single nucleotide polymorphisms [SNPs]) in the known MODY genes seem to contribute very modestly to the common forms of T2DM, as recently assessed in a staged case–control study from multiple clinical samples [45]. In this study, the strongest effects were found for an intronic variant of *TCF2/HNF-1 $\beta$*  and for the –30 G/A variant of *GCK*. The –30 G/A polymorphism in the  $\beta$ -cell specific promoter of glucokinase was found to modulate diabetes risk, with the (–30) A-allele being associated with an increased risk) [45]. A similar genetic association was observed with a stronger effect in a French prospective study of a middle-aged general population, along with a significant impact on the modulation of fasting glycemia and insulin secretion HOMA-B index [46]. Furthermore, a meta-analysis of previously reported association results for *GCK* (–30A) with T2DM showed a modest overall effect on disease risk of 1.08 ( $P = 0.004$ ) in European populations [45].

Mutations in *HNF1 $\alpha$*  were identified in African-Americans and Japanese subjects with atypical non-autoimmune diabetes with acute onset [47,48]. In the Oji-Cree native Canadian population the G319S mutation in *HNF1A*, found in approximately 40% of patients with diabetes, accelerates the onset of T2DM by 7 years [49]. Such findings show that *HNF1A* mutations can be associated with typical adult-onset insulin-resistant obesity-related diabetes in addition to MODY.

A population-based study in Swedish and Finnish cohorts using both *in vitro* and *in vivo* experiments has shown that common variants in and upstream of the *HNF1A* gene influence transcriptional activity and insulin secretion *in vivo* [50]. Some of these variants are associated with a modestly higher risk of diabetes in subsets of elderly overweight individuals. Mutations in *HNF4A* and *IPF1* genes were also identified in a number of families with late-onset T2DM [51]. IPF-1/Pdx-1 has a dosage-dependent regulatory effect on the expression of  $\beta$ -cell-specific genes and therefore assists in the maintenance of euglycemia. As a consequence, frequent variants in the regulatory sequences controlling IPF-1/Pdx-1 expression in the  $\beta$ -cell, or in genes coding for transcription factors known to regulate IPF-1, could contribute to common T2DM susceptibility. Two independent studies, from the Ashkenazim [52] and Finnish [53] populations, have reported significant associations between common variants adjacent to the *HNF4A* P2 promoter and T2DM. Interestingly, some of the diabetes-associated variants account for most of the evidence of linkage to chromosome 20q13 reported in these two populations. Consistent with these results, genetic variation near the P2 region of *HNF4A* is associated with T2DM in other Danish and UK populations, but not in French and other Caucasian populations [54] which argues for genetic heterogeneity in *HNF4A* variants susceptibility [55].

Recent studies have evaluated the genotype–phenotype correlation between the MODY genes and the common form of T2DM and have reported that several common variants (MAF >0.05) in *TCF2/HNF1 $\beta$*  may contribute to T2DM risk but with modest effects (allelic odds ratio [OR] <1.25); the strongest effect was found for an intronic variant with corrected  $P$  values <0.01 and OR of 1.13 [45]. Independently, a GWA scan performed to search for sequence variants conferring risk of prostate cancer demonstrated with replication from eight case–control groups that two intronic variants located in the first and second intron of *TCF2* gene confer protection against T2DM (OR 0.91,  $P \sim 10^{-7}$ ) in individuals of European, African and Asian descent [56]. Several epidemiologic studies have reported an inverse relationship between T2DM and the risk of prostate cancer, and a recent meta-analysis estimated the relative risk of prostate cancer to be 0.84 (95% CI 0.71–0.92) among patients with diabetes [57]. Previous explanations of this inverse relationship between T2DM and prostate cancer have centered on the impact of the metabolic and hormonal environment in men. The protective effect of the *TCF2* SNPs against T2DM is too modest to explain their impact on prostate cancer risk by a consequence of an effect on diabetes. The primary functional impact of *TCF2* variants may lie within one or more metabolic or hormonal pathway, and incidentally may modulate the risk of developing prostate cancer and T2DM throughout life.

Genetic variation in the *WFS1* gene, which encodes a 890-amino-acid polypeptide named wolframin, a transmembrane protein located in the endoplasmic reticulum (ER), which serves as an calcium channel, not only results in the rare Wolfram

syndrome (known as DIDMOAD and characterized by early-onset non-autoimmune diabetes mellitus, diabetes insipidus, optic atrophy and deafness) [58,59] but is also associated with susceptibility to adult T2DM [60]. In a pooled case-control analysis comprising >20 000 individuals, several SNPs in *WFS1* (including a non-synonymous SNP, R611H) were shown to modulate diabetes risk (OR ~0.92 for a minor allele frequency of ~40% [60]), with a population attributable fraction of 9%, which could explain 0.3% of the excess familial risk. This study provides further evidence that wolframin has an essential role in the ER stress response in insulin-producing pancreatic  $\beta$ -cells, and contributes to the risk of common T2DM.

### Search for T2DM genes in the pre-GWA era

Before the completion of GWA studies in early 2007, numerous focused candidate gene studies, driven by biologic or functional hypotheses, and the hypothesis-free linkage approach, have delivered a small number of validated T2DM susceptibility genes which effects the disease process (both insulin secretion and insulin sensitivity), although contributing at the individual level with a modest risk effect.

#### Candidate gene approach

The molecular screening of candidate genes to search for genetic variants (either rare when the allele frequency is <0.01, or common in the population tested) potentially associated with diabetes status (i.e. more frequent in individuals with T2DM) has so far been the most frequently used approach to tackle the genetic determinants of T2DM [61]. There are many reasons why specific genes may be candidates:

- A gene may have a known or presumed biologic function in glucose homeostasis or energy balance in humans.
- It may be implicated in subtypes of diabetes, such as MODY or neonatal diabetes.
- It may be associated with diabetes or associated traits in animal models.
- It may be responsible for an inherited disease that includes diabetes (e.g. mitochondrial cytopathies, Wolfram syndrome).
- The gene products may be differentially expressed in diabetic and normal tissues.

For obvious reasons, the insulin gene was among the first genes to be studied. Apart the more recent identification of rare mutations in the sequence of the preproinsulin gene responsible for neonatal and non-autoimmune early infancy diabetes [5,6], mutations in the coding regions of the insulin gene have been reported to be associated with familial hyperinsulinemia in less than 10 families, but are not consistently associated with T2DM [62]. Mutations in the promoter region, however, could affect the regulation of the insulin gene, leading to absolute or relative hypoinsulinemia. A variant allele of the promoter has been observed in about 5% of African-Americans with T2DM, and shown to be associated with decreased transcriptional activity

[63]. An association between T2DM and paternally transmitted class III alleles of the variable number tandem repeat (VNTR) region upstream of the insulin gene (*INS-VNTR*) was observed in British families [64]. Interestingly, class III alleles (one of the two main classes of *INS-VNTR* allele length, with 141–209 repeats) were also found to be associated with increased length and weight at birth [65] and with a dominant protection against type 1 diabetes [66] compared with type I alleles.

Key components of the insulin signaling pathways have also been tested. They were at first thought to be important players in the context of the insulin resistance of T2DM. Several of these genes are also expressed in pancreatic  $\beta$ -cells, and several studies from knockout animals have demonstrated that they may also have an important role in the mechanisms of insulin secretion [23,24]. More than 50 different mutations have been found in the coding regions of the insulin receptor gene on chromosome 19p (see Chapter 15) [67]; patients with these mutations seldom present with the common form of T2DM [68], but rather with a syndrome of severe insulin resistance associated with leprechaunism, or with acanthosis nigricans, hirsutism and major hyperinsulinemia [69]. Missense variants in the gene encoding the first substrate for the insulin receptor kinase (*IRS1*) on chromosome 2q have been detected in several populations [70–73] but an association of these variants with diabetes was not observed in all studies [74,75].

Similarly, an association between polymorphisms of the muscle glycogen synthase gene (*GYS1*) on chromosome 19q and T2DM has been observed in Finnish [76] and in Japanese [77] subjects, but not in French subjects [78]. Taken together, these results suggest that the *IRS1* and *GYS1* genes may act in some populations as minor susceptibility genes, which are neither necessary nor sufficient for disease expression, but may nevertheless modulate the phenotype in the patients. This is important in the light of more recent data obtained from combined and meta-analyses conducted by GWA follow-up studies, which report a significant effect of common variants at the *IRS1* locus on T2DM risk in European descent populations (unpublished results).

Functionally significant polymorphisms have also been identified in other proteins involved in insulin action, such as the phosphatidylinositol 3 kinase [79] and the ectonucleotide pyrophosphatase/phosphodiesterase 1 enzyme (ENPP1 or PC-1), a transmembrane glycoprotein that downregulates insulin signaling by inhibiting insulin-receptor tyrosine kinase activity [80]. ENPP1 is expressed in multiple tissues including three targets of insulin action: adipose tissue, muscle and liver. A missense variation in its gene *ENPP1*, in which lysine 121 is replaced by glutamine (K121Q, rs1044498), results in a gain-of-function mutation leading to greater inhibition of the insulin receptor and clinical insulin resistance [81]. Pizutti *et al.* [82] first identified the association while studying healthy non-obese non-diabetic Sicilian subjects. *ENPP1* K121Q is also associated with an earlier onset of T2DM in Europeans and obese children, suggesting that the variant may accelerate disease onset in predisposing individu-

als. Not all studies have replicated these results, and some studies have reported that high body mass index (BMI) exacerbates, or in some cases is a prerequisite for, the deleterious role of *ENPP1* K121Q on insulin resistance-related phenotypes and T2DM [83,84]. Meyre *et al.* [85] reported an effect of the Q121 variant on the risk of both morbid obesity and hyperglycemia in large samples of French children and adults, as observed in children from Germany [86] and British adults [87]. Given the major role of obesity in deteriorating glucose homeostasis, the different effect of the Q121 variant on BMI in different samples may be, at least partly, responsible for the non-homogeneous results so far reported on the risk of across different studies. A recent large meta-analysis performed on published case-control studies has shown that, although results are not homogeneous across all samples, individuals carrying the variant have an approximately 20% increased risk of T2DM [88].

Another biologic candidate gene that was extensively studied is the peroxisome proliferator-activated receptor  $\gamma$  gene (*PPARG*), where mutations that severely decrease the transactivation potential were found to cosegregate with extreme insulin resistance, diabetes and hypertension in two families, with autosomal-dominant inheritance [89]. A common amino-acid polymorphism (Pro12Ala) in *PPARG* has been associated with T2DM; homozygous carriers of the Pro12 allele are more insulin resistant than those having one Ala12 allele and have a 1.25-fold increased risk of developing diabetes [90]. This common polymorphism has a modest, yet extensively replicated effect on the risk of T2DM. There is also evidence for interaction between this polymorphism and the insulin secretion in response to fatty acids [91], and BMI [92]; the protective effect of the alanine allele was lost in subjects with a BMI greater than 35 kg/m<sup>2</sup>. A widespread Gly482Ser polymorphism of PGC1- $\alpha$  (known as *PPARGC1*), a transcriptional coactivator of a series of nuclear receptors including *PPARG*, has been associated with a 1.34 genotype relative risk of T2DM [93]. In this study, a test for interaction with the Pro12Ala variant in *PPARG* gave no indication for additive effects on diabetes status.

Other genes have been shown to be implicated in the genetic susceptibility to insulin resistance. Although they do not appear to be directly linked or associated with T2DM, they may also modulate the disease expression. A common and widespread polymorphism at codon 905 in the gene encoding the glycogen associated regulatory subunit of protein phosphatase 1 (PP1), which is expressed in skeletal muscle and plays a crucial part in muscle tissue glycogen synthesis and breakdown, has been shown to be associated with insulin resistance and hypersecretion of insulin in Danish subjects with T2DM [94]. A missense mutation in the intestinal fatty acid binding protein 2 (*FABP2*) gene on chromosome 4q has been found to be associated with increased fatty acid binding, increased fat oxidation and insulin resistance in the Pima Indians of Arizona [95], an ethnic group with the highest reported prevalence of T2DM and insulin resistance in the world. A rare P387L variant in protein tyrosine phosphatase-1B (PTP-1B), a negative regulator for insulin and

leptin signaling, has been described to be associated with a 3.7 genotype-relative risk of T2DM in a Danish Caucasian population, resulting in impaired *in vitro* serine phosphorylation of the PTP-1B protein [96]. In an extensive analysis of the *PTPN1* gene locus, Bento *et al.* [97] found convincing associations between multiple SNPs and T2DM in two independent Caucasian American case-control samples. A modest effect of *PTPN1* gene variants on disease risk was observed in the French population, whereas consistent associations with metabolic variables reflecting insulin resistance and dyslipidemia were found for two intronic SNPs, thereby influencing susceptibility to metabolic diseases [98].

Mutations in transcription factors have also been reported to contribute to the genetic risk for T2DM through various mechanisms: dysregulation of target genes involved in glucose or lipid metabolism (*HNFs*, *PPARG*, *IPF-1*, *IB1*, *TIEG2/KLF11*), impaired  $\beta$ -cell development and differentiation (*IPF-1*, *NEUROD1*/ $\beta$ 2, *TIEG2/KLF11*), and increased  $\beta$ -cell apoptosis (*IB1*/*MAPK8IP1*). Deleterious mutations that significantly impair the transactivation activity of these transcription factors can be responsible in some families for monogenic-like forms of diabetes with late age of onset, which may represent an intermediary phenotype between MODY and the most common forms of T2DM. This is the case for the *TIEG2/KLF11* gene encoding the Krüppel-like factor 11 (KLF11), an SP1-like pancreas expressed transcription factor that is induced by the transforming growth factor  $\beta$  (TGF- $\beta$ ) and regulates cell growth in the exocrine pancreas. A common polymorphism (Q62R) in *KLF11* was reported to be associated with polygenic T2DM developing in adulthood and to affect the function of KLF11 *in vitro* [99]. Insulin levels were found to be lower in carriers of the minor allele at Q62R [99] but attempts of replication in other populations only found a minor, or no detectable effect of the Q62R common variant on diabetes risk [100]. Sequencing of *KLF11* gene in families enriched for early-onset T2DM uncovered two missense mutations which segregated with diabetes in three pedigrees [99], but proof of their causality was only based on *in vitro* experiments. These findings suggest a role for the TGF- $\beta$  signaling pathway in pancreatic diseases affecting endocrine islets (diabetes) or exocrine cells (cancer) [101].

Another example is the identification of a mutation in islet brain 1 (*IB1*, *MAPK8IP1*) found to be associated with diabetes in one family [102]. *IB1* is a homologue of the *c-jun* amino-terminal kinase interacting protein 1 (JIP-1), which has a role in the modulation of apoptosis [103]. *IB1* is also a transactivator of the islet glucose transporter GLUT-2. The mutant *IB1* was found to be unable to prevent apoptosis *in vitro* [102]. It is thus possible that the abnormal function of this mutant *IB1* may render the  $\beta$ -cells more susceptible to apoptotic stimuli, thus decreasing  $\beta$ -cell mass. As glucotoxicity and lipotoxicity are known to induce both apoptosis and transcription factor down regulation in pancreatic  $\beta$ -cells, inherited or acquired defects in *IB1* activity could have deleterious effects in  $\beta$ -cell function.

Other genes encoding key components of insulin secretion pathways have also been tested as potential candidates for a role in the genetic susceptibility of T2DM. The pancreatic  $\beta$ -cell ATP-sensitive potassium channel (IKATP) has a central role in glucose-induced insulin secretion by linking signals derived from glucose metabolism to cell-membrane depolarization and insulin exocytosis (see Chapter 6) [104]. IKATP is composed of two distinct subunits: an inwardly rectifying ion channel forming the pore (Kir6.2), and a regulatory subunit, which is a sulfonylurea receptor (SUR1) belonging to the ATP-binding cassette (ABC) superfamily [105]; both subunits are expressed in neuroendocrine cells. The *KCNJ11* and *ABCC8* genes encoding these two subunits are located 4.5 kb apart on human chromosome 11p15.1. Inactivating mutations in each of these genes may result in familial persistent hyperinsulinemic hypoglycemia in infancy, and gain-of-function mutations are responsible of the opposite phenotype of neonatal diabetes (either permanent or transient forms of the disease with distinct distributions of mutations in each gene), demonstrating their role in the regulation of insulin secretion (see Chapter 15) [106]. Studies in various populations with different ethnic backgrounds have provided evidence for associations of SNPs in these genes with T2DM [107–112]. In particular, a common variant, E23K, of *KCNJ11*/Kir6.2 has now been convincingly associated with an increased risk of T2DM and decreased insulin secretion in glucose-tolerant subjects [113,114]. Large-scale studies and meta-analyses have consistently associated the lysine variant with T2DM, with an OR of 1.15 [115].

Increasing evidence from more recent studies also suggested that inflammatory processes may have a pivotal role in metabolic diseases: prospective studies have shown that high plasma interleukin 6 (IL-6) levels increased T2DM risk [116], but conflicting associations were found between a promoter polymorphism (G-174C) in *IL6* and T2DM [117,118]. In a large joint analysis of 21 case-control studies, representing >20 000 participants in one of the largest association studies addressing the role of a candidate gene in T2DM susceptibility, the *IL6* promoter variant was found to be associated with a lower risk (OR 0.91,  $P = 0.037$ ) [119]. In addition, association between T2DM and *IL6R*-D358A was reported in Danish white people [120], and with *TNF* G-308A promoter SNP in the Finnish Diabetes Prevention Study [118]. The effects of both *IL6* and *IL6R* variants on developing T2DM risk in interaction with age have been reported in a prospective study of a general French population [46].

### Hypothesis-free genome-wide approach and positional cloning of T2DM genes

The second approach used in the years 1995–2005 for identifying genes underlying common polygenic T2DM, the so-called genome-wide familial linkage (GWL) studies, was based on genome-wide scans to detect chromosomal regions showing linkage with diabetes in large collections of nuclear families or sib-pairs. This strategy required no assumptions regarding the function of genes at the susceptibility loci, because it attempted to map genes purely by position. Genotyping of approximately

400 multiallelic markers (short tandem repeats or microsatellites, with a density of  $\sim 1$  marker/10 cM) allows identification of polymorphic markers showing strong allele identity by descent in diabetic family members (i.e. allele sharing in sibships is significantly higher than 50%). Once identified, such susceptibility genes for diabetes may then be positionally cloned in the intervals of linkage.

This total genome approach has been used for some time in other multifactorial diseases such as type 1 diabetes [121] and obesity [5]. More than 20 genome scans for T2DM have been completed, involving thousands of pedigrees from different populations and ethnic groups. One of the limitations of the genome-scan approach is the relatively low power of the method, which is unable to detect a weak linkage signal because of the low relative risk for diabetes in siblings (about a three- to fivefold increase in comparison with the general population). Working on very large family collections (>500 sib-pairs), in more homogeneous ethnic groups (e.g. island populations), or in large pedigrees using quantitative intermediary traits instead of the dichotomous diabetes status, has improved the effectiveness of this approach in detecting linkage. Indeed, intermediary phenotypes were shown to have greater heritability than the dichotomous endpoint. To avoid bias brought about by the effect of chronic hyperglycemia on many traits, other strategies have been proposed to analyze the general population [122] or to collect sibships of the offspring of subjects with diabetes who are not yet diabetic but are at high risk of developing the disease [123]. False-positive results are likely to occur. Thus, stringent criteria for linkage (in the magnitude of  $P < 10^{-5}$ ) need to be used to minimize bias brought about by multiple testing. Indeed, a level of statistical significance at the genome-wide level (i.e. giving a less than 5% chance that a linked locus is false) implies a multipoint lod score higher than 3.6 at a given chromosomal region. This value is not a rigid one; each case is different, and sophisticated simulations are needed to provide an empirical  $P$  value, and therefore to assess the robustness of the data obtained. Indeed, the validation (or the absence of validation) of a linked locus has strong implications for further research, and careful examination is necessary. For this reason, another criterion for a true locus has been the replication of the findings by others. Although less stringent  $P$  values are required ( $10^{-3}$ ), replication is difficult, because genetic heterogeneity, ascertainment biases and phenotypic differences across studies may mask a confirmatory linkage. Furthermore, genotyping errors have a substantial effect on linkage analyses.

Since 1996, the results of several genome scans in families with diabetes have been published [123]. A summary of the best T2DM linkage replication results is presented in Table 12.3. A locus for T2DM on chromosome 2q (*NIDDM1*) was initially found in Mexican Americans [14], and it was shown that an interaction between this locus and a locus on chromosome 15 further increases the susceptibility to diabetes in this population [124]. A region of replicated linkage between diabetes and

\*The data on the number of LOD scores in each interval that met the threshold criteria are adapted from the study by Lillioja & Wilton [206].

<sup>†</sup> Ethnic origins of the populations showing a genetic linkage in each interval (Af, African; CJ, Chinese/Japanese; Eu, European; MA, Mexican American; Yc, other/combined data) followed in parentheses by the number of such results.

<sup>‡</sup> Phenotypes in each interval (D, type 2 diabetes; Q, quantitative trait) and the number of each type of result.

chromosome 1q21-25 was reported in different populations of European origin and in Pima Indians [123]. Linkages with diabetes and with the age at onset of diabetes were found on chromosome 3q27 [125–127], and in a region on chromosome 10q in Mexican American families from San Antonio, Texas [128]. Linkage was found at a locus near *TCF1* on chromosome 12q in Finnish T2DM families, characterized by a predominant insulin secretion defect [13]. Evidence for an obesity–diabetes locus on chromosome 11q23-q25 [129] and linkage of several chromosomal regions with prediabetic traits [14] were observed in Pima Indians from Arizona, an ethnic group with a high prevalence of diabetes and obesity. Evidence for the presence of one or more diabetes loci on chromosome 20 was found in different populations [130,131]. In these and other studies, a large number of loci showing only suggestive or weak indication of linkage with diabetes-related traits have also been reported, several of which fall in overlapping regions.

Some concerns have therefore been raised about the heterogeneity and reliability of genetic data in multifactorial diseases in general (e.g. the lack of replication), and in T2DM in particular. A new series of genome scans published in 2000 and later [125–127], however, has surprisingly shown that results obtained from T2DM families may be reproducible, despite differences in ethnicity and in environmental factors. It is likely that progress both in automated genotyping and statistical analyses of larger sample sets have improved the quality of the data. A meta-analysis of the data obtained from all European studies has confirmed findings

on 1q, 2p and 12q, and also revealed a new locus on 17p linked to the metabolic syndrome in the US population [132,133]. These data provide a strong basis for believing that some important genetic contributors to common T2DM exist.

Although genome-wide scans have mapped T2DM loci, each hit represents 10–20 million nucleotides. The challenge was to identify the diabetes-related genes within these intervals, knowing that hundreds of genes may be present. To identify the true etiologic gene variants associated with an enhanced risk for T2DM, one first positional cloning approach was to refine the chromosomal regions of linkage using a dense map of biallelic SNPs as markers for the detection of linkage disequilibrium (LD) mapping [134–136]. DNA polymorphisms located away from the true functional variant may be associated with the disease, or with the variation of a diabetes-associated trait. The strength of LD is quite variable within the genome, ranging from 10 to 300 kb or more. It has been postulated that working in a so-called “isolated” population should significantly enhance results with LD, but even research in Finns or in Icelanders may not resolve the problems [137].

The identification of the *NIDDM1/CAPN10* gene (coding for calpain-10, a non-lysosomal cysteine protease) on 2q37 confirmed that LD mapping may be a successful strategy for unravelling other polygenic diseases [138]. This work, however, also showed the complexity of the search, because in this case an intronic polymorphism (UCSNP-43) was associated with T2DM in Mexican Americans. In fact, three non-coding polymorphisms,

including SNP-43, SNP-44 and SNP-63, have been identified as defining an at-risk haplotype [138]. In other ethnic groups, such as French Caucasians, the rarity of this high-risk haplotype made it difficult to achieve a definite answer concerning the role of calpain-10 in T2DM. Nonetheless, recent pooled and meta-analyses as well as the LD and haplotype diversity studies suggest a role for genetic variation in *CAPN10* affecting risk of T2DM in Europeans [139]. *CAPN10* was thus the first diabetes gene to be identified through a genome-wide scan approach. Many investigators, but not all, have subsequently found associations between *CAPN10* polymorphism(s) and T2DM as well as insulin action, insulin secretion, aspects of adipocyte biology and microvascular functions. This has not always been with the same SNP or haplotype or the same phenotype, suggesting that there might be more than one disease-associated *CAPN10* variant and that these might vary between ethnic groups and the phenotype under study. Indeed, both genetic and functional data indicated that calpain-10 has an important role in insulin resistance and intermediate phenotypes, including those associated with the adipocyte [140]. In this regard, emerging evidence would suggest that calpain-10 facilitates GLUT-4 translocation and acts in the reorganization of the cytoskeleton. Interestingly, calpain-10 is also an important molecule in the  $\beta$ -cell. It is likely to be a determinant of fuel sensing and insulin exocytosis, with actions at the mitochondria and plasma membrane, respectively, and also of pancreatic  $\beta$ -cell apoptosis [141].

Only a few other chromosomal regions have shown highly significant lod scores in several populations. The best example is probably the chromosome 1q21-25 region (in particular the 30 Mb stretch adjacent to the centromere), which ranks alongside the regions on chromosomes 10 and 20 as amongst the strongest in terms of the replicated evidence for GWL to T2DM. Linkage has been reported in samples of European (UK, French, Amish, Utah), East Asian (Chinese, Hong Kong) and Native American (Pima) origin (summarized in [123]). The homologous region has also emerged as a diabetes-susceptibility locus from mapping efforts in several well-characterized rodent models [142]. The human region concerned is gene-rich and contains a disproportionate share of excellent biologic candidates, and genetic variation in a number of them has already been investigated with details in the populations showing 1q21-linkage (e.g. the genes *USF1* encoding the upstream stimulatory factor 1, *LMNA1* encoding Lamin A/C, *PBX1* encoding a TALE-homeodomain transcription factor that has a role in pancreatic development and is an important cofactor of Pdx1, the “master regulator” of pancreatic development and function, *ATF6* encoding activating transcription factor 6, or *DUSP12* encoding the glucokinase-associated, dual-specificity phosphatase 12). These studies have been conducted by an international consortium, which represent a coordinated effort by the groups with the strongest evidence for 1q linkage, by using a high-density, custom LD mapping approach applied to a well-powered set of multi-ethnic samples to identify variants causal for that signal [143]. Detection of low-frequency susceptibility variants also requires new approaches and the

future plans of the 1q consortium include deep resequencing of the 1q region of interest, focusing at least initially on exons and conserved sequence.

Linkage with chromosome 20 has been also found in several ethnic groups, from Finns to Japanese subjects [147], but the linked region is rather large, raising the issue of whether there may be several susceptibility genes. While common variants upstream of *HNF4A* that maps to chromosome 20q13 have been reported to explain the linkage signals seen in Finns and Ashkenazim [144,145], these associations have proved difficult to replicate in many other populations [146].

Loci overlapping between T2DM, obesity and the metabolic syndrome have appeared on chromosome 2p [125,147] and on chromosome 3q27 [125,126,127]. Several candidate genes map to the 3q27 region, including the *APM1/ACDC* gene encoding the differentiated adipocyte-secreted protein, adipocyte complement-related protein 30 (Acrp30/adiponectin), which is an adipokine abundantly present in plasma. The purified C-terminal domain of adiponectin has been reported to protect mice on a high-fat diet from obesity, and to rescue obese or lipotrophic mice models from severe insulin resistance, by decreasing levels of plasma free fatty acids (FFAs) and enhancing lipid oxidation in muscle [148]. Moreover, plasma levels of adiponectin have been shown to be decreased in obese subjects with diabetes and to correlate with insulin sensitivity [149], which makes *ACDC/ACRP30* an attractive candidate gene for fat-induced metabolic syndrome and T2DM.

Both common and rare variants of *ACDC/ACRP30* were found to be associated with T2DM in numerous obese populations, but do not contribute to the 3q27 linkage in the French families, suggesting that other genes may be involved. Common variants in and upstream of *EIF4A2* (encoding the eukaryotic translation initiation factor 4  $\alpha$ 2) have been shown to contribute to both age of onset of diabetes and linkage in the French families studied [150].

One notable exception is the identification of *TCF7L2* as a T2DM gene with the largest risk effect of intronic variants of any diabetes gene identified to date. In early 2006, common intronic variants of the *TCF7L2* gene encoding the transcription factor 7-like 2 (TCF7L2) were identified to be strongly associated with T2DM risk in the Icelandic population by DeCODE Genetics (Reykjavik, Iceland) during a follow-up positional cloning study from a modest linkage signal on chromosome 10q [151]; but it turned out that despite not explaining this linkage signal, multiple intronic SNPs also showed strong association in US and Danish samples [151]. This initial study was rapidly followed by widespread replications in different ethnic backgrounds from white Europeans, West Africans, Mexican Americans, Indian and Japanese populations [152], confirming that *TCF7L2* variants have the largest risk effect of any of the known T2DM susceptibility loci. As shown in a meta-analysis from >20 studies in diverse ethnicities, the estimated risk of rs7903146 T allele (the most T2DM-associated variant) was 1.46 ( $P = 5.4 \times 10^{-140}$ ) [153].

At the individual level, carrying one *TCF7L2* risk allele may increase diabetes risk by 40%–60% [152]. As a marked variation in *TCF7L2* rs7903146 T allele frequency exists between individuals from different ethnic groups, this implies a variable impact in the respective general populations. In European general populations, rs7903146 T allele has been estimated to contribute to 10–25% of all cases of diabetes in lean individuals [152]. In Eastern Asians, the population attributable risk fraction was assessed at 18.7% for other specific risk alleles [154]. The rs7903146 variant has been shown to influence progression to diabetes (with a hazard ratio of 1.81 for the homozygote TT group in the participants from the Diabetes Prevention Program) [155].

In the French and UK populations, rs7903146 T allele was associated with lower BMI in individuals with T2DM and with a higher risk for T2DM in non-obese subjects [152], but it is not a risk factor for obesity in European populations, whereas its effect on T2DM risk was found to be modulated by adiposity [156]. Watanabe *et al.* [157] suggested that an interaction between *TCF7L2* and adiposity may be caused by a better  $\beta$ -cell compensation in obese individuals.

*TCF7L2* is a member of the T-cell specific high mobility group (HMG) box containing family of transcription factors which, upon binding  $\beta$ -catenin, transduces signals generated by Wnt receptors at the cell surface to modify expression of multiple genes, many of which are associated with the cell cycle. Mutations in *TCF7L2* are also implicated in certain types of cancer [158], but rare *TCF7L2* mutations are not contributing to monogenic forms of diabetes such as MODY and neonatal diabetes [159]. One mechanism whereby *TCF7L2* variants increase diabetes risk might involve an impairment of incretin effects (i.e. GLP-1) on islet functions [160,161]. Indeed, variants of *TCF7L2* specifically impair GLP-1-induced insulin secretion [162], and the stimulation of  $\beta$ -cell proliferation by GLP-1 is *TCF7L2* dependent [163]. *TCF7L2* is also required to maintain glucose-stimulated insulin secretion and  $\beta$ -cell survival because its deletion in human islets reduces insulin secretion and increased apoptosis [164]. Furthermore, the overexpression of *TCF7L2* protects  $\beta$ -cells from glucose and cytokine-induced apoptosis [164]. Clinical studies have demonstrated that the at-risk SNP is associated with defects in  $\beta$ -cell function and insulin release. The study by Lyssenko *et al.* [161] suggested that pancreatic islets from subjects with T2DM bearing the at-risk TT genotype have increased *TCF7L2* RNA levels, indicating that excessive *TCF7L2* expression may be associated with the reported insulin secretory defects. Expression studies carried out by Elbein *et al.* [165] on adipose tissue and muscle, however, showed that *TCF7L2* expression was not altered by genotype and did not correlate with insulin sensitivity or BMI. As the most associated SNP rs7903146 is found in an intronic region, a potential mechanism through which it may confer an increased risk of diabetes is by altering *TCF7L2* expression levels, but the functional mechanisms through which *TCF7L2* modulates glucose sensing and insulin release in pancreatic  $\beta$ -cells remain to be clarified. A recent study showed that *TCF7L2* silenc-

ing in primary mouse islets as well as in clonal MIN6 and INS-1(832/13) cells decreases both basal and glucose-stimulated insulin secretion [166]. *TCF7L2* silencing also abolished the stimulatory effects of GLP-1 on secretion, whilst having little impact on glucose-induced changes in intracellular ATP or free  $\text{Ca}^{2+}$  concentrations. The study by da Silva Xavier *et al.* [166] showed that *TCF7L2* controls the expression of genes involved in insulin granule fusion at the plasma membrane (notably syntaxin 1A and Munc 18-1 which may be direct targets for regulation by *TCF7L2*). Thus, defective insulin exocytosis may underlie increased diabetes incidence in carriers of the at-risk *TCF7L2* alleles.

---

## The era of GWA studies improved knowledge of T2DM susceptibility genes

### New discoveries in the genetic etiology of T2DM

Important advances in T2DM genetics have been made with the completion of GWA studies based on HapMap-selected common SNPs. This has become reality with the outstanding breakthroughs made in the knowledge and assessment of human genome variations, their mapping and their links with the genetic background of common diseases [167], and in the development and accessibility to very high throughput genotyping techniques based on microarray technology and to biostatistical tools for large cohort data analyses.

Within only few months of 2007, five independent GWA screens for T2DM, based on the Illumina 300K or Affymetrix 500K genotyping arrays both capturing about 80% of common variants present in the human genome of Caucasian individuals, identified dozens of potential candidates; at least 15 new loci emerged as being most consistently associated with risk of T2DM across multiple studies (Table 12.4). These include variants within or near *SLC30A8*, *HHEX*, *CDKAL1*, *CDKN2A/2B*, *IGF2BP2* and *JAZF1* [15]. Three of the associated loci correspond to genes that had already been implicated in T2DM (*TCF7L2*, *KCNJ11*, *PPARG*). These studies also confirmed that *TCF7L2* was the highest genetic risk factor for T2DM in populations of European descent. The next strongest SNP is in a 33-kb LD block within the coding region of *SLC30A8* encoding a zinc membrane transporter (ZnT8) which is highly expressed in pancreatic islets [168]. Interestingly, the overexpression of ZnT8 in the HeLa cell line is associated with an accumulation of zinc in intracellular vesicles [168]. In the INS-1E  $\beta$ -cell line, which overexpresses ZnT8, the intracellular zinc level is increased and the insulin secretion is stimulated [169]. Furthermore, overexpressing ZnT8 does not sensitize the cells to toxic doses of zinc but confers a resistance to apoptosis after zinc depletion [169]. The non-synonymous polymorphism showing an increased risk of T2DM (OR per risk allele: 1.18) corresponds to an arginine to tryptophan substitution at position 325, and the at-risk C-allele is associated with impaired  $\beta$ -cell function *in vivo*. An impaired transporter function may decrease the amount of zinc available for co-crystallization with insulin in the secretory vesicles of

<sup>†</sup> Under a recessive model of inheritance in white populations (according to the meta-analysis by McAteer *et al.* [88]).

$\beta$ -cells. *SLC30A8*/ZnT-8 has also recently been identified as an autoantigen in human type 1 diabetes [170].

A locus on 10q23 ranked third for association with T2DM in the French GWA study was then independently replicated in the other large studies, but with a combined OR of only 1.13. SNPs at this locus have been found to be associated with measures of insulin secretion in a large multicentric study from Europe and in the Diabetes Prevention Program (DPP) study [171]. The association signal lies in a 295-kb block of LD that includes at least three potential T2DM genes: *HHEX* (a homeobox transcription factor); *KIF11* (a kinesin interacting factor); and *IDE* (an insulin degrading enzyme).

Another well-replicated association signal maps to 6q22 within a 15-kb LD block in the intron 5 of the *CDKAL1* gene coding for CDK5 regulatory subunit-associated protein 1-like 1, with the strongest association observed in the DeCODE study [172]. CDK5 itself has been shown to blunt insulin secretion in response

to glucose and to have a permissive role in the decrease of insulin gene expression that results from glucotoxicity. Thus, it is speculated that reduced expression of *CDKAL1* would result in enhanced activity of CDK5 in  $\beta$ -cells, and lead to decreased insulin secretion; in agreement, variants at this locus were significantly associated with small decreases in insulin response to a glucose load [171,173].

A meta-analysis of three GWA scans followed by a large-scale replication (Diagram consortium including more than 50 000 individuals in total) has identified additional susceptibility loci for T2DM, with OR ranging from 1.09 to 1.15, near six genes: *JAZF1*, *CDC123-CAMK1D*, *TSPAN8-LGR5*, *THADA*, *ADAMTS9* and *NOTCH2* [174]. Variants at *JAZF1*, *CDC123-CAMK1D* and *TSPAN8-LGR5* are associated with small alterations in insulin secretion, whereas the mechanisms linking the other loci to T2DM remain to be clarified [175]. In each GWA scan, other loci showed significant associations with T2DM, but were not fol-

**Figure 12.1** Chronology in the discovery of the genetic loci associated with type 2 diabetes. Validated type 2 diabetes-associated genes are plotted by year of publication and approximate effect size. Allelic effect sizes (OR value) are derived from major publications of definitive associations (as indicated in Table 12.4). Color code: purple indicates candidate genes with a biologic effect on insulin sensitivity at different sites; red with an effect on pancreatic islet function

and insulin secretion; yellow with effects on both insulin secretion and sensitivity; red with pink lines indicates genes uncovered via genome-wide association studies, for which common variants increase disease risk through impaired  $\beta$ -cell function (for most of them); blue for one gene modulating fasting plasma glucose and type 2 diabetes risk through impaired  $\beta$ -cell function and other mechanism(s).

lowed up because of lack of replication across multiple studies. A larger meta-analysis study including almost all GWA studies for T2DM performed in European populations will extend the list of potentially at-risk alleles and genes (Figure 12.1).

These GWA results suggest that T2DM may be more heterogeneous and more polygenic than previously believed, and thereby represents a large number of different disorders which might also differ at a clinical level. The second finding is the relatively high frequency of each of the risk variants in the population (ranging from 0.26 for *TCF7L2* to 0.90 for *THADA*), together with a small risk of disease conferred by each allele translating into a very large number of individuals who carry several of the susceptibility variants but do not develop T2DM. Such low penetrance is consistent with the mild effect of the risk variants, requiring the presence of other factors, presumably environmental for the development of hyperglycemia, and may also be explained by the fact that most of these variants are in non-coding regions of the gene, where they may produce only subtle differences in regulation of expression. This is in contrast

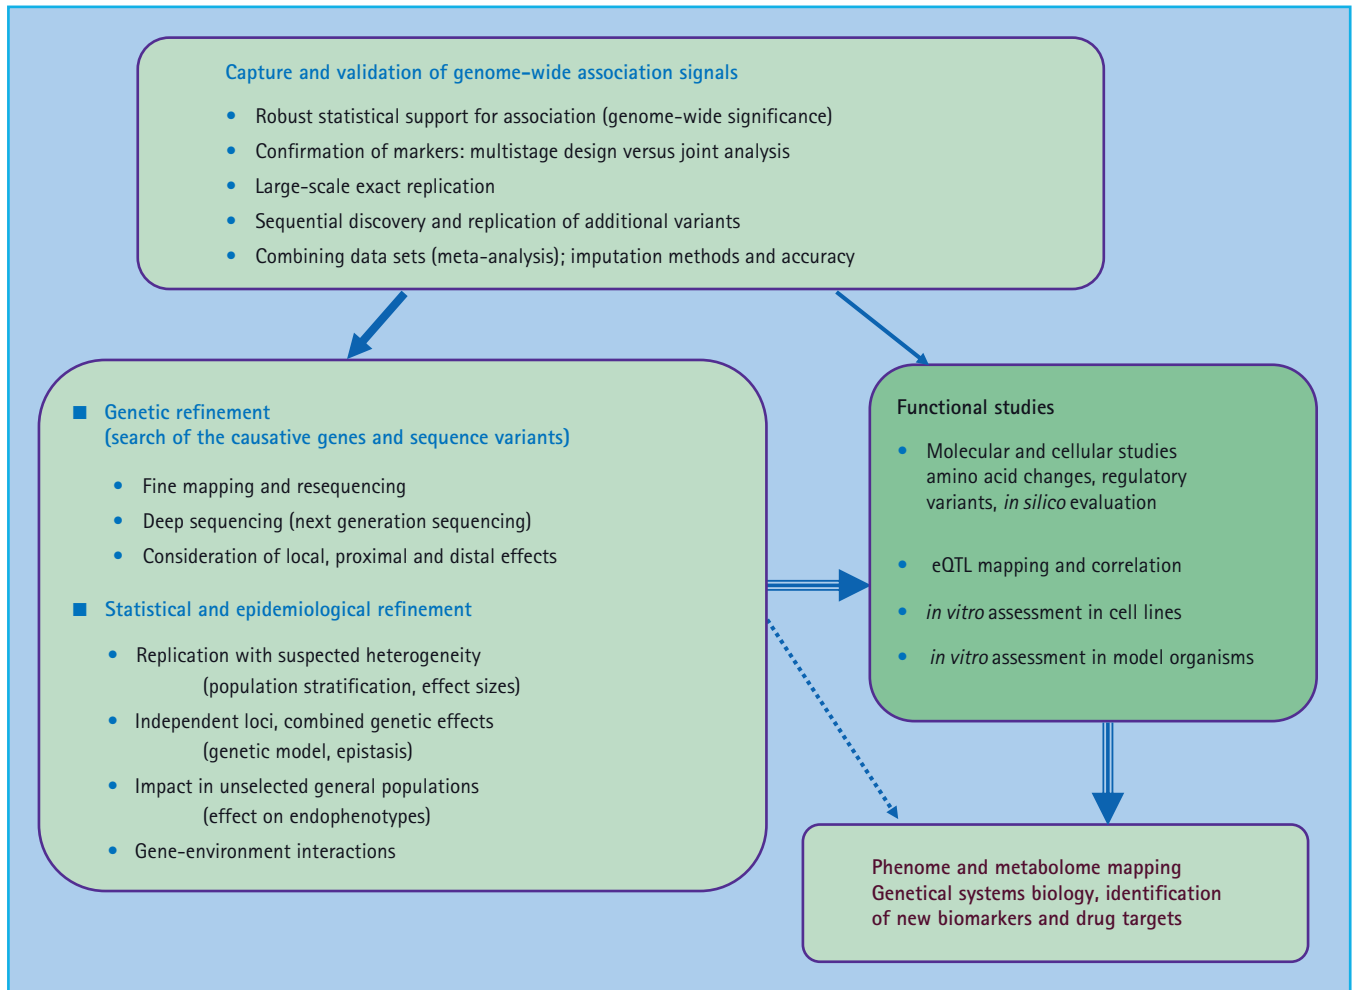

with Mendelian forms of diabetes, such as MODY, which are caused by rare mutations in the coding sequence resulting in significant amino acid substitutions or truncated proteins, leading to hyperglycemia even in the absence of other diabetogenic exposures.

It is also worthy of note that the loci identified to date appear to explain only a small proportion of the familial clustering of T2DM, and thus are just the tip of the iceberg. Indeed, there is a discrepancy between the linkage and GWA studies, and this may be explained by the presence of multiple, uncommon, mildly deleterious polymorphisms scattered throughout the regulatory and coding regions of genes for T2DM.

The current genetic models of how genes interact with each other and with the environment may be too simplistic, and probably clouded by our underestimation of the role of genetic imprinting and/or epigenetics on gene expression and disease.

These new discoveries lead to the proposal of new etiologic mechanisms for T2DM, and would suggest that the genetic components to T2DM risk act preferentially through  $\beta$ -cell

**Figure 12.2** From the capture of genomic information to phenome and metabolome mapping. Flow chart of the research approaches and methods required to document, refine and validate genome-wide association signals. These steps have a rationale sequence, but this can also be modulated by the availability of resources and data, and the specific challenges that arise in each field.

defects, given that several of the genes placed in the proximity of GWA signals are expressed in  $\beta$ -cells and risk alleles at many of these loci alter insulin secretion capacity of the  $\beta$ -cells. Variants predisposing to diabetes through effects on insulin sensitivity, however, may be more difficult to track down because of strong environment–gene interactions for insulin resistance with body weight, physical activity, nutrient intake and other factors, compared with the potentially purer genetic control on insulin secretion. More generally, exploring these novel association data and truly causative DNA sequences as well as functional mechanisms requires pursuing other research efforts (Figure 12.2).

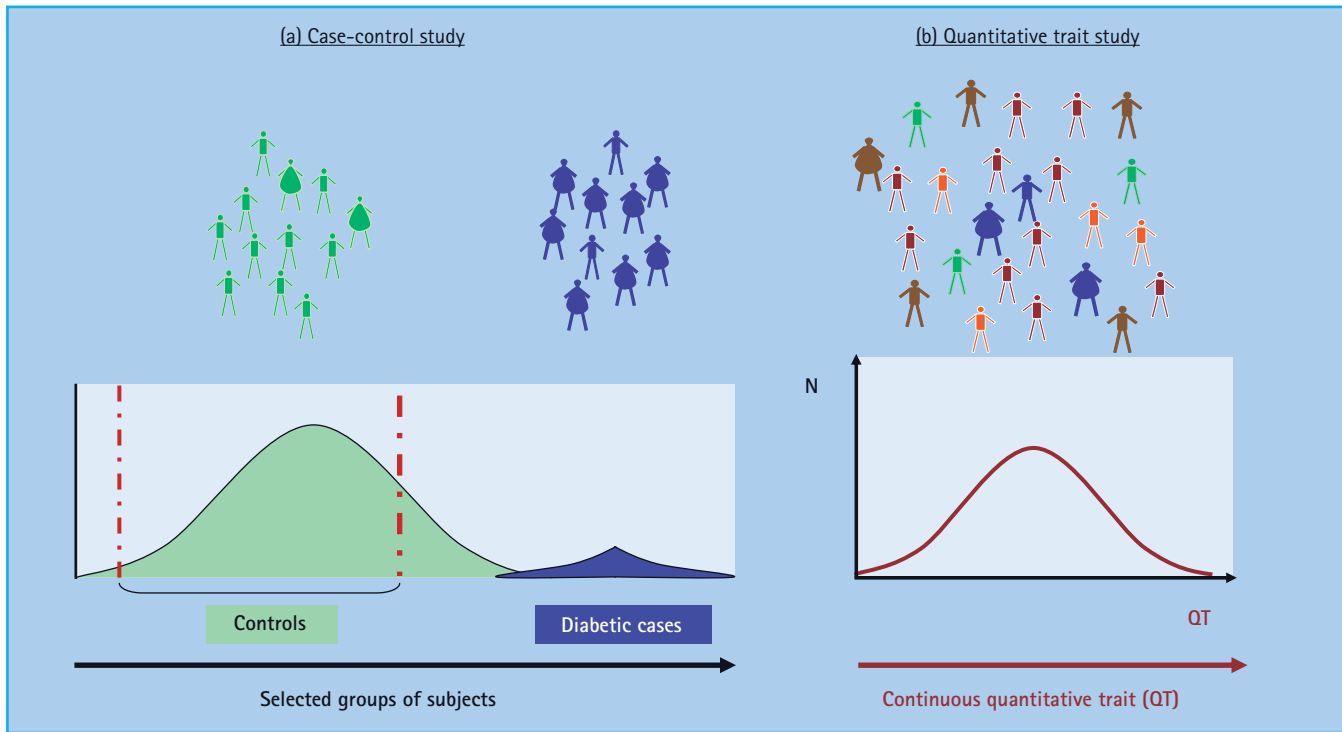

A concept emerging from these new discoveries is that there is a genetic overlap between T2DM and prostate cancer. Common variants in the T2DM susceptibility genes *TCF2* and *JAZF1* also influence prostate cancer risk [176]. For *TCF2*, the risk allele for T2DM has a protective effect on prostate cancer susceptibility, whereas two variants in *JAZF1* predispose to the two diseases, which are not correlated with each other [174,177]. The mecha-

nisms by which these genes influence disease are unknown; however, they are thought to be involved in cell-cycle control.

### Additional loci associated with quantitative metabolic traits

Analyses of quantitative traits among the non-diabetic controls in GWA studies have also identified common variants that modulate fasting glycemia, although these effects do not always appear to translate into an increased risk of T2DM (Figure 12.3).

Fasting plasma glucose (FPG) levels are tightly regulated within a narrow physiologic range by a feedback mechanism that targets a particular fasting glucose setpoint for each individual. Disruption of normal glucose homeostasis and substantial elevations of FPG are hallmarks of T2DM and typically result from sustained reduction in pancreatic  $\beta$ -cell function and insulin secretion [178,179]. Elevated FPG levels within the normal range are an independent risk factor for T2DM and are associated with increased risk of mortality in prospective studies [178].

**Figure 12.3** Schematic representation of the two major study designs used in the genetic mapping of complex traits and complex diseases. (a) Case-control study to search for genes and gene variants associated with disease risk. (b) Quantitative trait study to correlate genotype effects with modulation of continuous quantitative variables (i.e. values of a biologic measure, measured or calculated metabolic variables).

Even within the healthy non-diabetic population, however, there is substantial variation in fasting glucose levels; around one-third of this variation is genetic. There is growing evidence to suggest that common variants contributing to variation in FPG are largely distinct from those associated with major disruptions of  $\beta$ -cell function that predispose to established T2DM. Common sequence variants in the *GCK* (glucokinase) promoter and around genes encoding glucokinase regulatory protein (*GCKR*) and the islet-specific glucose-6-phosphatase (*G6PC2*) [180] have been associated with individual variation in FPG, whereas weak effects on T2DM risk were found. Three large independent studies in European populations, however, have recently demonstrated that non-coding variants in *MTNR1B* (encoding melatonin receptor 1B) are consistently associated with increased FPG levels (0.07 mmol/L per G-allele of rs10830963, the strongest signal observed at the locus), reduced  $\beta$ -cell function as measured by the homeostasis model assessment (HOMA-B index) and increased T2DM risk (OR of 1.09 for the same G-allele) [181–183], and with impairment of early insulin response to both oral and intravenous glucose and with faster deterioration of insulin secretion over time [183,184]. *MTNR1B* encodes one of the two known melatonin receptors and, as well as being highly expressed in the brain (mainly in the suprachiasmatic nucleus that controls the circadian rhythm) and retina, MT2 is also transcribed in human islets and sorted  $\beta$ -cells [181,185]. The study by Lyssenko *et al.* [183] showed an

increased expression of MT2 in islets of individuals without diabetes carrying the risk allele and of individuals with T2DM, and that insulin released from clonal  $\beta$ -cells in response to glucose was inhibited in the presence of melatonin. These data support a direct role of MT2 in mediating the inhibitory effect of melatonin on insulin secretion, and that the circulating hormone melatonin, which is released from the pineal gland in the brain to regulate the circadian rhythm by translating photoperiodic information from the eyes to the brain, is involved in the pathogenesis of T2DM. These pathogenic effects are likely to be exerted via a direct inhibitory effect on  $\beta$ -cells. In view of these results, blocking the melatonin ligand-receptor system could be a therapeutic option in T2DM.

The total variance in FPG attributable to these four signals is approximately 1.5%, indicating that additional loci remain to be found. The ongoing MAGIC (Meta-Analyses of Glucose and Insulin-related traits Consortium) transnational study group, which represents a collaborative effort to combine data from multiple GWAs to identify additional loci that affect glycemic and metabolic traits, and other studies from the Northern Finland Birth Cohorts, the ENGAGE consortium (including 20 000 individuals in multiple European cohorts and family studies) or other large cohorts, case-control studies and clinical trials from Europe and the USA, will continue to deliver novel association signals in additional loci, which may highlight novel pathways involved in regulation of common metabolic traits.

One recent study has reported a novel association between glycated hemoglobin (HbA<sub>1c</sub>) levels and intronic variants of *HK1* encoding the hexokinase type 1 isoform predominantly found in erythrocytes, although it is also expressed in other human tissues that depend strongly on glucose utilization for their physiologic functioning such as brain and muscle [186]. Three other loci – *GCK*, *G6PC2* and *SLC30A8* – have been identified in this study as being significantly associated with HbA<sub>1c</sub> levels in individuals without diabetes. While genetic variants of *GCK* and *G6PC2* are known to influence FPG levels in people without diabetes, the association with the diabetes gene *SLC30A8* has not been previously identified. Because intra-erythrocyte glucose concentration is thought to be the main determinant of HbA<sub>1c</sub> rate and HK1 is the initial and rate-limiting enzymatic step in erythrocyte glucose metabolism after glucose transporter mediated-diffusion, it is likely that variation in HK1 activity would affect glycation. Alternatively, genetic variations at HK1 might modulate systemic glucose metabolism, raising the possibility that these variations are associated with the risk of incident diabetes. Indeed, HK1 is expressed in muscle, an insulin-sensitive tissue recognized for its importance in glucose metabolism. Whether the differences in hemoglobin glycation associated with genetic polymorphisms are paralleled by differences in glycation in other tissues that are thought to underlie long-term complications of diabetes remains an open question.

Serum lipids are important determinants of cardiovascular diseases and are related to morbidity [187]. The high heritability of circulating lipid levels is well established, and earlier studies of individuals with extreme lipid values or families with Mendelian forms of dyslipidemias have reported the involvement of numerous genes and respective proteins in lipid metabolism [188]. Recent GWA studies mostly carried out in samples enriched for T2DM cases have implicated a total of 19 loci controlling serum high density lipoprotein (HDL) cholesterol, low density lipoprotein (LDL) cholesterol and triglycerides (TG). The loci include the genes encoding *ABCA1*, *APOB*, *CELSR2*, *CETP*, *DOCK7*, *GALNT2*, *GCKR*, *HMGCR*, *LDLR*, *LIPC*, *LIPG*, *LPL*, *MLXIPL*,

*NCAN*, *PCSK9* and *TRIB1*, and three genomic regions with multiple associated genes including *MVK-MMAB*, *APOA5-APOA4-APOC3-APOA1* and *APOE-APOC1-APOC4-APOC2* [188,189].

Many of these have also been consistently associated with lipid levels in candidate gene studies reported over the past 30 years; many of the same loci with common variants have already been shown to lead to monogenic lipid disorders in humans and/or mice, suggesting that a spectrum of common and rare alleles at each validated locus contributes to blood lipid concentrations [188].

More recently, larger scale GWA studies have identified additional loci for lipid levels [190,191], and sequencing of these loci should pinpoint all associated alleles. For three loci (*HMGCR* encoding HMGCoA, the drug target for statins, *NCAN* and *LPL*) effect sizes differed significantly by sex (i.e. gene–sex interactions) [190]. The construction of genetic risk profiles suggests that the cumulative effect of multiple common variants contributes to polygenic dyslipidemia [191].

With a full catalog of DNA polymorphisms in hand, a panel of lipid-related variants can be studied to provide clinical risk stratification and targeting of therapeutic interventions.

### Combined genetic effects of multiple susceptibility gene variants and clinical implications

GWA studies have dramatically increased the number of common genetic variants that are robustly associated with T2DM. A possible clinical use of this novel information is to identify individuals at high risk of developing the disease in the general population, so that preventative measures may be more effectively targeted (Figure 12.4).

A first study in a UK population showed that individuals combining T2DM risk alleles in *TCF7L2*, *PPARG* and *KCNJ11* had an OR of 5.71-fold compared with those with no risk alleles to develop the disease [192]. Then, using a similar case–control design, a second study in a French population reported that after adjustment for age, BMI and gender, subjects with at least 18 risk alleles (representing 14.5% of French subjects with T2DM) had

**Figure 12.4** Additive effects of common genetic variants (i.e. SNPs) on T2DM risk in the population. The distribution of normoglycose-tolerant (NGT, indicated by red bars) individuals and individuals with diabetes (T2DM, indicated by yellow bars) is shown according to the number of at-risk alleles in each class (for a total of 15 single nucleotide polymorphisms genotyped in each individual, from the best replicated variants following the results of genome-wide association studies). The study was performed in 4232 patients with diabetes and 4595 normoglycemic adult subjects. Adapted from Cauchi *et al.* [193].

**Figure 12.5** The predictive value of type 2 diabetes gene variants. Examples of receiver operator characteristic (ROC) curves for a test including classic clinical risk factors (in green) or three genetic variants at-risk for T2DM (in orange) or 15 genetic variants at-risk for T2DM (in red). The area under the ROC curve (AUC) is a measure of the discriminatory power of the test evaluating the predictive power of defined clinical factors or genetic variants (a test with no discriminatory power would have an AUC of 0.50). For details see [46,192–196].

approximately ninefold higher risk of developing T2DM compared with the reference group (with an area under the receiver operator characteristic (ROC) curve, a measure of discriminative accuracy, of 0.86; Figure 12.5) [193].

Two more recent population-based studies using a longitudinal design with prospectively investigated cohorts have examined the predictive value of a genotype score in addition to common risk factors for prediction of T2DM [194,195]. Meigs *et al.* [194] reported that a genotype score based on 18 risk alleles predicted new cases of diabetes in the community but provided only a slightly better prediction of risk than knowledge of common clinical risk factors alone [195]. A similar conclusion was drawn in the paper by Lyssenko *et al.* [196], along with an improved value of genetic factors with an increasing duration of follow-up, suggesting that assessment of genetic risk factors is clinically more meaningful the earlier in life they are measured. They also showed that  $\beta$ -cell function adjusted for insulin resistance (using the disposition index) was the strongest predictor of future diabetes, although subjects in the prediabetic stage presented with many features of insulin resistance. It is also noteworthy that many of the variants that were genotyped appear to influence  $\beta$ -cell function. The addition of DNA data to the clinical model improved not only the discriminatory power, but also the reclassification of the subjects into different risk strategies. Identifying subgroups of the population at substantially different risk of disease is important to target these subgroups of individuals with more effective preventative measures. As more genetic variants are now identified, tests with better predictive performance should become available with a valuable addition to clinical practice.

### Pharmacogenetics of T2DM in adults

An early focus of T2DM pharmacogenetic studies has been to examine the effect of *PPARG* P12A on the response to thiazolidinediones, because the nuclear receptor PPAR- $\gamma$  is the known

drug target of thiazolidinedione medications. In the TRIPOD study, one-third of subjects showed no increase in insulin sensitivity in response to troglitazone (400 mg/day); however, the P12A variant did not explain this failure [197]. Similarly, in the DPP study, no effect of *PPARG* P12A or five other polymorphisms was observed on response to troglitazone therapy in 340 participants randomized to this thiazolidinedione [198]. Knowledge of allelic variation at this locus does not seem to offer a rationale for therapeutic choices. The impact of the *KCNJ11* genetic variant (E23K) on the effectiveness of sulfonylurea therapy is also unclear. In the study by Sesti *et al.* [199], which genotyped the E23K variant in 525 white patients with T2DM, carriers of the 23K allele have a relative risk of failure (defined as FPG >300 mg/dL) of 1.45 compared with E23E homozygotes, and the risk allele was also associated with an earlier onset of diabetes and worse metabolic control in non-responders. These results stand in contrast to those of the UK Prospective Diabetes Study (UKPDS), in which no significant association was found between the E23K variant and response to sulfonylurea therapy in 364 patients with newly diagnosed T2DM [200]. Interestingly, in the DPP study, metformin was effective in lowering the risk of diabetes for the E23E homozygotes, but failed to protect carriers of the risk K-allele. In addition, K23K homozygotes randomized to metformin did not show the expected improvement in insulin sensitivity at 1 year [201].

In regard to a possible drug-*TCF7L2* genotype interaction, the GoDARTs study genotyped 6516 UK participants for the rs7903146 variant and found that the TT homozygote case and control subjects had a higher HbA<sub>1c</sub>, with the TT cases with diabetes being more likely to require oral medication or insulin than the CC homozygotes [202]. This suggests that *TCF7L2* risk variants may be associated with increased disease severity and therapeutic failure. The same group reported the effect of *TCF7L2* genotypes on therapeutic response in 901 patients with diabetes treated with sulfonylurea and 945 patients treated with metformin. Carriers of the risk *TCF7L2* variants were more likely not

to respond to sulfonylurea but to respond to metformin therapy as measured by a HbA<sub>1c</sub> >7% within 3–12 months after treatment initiation [203]. This finding further supports the hypothesis that *TCF7L2* variation is important in  $\beta$ -cell function. The DPP study reported that the lifestyle intervention was effective in reducing the genetic risk conferred by the high-risk homozygous genotype in the participants with impaired glucose tolerance and elevated fasting glucose [204].

Another example in which genetic variability may have a significant impact on therapy response is the organic cation transporter 1 (*OCT1*), which participates in the hepatic uptake of metformin, a widely used biguanide, and was shown to be highly polymorphic in humans. A clinical study by Shu *et al.* [205] reported that genetic variation in *OCT1* affects the metformin therapeutic action and the response to the drug.

## Conclusions and perspectives

Our knowledge of the genetic architecture of T2DM has greatly improved with the new GWA findings, and this will have promising implications on new diagnostics and therapeutics for T2DM. It is likely, however, that other yet unidentified genes may contribute to the genetic risk of T2DM, because only a part of the inheritance of T2DM in families has so far been explained. It should be emphasized that the current GWA studies are based on the “common disease/common variant” hypothesis, whereas the alternative “allelic heterogeneity” hypothesis holding that susceptibility to common disorders may result from a large number of rare variants, each having a relatively large effect, still has to be tested. Identification of such rare variants, if they exist, will require deep resequencing of T2DM loci (those already established, and novel) in cases of diabetes and in normoglycemic individuals, which is becoming more realistic with the ongoing development of new powerful sequencing methods. Likewise, the contribution of structural variants, such as copy number variants, insertions, deletions and duplications, could also contribute to genetic susceptibility not explained by single nucleotide substitutions. Further more novel approaches looking at epigenetic sites, multitissue genome expression related to genetic traits, metabolomics and metagenomics should bring even more knowledge in the near future.

Together, these discoveries will continue to improve our understanding of the biologic mechanisms that maintain glucose homeostasis, and of still hidden molecular defects leading to chronic hyperglycemia, and could also lead to the development of more specifically targeted antidiabetic drugs or even gene-based therapies. Moreover, pharmacogenetic testing might then be used to predict, for each patient, the therapeutic response to different classes of drugs. The identification of T2DM genes will also provide the tools for the timely identification of high-risk individuals who may benefit from early behavioral or medical intervention to prevent the development of diabetes. An important reduction in diabetes-related morbidity and mortality could

be then expected, along with a reduction in the costs of the treatment of diabetes and its complications.

## Metabolic Disturbances in Diabetes

**Adrian Vella & Robert A. Rizza**

Department of Internal Medicine, Division of Diabetes, Nutrition, Endocrinology & Metabolism, Mayo Clinic, Rochester, MN, USA

### Keypoints

- Type 1 diabetes is an immune-mediated disorder that leads to destruction of the islets of Langerhans causing profound insulin deficiency.
- Metabolic changes observed in type 1 diabetes are secondary to insulin deficiency interacting with environmental influences such as diet and exercise.
- The pathogenesis of type 2 diabetes mellitus is complex and incompletely understood. It appears to be caused by an interaction of genetic and environmental factors that lead to defects in insulin secretion, insulin action and glucose effectiveness.

### Introduction

Hyperglycemia, for better or for worse [1], is the metabolic abnormality that has been used to define the presence of, and characterize, diabetes. Diabetes comprises a heterogeneous group of disorders characterized by fasting and/or post-prandial hyperglycemia. The underlying abnormalities that lead to the development of hyperglycemia, however, differ amongst subgroups. Conventionally, diabetes has been categorized into two subgroups that, from a metabolic standpoint, differ in the degree of insulin deficiency present. This broad dichotomy is simplistic as a given patient may exhibit metabolic abnormalities previously considered unique to each category [2].

Type 1 (T1DM), or immune-mediated diabetes, is characterized by evidence of immune-mediated destruction of the insulin-secreting  $\beta$ -cells in the islets of Langerhans. Usually this leads to absolute insulin deficiency, which is insufficient to prevent unrestrained lipolysis during systemic illness or severe physical stress. In type 2 diabetes (T2DM), however, although the endocrine pancreas can produce insulin, secretion and circulating concentrations of insulin are inappropriate for the prevailing glucose concentrations. T2DM has traditionally been considered a disorder of insulin signaling (exacerbated by poor diet, obesity and lack of physical activity) rather than a deficiency of insulin.

It is important to remember that obese patients with T1DM can behave in a fashion similar to patients with long-standing T2DM and that metabolic differences between the two categories may be more imagined than real.

### Carbohydrate metabolism

In the fasting state, glucose appearance is determined by the rate of endogenous glucose release from the liver and to a lesser extent the kidney. This is collectively referred to as endogenous glucose production. Glucose concentrations increase when glucose appearance exceeds glucose disappearance and continues to increase until these rates are equal. In humans without diabetes, glucose concentrations average 4.5–5.5 mmol/L following a 6–12-hour overnight fast.

Gluconeogenesis is responsible for approximately 50–60% of endogenous glucose production following an overnight fast, with the proportion increasing with increasing duration of the fast [3]. Gluconeogenesis utilizes three-carbon precursors such as lactate, alanine and glycerol to synthesize glucose molecules.

Following an overnight fast, approximately 80% of glucose disposal is insulin independent and occurs in the brain, splanchnic tissues and erythrocytes [4]. The majority of insulin-mediated glucose disposal occurs in muscle [5]. Because insulin levels are low in the post-absorptive state, muscle predominantly uses free fatty acids (FFA) for fuel [6]. In the presence of low insulin concentrations, glucose taken up by tissues predominantly is oxidized or undergoes glycolysis to release alanine and lactate which can be re-utilized by the liver for gluconeogenesis [7].

Sensitivity to insulin varies amongst tissues. Low concentrations of insulin limit lipolysis and prevent unrestrained breakdown of fat. The insulin concentrations sufficient to prevent lipolysis are insufficient to stimulate significant muscle glucose uptake. Whereas maximal suppression of endogenous glucose production occurs at insulin concentrations of approximately 250 pmol/L, these concentrations result in only half maximal stimulation of glucose uptake (Figure 13.1) [8].

**Figure 13.1** Insulin dose–response curves for glucose production and utilization in non-diabetic subjects. Adapted from Vella A. *Diabetologia* 2002; **45**:1410–1415, with permission from Springer-Verlag.

Increases in plasma glucose, which occur within 5–10 minutes after eating stimulate insulin secretion and suppress glucagon secretion. The reciprocal changes in hepatic sinusoidal insulin and glucagon concentrations in concert with the elevated glucose concentrations enhance hepatic glucose uptake and suppress hepatic glucose production [9,10]. The splanchnic tissues initially extract 10–25% of ingested glucose and eventually dispose of approximately 40% of ingested glucose, with muscle accounting for most of the remainder [11]. These coordinated changes in hepatic and extrahepatic glucose metabolism generally limit the post-prandial rise in glucose to 7–8 mmol/L. Late post-prandial hypoglycemia is avoided by a smooth increase in hepatic glucose output to rates that closely approximate glucose uptake.

In the transition from normal glucose metabolism to overt diabetes, the relative contribution of alterations in glucose disappearance or appearance is uncertain. Most [12–15] but not all [16] epidemiologic studies that have attempted to elucidate the pathogenesis of impaired fasting glucose (IFG; defined as a fasting glucose of 5.8–6.9 mmol/L) have reported that insulin action is decreased in individuals with IFG. Weyer *et al.* [15] reported that fasting endogenous glucose production was increased in people with IFG. Bock *et al.* [17] subsequently established that insulin-induced suppression of endogenous glucose production and gluconeogenesis are impaired in people with IFG indicating hepatic insulin resistance. Epidemiologic studies have shown that 20–30% of people with IFG will develop frank diabetes within 5–10 years [18,19]. Indeed, subjects with a fasting glucose between 5.3

and 5.7 mmol/L have an 8% risk of developing diabetes within the next 10 years.

Regulation of glucose concentrations after meal ingestion is more complex. The pattern of change of post-prandial plasma glucose concentrations is determined by the extent to which glucose entering the systemic circulation (equal to the sum of endogenous glucose production and the systemic appearance of ingested glucose) exceeds or is exceeded by the rate at which glucose leaves the systemic circulation (glucose disappearance). Therefore, differences in post-prandial glucose concentrations could theoretically arise because of differences, alone or in combination, in rates of meal glucose appearance, suppression of endogenous glucose production or stimulation of glucose uptake [20,21].

Post-prandial hyperglycemia is primarily caused by reduced post-prandial glucose disappearance because suppression of endogenous glucose production and the rate of appearance of ingested glucose do not differ in people with IFG and normal fasting glucose [17]. The insulin secretion in response to higher post-prandial glucose concentrations is impaired in the subjects with IFG with accompanying defects in glucose disappearance and consequent post-prandial hyperglycemia. A further reduction in insulin secretion eventually results in overt T2DM [17].

Endogenous glucose production is regulated (inhibited) by insulin which increases hepatic glucose uptake by stimulating glucokinase activity and decreases hepatic glucose release by decreasing the conversion of glucose-6-phosphate to glucose.

**Figure 13.2** Major sites of glucose metabolism in the post-absorptive and post-prandial states. After meal ingestion, the primary site of glucose uptake shifts from insulin-independent organs to insulin-dependent tissues. Gluconeogenic substrates are derived predominantly from peripheral tissues. Hepatic glycogen synthesis may occur via the direct or indirect (gluconeogenesis) pathways. Adapted from Dinneen *et al.* [21]. Copyright © 1992 Massachusetts Medical Society. All rights reserved.

This latter step is regulated by glucose-6-phosphatase. Insulin can also stimulate glycogen synthesis, inhibit glycogen breakdown and suppress gluconeogenesis. Post-prandial hyperglycemia and hyperinsulinemia stimulate hepatic glycogen synthesis thereby replenishing hepatic glycogen stores. Hepatic glycogen synthesis occurs via both the direct (i.e. glycogen synthesis utilizing glucose-6-phosphate derived directly from extracellular glucose) or indirect pathway (i.e. glycogen synthesis utilizing glucose-6-phosphate derived from gluconeogenesis). The relative contribution of these two pathways appears to be determined by multiple factors including the duration of fast, composition of the meal and the prevailing insulin and glucagon concentrations [22,23].

In the presence of euglycemia, rising hepatic sinusoidal concentrations of insulin suppress endogenous glucose production by decreasing glycogenolysis. Insulin concentrations within the physiologic range in healthy humans do not appreciably suppress gluconeogenesis and direct glucose-6-phosphate (derived from gluconeogenesis) into glycogen (Figure 13.2) [24].

## Carbohydrate metabolism in type 1 diabetes

T1DM is characterized by insulin deficiency as a result of autoimmune destruction of the pancreatic  $\beta$ -cells. Fasting hyperglycemia does not develop until most (>80%) of  $\beta$ -cells are lost to the underlying autoimmune process. Defects in insulin secretion, however, are evident years before the development of diabetes in asymptomatic affected individuals. For example, siblings of people with T1DM who are islet antibody positive (a group at high risk for the development of T1DM) frequently exhibit a decreased first-phase of insulin secretion in response to intravenous glucose injection [25,26]. This usually occurs at a time when the response to other stimuli such as oral glucose or mixed meal ingestion is intact, suggesting that incretins and other secretagogues are capable of compensating for decreased islet cell mass.

Impaired insulin secretion is frequently accompanied by impaired insulin action [27,28]. The severity of insulin resistance

is related to the degree of glycemic control. People with poorly controlled T1DM may exhibit the same degree of insulin resistance as people with T2DM [28,29]. In people with T1DM, the defect in insulin action is tissue-specific; for example, glucose uptake in cardiac muscle, as opposed to skeletal muscle, is normal [30]. Glucose oxidation and non-oxidative storage in people with T1DM is decreased in proportion to glucose uptake, suggesting that glucose transport and/or phosphorylation (after transport across the membrane) are the sites of defective insulin action [31]. In contrast, insulin-induced suppression of glucose production is not impaired and may in fact be increased in people with T1DM [32,33].

Insulin binding and action has been reported to be decreased in adipocytes [34,35] but normal in fibroblasts [36,37] of people with T1DM. This may be explained by the fact that insulin binding in adipocytes is measured immediately after biopsy while insulin binding to fibroblasts is measured following several days of culture. Decreased insulin binding in the former but not the latter suggests an effect of abnormal metabolic milieu rather than an intrinsic defect of insulin action. This is supported by several observations that improved chronic glycemic control is accompanied by improved whole-body insulin action [38,39]. It should be noted that when insulin action is measured by means of a hyperglycemic hyperinsulinemic clamp, hyperglycemia may compensate for small defects in insulin action by means of its ability (glucose) to stimulate its own uptake and suppress its own release (glucose effectiveness) [33].

Because insulin is typically delivered via the subcutaneous, rather than the intraportal route, treatment with insulin leads to systemic hyperinsulinemia which has been shown to impair insulin action in humans without diabetes [40]. The improved insulin action observed in people with T1DM following treatment with insulin, however, suggests that any negative effects of systemic hyperinsulinemia on insulin action are more than offset by the lowering of glucose concentrations and the reversal of glucose toxicity.

In the absence of insulin-stimulated muscle glucose uptake, substantial glucose disappearance in insulin-deficient people with T1DM occurs by glucose excretion in the urine and by glucose uptake via non-insulin-mediated pathways [41]. Food ingestion does not result in a rise in insulin or a reciprocal decrease in glucagon concentration [42]. Because of this, the increase in splanchnic glucose uptake and the decrease in endogenous glucose production are not appropriate for the prevailing glucose concentration. Post-prandial glycogen synthesis is markedly decreased, with most of the glycogen being synthesized by the indirect gluconeogenic pathway [43,44].

Consequently, because of abnormal hepatic glucose handling, excessive amounts of glucose reach the systemic circulation. The excessive rise in post-prandial glucose concentrations is compounded by the low insulin concentrations and defective insulin action present in people with poorly controlled T1DM [41,45]. In contrast, the ability of glucose to stimulate its own uptake and suppress its own release (glucose effectiveness) is normal in T1DM and most post-prandial glucose disposal occurs predominantly via non-insulin mediated pathways and by glucose excretion in the urine [46].

Post-prandial glucose metabolism in the splanchnic and extra-splanchnic tissues can be almost completely normalized by insulin administration which increases circulating insulin concentrations and prevents the excessive rise in counter-regulatory hormones that accompanies insulin deficiency. Insulin administration also restores post-prandial suppression of glucose production and stimulation of glucose uptake to rates similar to those observed in subjects without diabetes [41,47].

Animal studies have shown diabetes to be associated with hypertrophy of the intestinal mucosa and increased intestinal glucose transport [48,49]. By contrast, when glucose, insulin and glucagon concentrations are matched in individuals with T1DM and age- and weight-matched controls, initial splanchnic glucose extraction and uridine diphosphate (UDP)-glucose flux (an index of hepatic glycogen synthesis) do not differ between groups. This demonstrates that relative insulin deficiency, glucagon excess or both, rather than an intrinsic defect in splanchnic glucose metabolism are the primary causes of post-prandial hyperglycemia in people with poorly controlled T1DM (Figure 13.3) [33].

### Carbohydrate metabolism in type 2 diabetes

People with T2DM have elevated fasting glucose levels and excessive glycemic excursions following carbohydrate ingestion. Insulin secretion in those with T2DM is typically decreased and delayed following food ingestion [9,21]. Defects in insulin secretion are observed early in the evolution of T2DM. In fact, alterations in both the timing and amount of insulin secreted have been reported in relatives of patients with T2DM prior to the development of hyperglycemia [50,51].

Chronic hyperglycemia alone or in combination with elevated FFA impairs insulin secretion. Abnormalities in glucose sensing,

**Figure 13.3** In the presence of matched glucose, insulin and glucagon concentrations initial splanchnic glucose extraction and UDP-glucose flux do not differ in individuals with type 1 diabetes and age- and weight-matched controls. FFA, free fatty acids; UDP-glucose, uridine diphosphate glucose. Adapted from Vella *et al.* [33].

insulin processing or intracellular signaling can alter insulin secretion [52]. In addition,  $\beta$ -cell mass decreases with increasing duration of diabetes [53,54]. Alterations in  $\beta$ -cell morphology occur in most people with T2DM with extensive intra-islet deposition of amylin commonly being observed [55,56].

Prolonged elevations in glucose concentration following ingestion of a carbohydrate-containing meal occur because post-prandial glucose appearance exceeds disappearance. The more

significant the defects in insulin secretion and action, the higher glucose concentrations have to rise to balance glucose appearance and disappearance [57]. Glucose appearance is elevated because of failure to suppress hepatic glucose production because the systemic rate of appearance of ingested glucose does not differ from that observed in individuals without diabetes [9,11,17,58]. Although glucose disappearance is commonly higher in people with diabetes than in individuals without diabetes following a meal, this is in large part is accounted for by elevated rates of urinary glucose excretion. Furthermore, although elevated, the rates of glucose disappearance are not appropriate for the prevailing glucose concentrations [59,60].

Defects in insulin secretion and action both contribute to post-prandial hyperglycemia. A delay in the early rise in insulin concentrations causes a delay in suppression of glucose production, which in turn results in an excessive glycemic excursion. In contrast, a decrease in insulin action results in sustained hyperglycemia but has minimal effect of peak glucose concentrations. Whereas an isolated alteration in either hepatic or extrahepatic insulin action impairs glucose tolerance, a defect in both results in severe hyperglycemia [57].

Glucose is also an important regulator of its own metabolism. In the presence of basal insulin concentrations, an increase in plasma glucose stimulates glucose uptake and suppresses glucose production. The ability of glucose to regulate its own metabolism is impaired in T2DM. This is commonly referred to as a defect in “glucose effectiveness.” Whereas intravenous infusion of 35 g glucose in individuals without diabetes whose insulin concentrations are clamped at basal levels produces only a modest rise in plasma glucose concentration, infusion of the same amount of glucose results in severe hyperglycemia in people with T2DM [61]. The excessive rise in glucose is caused by impaired glucose induced stimulation of glucose uptake because glucose induced suppression of glucose production is normal [61,62].

Inhibition of glucagon secretion lowers both fasting glucose and post-prandial glucose concentrations. Failure to suppress glucagon secretion appropriately, however, has minimal effect on glucose production and glucose tolerance when insulin secretion is intact [63,64]. In contrast, it causes marked hyperglycemia when insulin secretion is decreased and delayed, as is typical of T2DM. Taken together, these data suggest that agents that simultaneously improve insulin secretion, insulin action, glucose effectiveness as well glucagon secretion are likely to have a profound effect on glucose metabolism in people with T2DM (Figure 13.4) [64,65].

Amylin is a 37 amino acid polypeptide that is co-secreted with insulin by the pancreatic  $\beta$ -cells in response to nutrient stimuli and other secretagogues. Human studies have shown that the plasma concentrations of amylin and insulin rise and fall in parallel in both the fasted and fed states [66]. Because amylin is potentially toxic to  $\beta$ -cells, it has been suggested that excessive amylin secretion may contribute to  $\beta$ -cell destruction in T2DM [67,68].

The secretion of incretins such as glucagon-like peptide 1 (GLP-1), in response to meal ingestion is decreased in T2DM

**Figure 13.4** Healthy subjects received a non-diabetic (a) or a diabetic (b) insulin profile on two occasions. On one occasion glucagon was infused in a manner that replicated the fall in glucagon concentrations that normally occurs after meal ingestion. On the other occasion glucagon was infused constantly to replicate the lack of glucagon suppression observed in type 2 diabetes in response to meal ingestion. Glycemic excursion was significantly higher in the absence of glucagon suppression in subjects receiving an insulin profile similar to that observed in patients with type 2 diabetes. Adapted from Shah *et al.* [64], with permission from the American Physiological Society.

[69–71]. Supraphysiologic concentrations of GLP-1, achieved by either intravenous infusion or subcutaneous injection, lower both fasting and post-prandial glucose concentrations in people with T2DM. GLP-1 does so by increasing insulin secretion, inhibiting glucagon secretion and delaying gastric emptying [72–75]. By contrast, GLP-1 does not appear to alter insulin action or glucose effectiveness in T2DM [76].

In addition to defects in insulin secretion, people with T2DM commonly exhibit defects in insulin action. Numerous studies have shown that insulin-induced stimulation of glucose uptake in muscle and adipose tissues as well as insulin-induced suppression of glucose production are impaired in T2DM [77,78]. The severity of insulin resistance is influenced by multiple factors including exercise, obesity and diet as well as genetic factors. Insulin resistance increases with increasing severity of diabetes and improves but is not normalized by improved glycemic control [79]. Defects in the ability of insulin to regulate muscle and fat glucose metabolism are evident in normoglycemic relatives of people with T2DM strongly implying a genetic basis for at least some degree of insulin resistance [50,80].

Both glucose production and the contribution of gluconeogenesis to glucose production are increased in people with “mild” as

well as “severe” T2DM [81]. The increase in glucose production is correlated with the severity of hyperglycemia [21,58,82]. Insulin-induced stimulation of splanchnic (and therefore presumably hepatic) glucose uptake is also impaired in T2DM. The lower rates of hepatic uptake in subjects with diabetes are almost entirely accounted for by decreased uptake of extracellular glucose suggesting lower glucokinase activity [83,84].

### **Lipid metabolism in type 1 and type 2 diabetes**

Triglycerides are an important energy source (and storage form) and are mobilized as FFA. Plasma FFA concentrations represent a balance between release and disposal. FFA are taken up by and re-esterified in adipose and hepatic tissues, or oxidized in muscle (cardiac and skeletal) or the liver. They are released from intravascular lipolysis of triglyceride-rich lipoproteins and intra-adipocyte lipolysis of triglyceride stores. In the fasting state, FFA concentrations are determined largely by the rate of entry into the circulation while in the post-prandial period the rate of uptake by adipose and hepatic tissue is also a major determinant in FFA concentrations [85].

Hormone-sensitive lipase is the principal regulator of FFA release from adipose and is exquisitely sensitive to insulin. Insulin is the main hormonal regulator of lipolysis. Increasing plasma glucose concentrations (e.g. after a meal) normally leads to increased insulin secretion which inhibits lipolysis [86]. Rising insulin concentrations suppress lipolysis leading to a fall in FFA concentrations. This insulin-induced suppression of FFA concentrations enhances insulin-dependent glucose disposal and insulin-induced suppression of endogenous glucose production [87].

Conversely, in individuals without diabetes, falling blood glucose concentrations increase lipolysis because of suppression of insulin secretion [88]. The resulting rise in FFA will stabilize or raise glucose concentrations. Hypoglycemia caused by exogenous hyperinsulinism will also suppress lipolysis and impair counter-regulation.

Absolute or relative insulin deficiency is responsible for most of the excess FFA available for oxidation in T1DM. Elevated FFA directly impair peripheral glucose uptake [89] and, at least acutely, stimulate endogenous glucose production [90]. Another consequence of elevated FFA flux is increased ketogenesis, a precursor to ketoacidosis [91]. Insulin is able to counteract the lipolytic effects of other hormones so that growth hormone or cortisol have little effect on lipolysis unless insulin availability is reduced [92]. Similarly, the lipolytic effect of catecholamines is blunted by hyperinsulinemia and accentuated by hypoinsulinemia [93]. Although glucagon has no effect on systemic FFA availability, increased concentrations, as seen in uncontrolled diabetes, may drive hepatic metabolism towards ketogenesis [91].

Moderate intensity exercise is normally accompanied by a fall in insulin and a rise in catecholamine concentrations which increases FFA availability and fatty acid oxidation [94]. Plasma insulin concentrations do not decrease with exercise in T1DM

and, depending on the timing of exercise in relation to insulin administration, may not allow the normal increase in FFA that accompanies exercise [95]. In these instances, people with T1DM become dependent on the catecholamine response to exercise to mobilize FFA, a response that may be impaired in individuals with long-standing diabetes [96]. In people with fasting hyperglycemia, low insulin concentrations and, consequently, elevated resting FFA flux, exercise will increase FFA flux further [97]. This combined with the high glucagon concentrations commonly present in these situations will result in high rates of ketone body production.

FFA concentrations commonly are increased in the post-absorptive and post-prandial state in people with T2DM [77,98]. The ability of insulin to suppress lipolysis is impaired likely because of decreased sensitivity of hormone-sensitive lipase to insulin [99]. Insulin also promotes FFA disposal, however, by stimulating re-esterification in adipocytes to form triglyceride. This process is dependent on the provision of glycerol-3-phosphate derived from glucose uptake (also insulin-driven) and intra-adipocyte glycolysis. It is unknown, however, whether defects in adipose FFA esterification contribute to the FFA elevation observed in diabetes [85].

Circulating plasma triglycerides are dependent on the activity of lipoprotein lipase (LPL) to deliver FFA to the adipocyte. Insulin and glucose preferentially stimulate adipose LPL and inhibit muscle LPL thereby partitioning triglyceride and lipoprotein-derived fatty acids away from muscle and into adipose tissue [100]. By contrast, in T2DM, insulin-induced activation of adipose LPL is delayed while skeletal muscle LPL is activated [101]. Given that elevated FFA decrease muscle glucose uptake, this is especially of consequence in patients with already diminished insulin action. FFA decrease muscle glucose uptake by inhibiting glucose transport, glucose phosphorylation and muscle glycogen synthase [102].

Although elevated FFA concentrations have been reported to decrease hepatic insulin metabolism in animals, direct measurement of splanchnic insulin clearance suggest that this may not be the case in humans [103]. Elevated FFA stimulate both hepatic gluconeogenesis and triglyceride synthesis. Acute increases in FFA stimulate insulin secretion whereas chronic elevations inhibit insulin secretion [104]. Thus, elevated FFA have been implicated in many, but not all, of the metabolic abnormalities associated with T2DM.

---

### **Protein metabolism in type 1 and type 2 diabetes**

Substrate availability and the hormonal milieu regulate protein synthesis and breakdown at any given time. Insulin is an important hormone in this regard and profound changes in body composition occur after the initiation of therapy in people with T1DM, especially if insulin deficiency has been severe and prolonged [105]. Urinary nitrogen excretion, a marker of protein

catabolism, increases during insulin deprivation. If this is sufficiently prolonged, cachexia and a loss of muscle mass occurs [106,107]. Insulin deprivation increases the concentration of circulating amino acids because of the net increase in protein breakdown with an accompanying decline in amino acid disposal (utilization in protein synthesis or amino acid oxidation) [108,109].

Glucagon secretion is enhanced by ingestion of protein and facilitates disposal of glucogenic amino acids such as alanine or glutamine. The elevated glucagon concentrations present in poorly controlled T1DM stimulate alanine and glutamine uptake, resulting in normal or low concentrations despite increased appearance from protein breakdown from insulin deprivation [110]. Concentrations of branched chain amino acids are elevated in these situations but are rapidly lowered to non-diabetic levels by treatment with insulin [108,111].

In contrast, the effect of T2DM on protein metabolism is less clear-cut with some studies showing no evidence of increased catabolism [112,113] while others have reported increased protein turnover and/or amino acid catabolism [114–117]. The difference in protein metabolism between T1DM and T2DM likely occurs because people with T2DM have sufficient residual insulin secretion to limit protein catabolism and preserve lean body mass. Nevertheless, whole body nitrogen flux, protein synthesis and breakdown are increased in people with poorly controlled diabetes. These defects are restored to normal when glycemic control is improved by treatment with either oral agents or insulin [114,115]. Of interest, whereas T2DM impairs the ability of insulin to regulate glucose and fat metabolism, the effects of insulin on whole body protein synthesis and breakdown appear to be preserved [113].

Relatively few studies have examined regional protein dynamics in T2DM. Increased 3-methylhistidine excretion, an index of myofibrillar protein breakdown, has been demonstrated in subjects with poorly controlled T2DM when compared with healthy and obese subjects without diabetes [114]. Improved glycemic control reduced 3-methylhistidine excretion. People with T2DM and/or insulin resistance have been noted to have elevated circulating concentrations of certain clotting factors such as tissue plasminogen activator and plasminogen activator inhibitor 1 (PAI-1). This would imply that the synthesis of certain proteins by the liver and endothelium is clearly abnormal [118]. Preliminary evidence suggests that agents that improve the ability of insulin to regulate muscle and hepatic glucose metabolism (e.g. thiazolidinediones) will also restore concentrations, and possibly the activity, of these proteins to normal [119,120].

---

## Counter-regulatory hormones

In humans without diabetes, insulin and glucagon exhibit coordinated and reciprocal changes in concentration in response to glucose ingestion [21]. In people with T1DM, however, carbohydrate ingestion fails to suppress glucagon [121,122], while

protein ingestion commonly results in an excessive rise in glucagon concentrations [123]. The cause of these abnormalities in glucagon secretion is thought to be intra-islet insulin deficiency as insulin infusion inhibits glucagon secretion [124] and neutralization of intra-islet insulin with anti-insulin antibodies stimulates glucagon secretion [125]. Treatment with exogenous insulin rapidly lowers glucagon concentrations in people with T1DM but does not restore hypoglycemia-induced glucagon secretion [126].

Glucagon excess exacerbates hyperglycemia by increasing hepatic glucose release and decreasing hepatic glucose uptake [127,128]. In humans without diabetes, any increase in glucose concentrations is promptly accompanied by an increase in insulin secretion which antagonizes the effects of glucagon on the liver. By contrast, in people with diabetes who cannot increase insulin secretion (and consequently glucose disposal) to compensate for the increase in glucagon concentrations, increased hepatic glucose release is accompanied by further increases in glucose concentration [127].

Fasting epinephrine and norepinephrine concentrations may be elevated in individuals with poorly controlled diabetes [129,130] and may cause further deterioration in glycemic control by impairing insulin action at the hepatic and extrahepatic tissues [131]. Epinephrine also stimulates glucagon secretion leading to further increases in endogenous glucose production [132]. In the absence of circulating insulin, catecholamines will enhance lipolysis thereby increasing FFA concentrations and increased production of ketone bodies [133].

In the presence of severe defects in endogenous insulin secretion, as usually encountered in people with T1DM, the normal diurnal variation in plasma cortisol concentrations can adversely affect glycemic control [134]. Cortisol increases endogenous glucose production while decreasing tissue glucose uptake. The nocturnal rise in cortisol also increases ketone body concentrations, gluconeogenesis and lipolysis [134,135].

Growth hormone release increases in both amplitude and frequency in people with poorly controlled diabetes [136,137]. Growth hormone stimulates gluconeogenesis, proteolysis and lipolysis while impairing insulin-induced suppression of endogenous glucose production and stimulation of glucose uptake [138]. This is likely to occur in situations where insulin secretion cannot rise to match the increased insulin requirements because of excessive growth hormone secretion.

---

## Diabetic ketoacidosis

Insulin deficiency to a degree sufficient to allow unrestrained lipolysis and hepatic ketogenesis is a necessary condition for the development of diabetic ketoacidosis [139]. Because of this, ketoacidosis is more commonly encountered in patients with T1DM than in people with T2DM because the latter generally have some degree of residual insulin secretion. Although insulin deficiency is a necessary condition for the development of

ketoacidosis, the condition is often triggered by physical stress such as infection or surgery.

Glucagon concentrations rise in the presence of insulin deficiency and during physical stress. A decrease in effective circulating volume may also increase glucagon concentrations because glucagon is cleared by the kidneys. The concentrations of other counter-regulatory hormones also rise, which in turn further increase lipolysis [140].

Ketone bodies and glucose produce an osmotic diuresis that exacerbates the hypovolemia and electrolyte disturbances caused by metabolic acidosis. Furthermore, ketone bodies can induce vomiting, causing electrolyte and fluid losses. These losses also can directly contribute to metabolic acidosis. Cardiovascular collapse can occur if acidosis is sufficiently severe. Intracellular metabolic acidosis interferes with the activity of several enzymatic processes, which exacerbates the consequences of circulatory failure. Death is often caused by underlying comorbidities, the physical illness that precipitated ketoacidosis – myocardial infarction, pneumonia – or a direct consequence of severe metabolic acidosis [141].

# 14 Obesity and Diabetes

**Hans Hauner**

Else Kröner-Fresenius-Center for Nutritional Medicine, Technical University of Munich, Munich, Germany

## Keypoints

- Obesity is characterized by an excess of body fat mass and is defined by a body mass index equal to or greater than 30 kg/m<sup>2</sup>. Its prevalence has increased considerably over the past decades in all parts of the world and currently affects 15–30% of the adult populations in Western countries.
- Overweight and/or obesity represents by far the most important modifiable risk factor for type 2 diabetes mellitus (T2DM). An abdominal type of body fat distribution is also closely associated with T2DM, particularly in the lower body mass index categories.
- Both obesity and T2DM have a strong genetic background. The known susceptibility genes for obesity mainly affect central pathways of food intake, whereas most risk genes for T2DM compromise  $\beta$ -cell function.
- Important environmental factors contributing to the development of obesity include energy-dense diets including large portion sizes and permanent availability of foods, lack of physical activity and low socioeconomic status.
- An expanded adipose tissue impairs insulin action and causes insulin resistance in muscle, adipose tissue, liver and possibly other organs.
- Obesity is also characterized by subacute chronic inflammation in adipose tissue because of an impaired paracrine–endocrine function of adipose tissue, but also by mitochondrial dysfunction, local hypoxia and other still poorly understood disturbances at the cellular level.
- Weight loss in obese individuals is followed by rapid amelioration of all metabolic disturbances including chronic inflammation and insulin resistance. These improvements are brought about by caloric restriction rather than the macronutrient composition of the dietary intervention.
- Bariatric surgery is the most powerful approach to treat morbid obesity and may lead to a marked improvement of the metabolic disturbances if not the resolution of T2DM.

## Introduction

Obesity is defined as a common chronic disorder of excessive body fat and has become a global epidemic which is present not only in the industrialized world but also in many developing and even in underdeveloped countries. At present, the prevalence of obesity (defined as body mass index [BMI]  $\geq 30$  kg/m<sup>2</sup>) is in the range 15–30% in the adult populations in Europe, North America and in many Arabic countries, with an unequivocal trend for further increases [1]. This condition increases the risk of developing a variety of adverse consequences to human health ranging from metabolic disturbances including type 2 diabetes mellitus (T2DM) and cardiovascular complications to disorders of the locomotor system and many types of cancer [2]. In addition, obesity impairs the subjective quality of life in affected people and can reduce life expectancy [3]. Although there is a very specific close relationship between excessive body weight and the risk of

diabetes, the presence of obesity may induce many other disturbances that may aggravate the diabetic state.

## Definition of obesity and the body fat distribution pattern

The diagnosis and classification of obesity is usually based on the BMI. This simple anthropometric index can be calculated from body weight and height, is independent of body height and correlates reasonably well with body fat mass ( $r = 0.4$ – $0.7$ ). The current classification of body weight according to the World Health Organization (WHO) is presented in Table 14.1. A BMI greater than 30 kg/m<sup>2</sup> is considered to be the central formal criterion for the definition of obesity which is further subdivided into three classes depending on the severity of excessive body fat. The BMI range of 25–29.9 kg/m<sup>2</sup> represents the category of overweight or pre-obesity which requires additional criteria to assess the concomitant health risks. In Western countries, 30–50% of the population fall into the category of overweight [1].

Not only the extent of excessive body fat mass, but also the anatomic location of the body fat mass determines the risk for metabolic and cardiovascular complications. This is particularly

**Table 14.1** Classification of human obesity based on body mass index (BMI) classification (kg/m<sup>2</sup>). Reproduced from World Health Organization [1] with permission.

Classification	kg/m <sup>2</sup>
Underweight	<18.5
Normal weight	18.5–24.9
Overweight	≥25.0
Obesity	
grade I	30–34.9
grade II	35–39.9
grade III	≥40

important for the category of moderate overweight and even in the upper normal range of BMI. At a defined BMI, the pattern of fat distribution can vary substantially. This has been most impressively shown using computed tomography (CT) or magnetic resonance imaging (MRI) scans which are the only imaging techniques to provide a direct assessment of the size of the intra-abdominal visceral adipose tissue. For practical means, waist circumference measured mid way between the lower rib margin and the upper iliac crest is used as a simple anthropometric measure to assess the fat distribution pattern. This variable has been used in many cross-sectional and longitudinal studies; therefore, the threshold levels demonstrated in Table 14.2 are now well based on human data sets concerning associated health risks. The waist circumference is closely correlated with BMI but cannot discriminate between subcutaneous and intra-abdominal fat depots.

### Obesity is the most potent risk factor for type 2 diabetes

A large body of clinical data consistently demonstrates a close relationship between body fat mass and the risk of diabetes. It is noteworthy that in contrast to other obesity-associated metabolic disturbances, the diabetes risk already increases in the upper normal range of BMI. This has been shown for both men and women. In the prospective Nurses’ Health Study, women in the upper normal range with a BMI of 23.0–24.9 kg/m<sup>2</sup> had a four- to fivefold increased risk of developing diabetes over a 14-year observation period compared with women with a BMI of <22 kg/m<sup>2</sup>. In women with a BMI of 29.0–30.9 kg/m<sup>2</sup> the risk of diabetes was 27.6-fold higher than in the lean reference group. Almost two-thirds of newly diagnosed women with T2DM were obese at the time of diagnosis [4]. Similar observations were made for males in the Health Professionals’ Study [5]. Moreover, changes in body weight also predicted the risk of diabetes. Weight gain in women after the age of 18 of 11.0–19.9 kg, which is the average range of weight change between adolescence and meno-

**Table 14.2** Classification of fat distribution pattern, threshold values for the moderately and markedly elevated risk for metabolic and cardiovascular diseases.

	Waist circumference (cm)	
	Elevated metabolic and cardiovascular risk	
	Moderately	Markedly
Men	>94	>102
Women	>80	>88

pause in industrialized countries, was found to be associated with a 5.5-fold higher risk of diabetes compared with weight-stable women, whereas weight reduction of the same extent reduced the risk of diabetes by about 80% [4]. Very similar data were reported for men [5]. A recent analysis of the EPIC Potsdam cohort revealed that a weight gain of 1 BMI unit between the age of 25 and 40 years increased the relative risk of T2DM by 25% and had a greater effect than the same weight gain between 40 and 55 years of age [6]. It is also important to note that the duration of obesity has a strong impact on the risk of developing T2DM.

In a recent analysis of the relative contributions of different levels of overweight and obesity to the prevalence of diabetes between 1976–1980 and 2000–2004 in the USA it was found that the increase in total diabetes prevalence from 5.08% to 8.83% was largely caused by the increase in obesity. Of the increased number, 81% was attributed to the different classes of obesity (Figure 14.1). The authors concluded that the increase in diabetes prevalence over recent decades has disproportionately included persons with extreme levels of obesity [7]. Thus, obesity appears to be the main environmental driving force for the manifestation of T2DM.

In addition to the level and the duration of obesity, the risk of developing diabetes is also potentially influenced by the fat distribution pattern. In an early study in humans, an abdominal pattern of fat distribution was found to be an independent risk factor for T2DM [8]. Subsequent studies confirmed this observation in many age groups and ethnic populations. Particularly at low degrees of overweight, and even in the upper normal range, the fat distribution pattern strongly predicts the risk for diabetes and the metabolic syndrome. Therefore, waist circumference should be routinely assessed when estimating the risk of diabetes even in normal-weight subjects. In the clinical setting, it is striking to observe that the majority of subjects with diabetes, particularly those of middle age, show a visible preferential truncal accumulation of excess body fat. It is also interesting to note that similar observations were made for the association between BMI and cardiovascular disease. Among overweight and obese subjects, only those with an abdominal type of fat distribution are at increased risk of coronary heart disease as recently documented in the INTERHEART study [9].

**Figure 14.1** Contribution of five body mass index (BMI) categories to the overall prevalence of diabetes. National Health and Nutrition Examination Survey (NHANES) samples of 1976-1980 and 1999-2004 were compared. Reproduced from Gregg *et al.* [7], with permission from Elsevier.

## Genetic predisposition for obesity and type 2 diabetes

It is well known from family, adoption and twin studies that obesity, like T2DM, has a strong genetic basis. In the classic adoption study by Stunkard *et al.* [10] there was no resemblance between the adult BMI of adopted Danish children and the BMI of the adopting parents, but a significant correlation to the BMI of the biologic parents, especially to the BMI class of the biologic mother. In a twin study of obesity, concordance rates for different degrees of overweight were twice as high for monozygotic twins as for dizygotic twins. This high heritability for BMI was seen at the age of 20 years and to a similar extent at a 25-year follow-up, suggesting that body fatness is under substantial genetic control [11]. There is also a very close correlation in monozygotic twins who were reared apart, also indicating a high heritability of the BMI trait. In a recent study of 5092 twins living in the London area, the authors estimated the heritability of BMI and waist circumference as 0.77, further supporting the strong effect of the genetic components irrespective of the force of the obesogenic environment [12].

During the last decade, a number of monogenic disorders that result in human obesity have been uncovered. These genetic dis-

orders were only found in rare cases, however, usually children and adolescents with early onset of obesity. At present, a variety of homozygous and compound heterozygous mutations have been described in the leptin-melanocortin signaling pathway, some of them with functional consequences resulting in human obesity. Functional mutations in the melanocortin-4-receptor gene are considered to be the most frequent cause of monogenic obesity in children with a frequency of 2-4% of all obese cases. It is striking that these defects affect genes that are involved in the central control of food intake [13].

Recent genome-wide association (GWA) studies in large cohorts with BMI as phenotype reported common genetic variants on various chromosomes. These polymorphisms predisposing to obesity at the population level are also largely related to central pathways of food intake [14-16]. Thus, human obesity may represent a heritable neurobehavioral disorder that is highly sensitive to environmental conditions, especially an energy-dense palatable foods which are abundantly available in many societies [13]. Despite these remarkable advances in our understanding of the genetic factors related to obesity, the effect size of most of the novel "obesity genes" is rather modest. Only individuals who are homozygous for the high-risk allele of the *FTO* gene weigh on average 3 kg more than individuals with two low-risk alleles [14]. The gene is encoding a 2-oxoglutarate-dependent nucleic acid

demethylase which is mainly expressed in the brain and in the arcuate nucleus of the hypothalamus [17]. Among the almost 20 gene variants found in GWA studies so far, variants near to the *FTO* and the *MC4R* gene appear to have the strongest effect size on body weight. All other recently discovered gene polymorphisms influence body weight by far less than 1 kg.

Thus, it is apparent from recent work that obesity represents a rather heterogeneous disorder in terms of genetic background and susceptibility to etiologic environmental factors. In addition, the risk for developing co-morbidities including T2DM may strongly depend on the individual genetic predisposition towards such diseases. In the case of T2DM, the lifetime risk of developing this disease is about 30% in the white North American population and similar in other ethnic groups [18]. It is currently assumed that only those obese subjects who exhibit a genetic failure of the pancreas to compensate for insulin resistance, which is a characteristic consequence of obesity, will develop T2DM [19]; even among severely obese subjects (BMI  $\geq 40$  kg/m<sup>2</sup>) only 30–40% will develop diabetes throughout life. Thus, the development of T2DM requires the presence of “diabetes genes” which probably limit  $\beta$ -cell function.

---

### Developmental programming of obesity and diabetes

A new component that may have a major role in the development of obesity and T2DM is the modification of gene expression by epigenetic mechanisms during fetal life. Although this is still a poorly defined phenomenon and it is rather unclear which mechanisms may underlie this association, there is some clue that epigenetics may also operate in this context. Observational studies suggest that infants of mothers with gestational diabetes are at increased risk of developing childhood obesity [20]. In another study, siblings born after the mother had developed gestational diabetes (i.e. exposed to diabetes *in utero*) have a much greater risk of T2DM in young adulthood than siblings not exposed to diabetes *in utero* (odds ratio 3.7;  $P = 0.02$ ) [21].

Another interesting clinical observation is that excessive weight gain during pregnancy, independent of initial BMI, may also increase the risk of early development of obesity in the offspring [22,23]. It is speculated that both hyperglycemia and chronic overnutrition during pregnancy may cause fetal hyperinsulinemia, hypercortisolemia and hyperleptinemia. These hormonal changes may result in a persisting malprogramming of hypothalamic centers controlling energy homeostasis and metabolism, thereby increasing the lifetime risk for obesity and T2DM and possibly the risk for other adverse long-term health consequences [24]. The mechanisms mediating these effects are largely elusive, but it is speculated that epigenetic processes such as DNA methylation, histone modification and changes of the microRNA pattern are involved. Animal experiments suggest that this imprinting process may mainly affect central neuroendocrine pathways which may finally modify appetite regulation [24].

---

### Pathophysiology of obesity

Irrespective of the strong genetic influence on body weight, there is also no doubt that the evolving worldwide epidemic of obesity is primarily a consequence of substantial changes in the environment and lifestyle (see Chapter 8). It is rather new to mankind that food is abundant in many countries and that physical activity is no longer a prerequisite for survival. These dramatic changes in environment and the subsequent changes in lifestyle have occurred within a few decades, a period probably too short to result in adaptations of the genetic background and biologic systems to optimize survival. To date, the relative contributions of the various environmental factors to the epidemic of obesity are hard to quantify in detail and there exist considerable differences between populations.

Humans, like other mammals, are characterized by a tight control of energy homeostasis allowing a stable body weight to be maintained. This setpoint of body weight can vary substantially among individuals and may also vary across lifetime. A complex regulatory system controls energy homeostasis which involves central pathways and peripheral components such as the size of adipose tissue which is sensed to the brain via the secretion of leptin. In addition, gut hormones, signals from the gastrointestinal nervous system and nutrients signal to the brain and induce a complex central integration according to the dietary intake and nutrient requirements of the organism. Central pathways are the anorexigenic leptin–melanocortin link and the orexigenic NPY–AgRP pathway. Many other factors such as insulin modify these signaling processes and thereby influence energy balance [25]. This complex and potent homeostatic system also serves to defend body weight against a critical energy deficiency but also against chronic overnutrition. Several adaptive systems are known to restore the initial body weight under such fluctuations of energy intake and expenditure. This may explain why obese humans exhibit a strong tendency to regain weight after intentional dietary weight reduction. The same tendency to return to initial body weight is observed after experimental overfeeding.

The role of energy homeostasis in the development of obesity has been elaborated by previous studies using indirect calorimetry to investigate the contribution of the resting metabolic rate (RMR) to the risk of obesity. In a study of Pima Indians, RMR was found to be a familial trait and to vary considerably across families [26]. In prospective studies in American Indians, a reduced rate of energy expenditure assessed in a respiratory chamber turned out to predict body weight gain over a 2-year follow-up period. This finding was confirmed in another group over a 4-year-follow-up period in the same paper, indicating that a low rate of energy expenditure may contribute to the aggregation of obesity in families [27]. At present, the genetic components for these differences in energy metabolism are still unknown.

## Environmental factors promoting obesity and type 2 diabetes

It is now established that a complex gene–environment interaction determines the individual risk to develop obesity (Table 14.3). Even in societies with an abundance of affordable, highly palatable food there is a high variation in body weight across the populations ranging from lean individuals to extremely obese persons. Many other factors such as physical activity, education and socioeconomic status may also act as strong modifiers of body weight. After two to three decades of modern lifestyle the trend towards obesity appears to reach a plateau, as suggested by recent data from the USA and other Western countries. This observation also supports the concept that genetic and biologic factors contribute substantially to the susceptibility to develop obesity.

Despite the genetic predisposition it is widely accepted that the current worldwide epidemic of obesity is largely a consequence of dramatic changes in lifestyle and environment which emerged over the past 30–50 years. A dramatic change in eating habits and food selection took place, whereas physical activity decreased remarkably because of technologic development concerning transportation and workplaces. Although dietary abundance and sedentary lifestyles have multiple origins, both may equally contribute to a chronic positive energy balance which may result in energy storage in adipose tissue.

A rather novel phenomenon is the expansion of the fast-food culture characterized by high-fat, low-starch foods together with a high intake of sugar-sweetened beverages. In addition to having a high energy density, fast-food menus have large portion sizes. This combination has led to the assumption that frequent fast-food consumption is linked to body weight gain and maintenance of overweight and obesity in the population. Despite this popular explanation, there is rather limited evidence for this association in the scientific literature. Nevertheless, a recent systematic review of six cross-sectional and seven prospective cohort studies concluded that sufficient evidence exists, at least for the adult population [28]. In addition, a high intake of sugar-sweetened beverages is another part of the global fast-food culture. Another systematic review clearly concluded that a high intake of calorically sweetened beverages can be regarded as a determinant of

obesity, although there was no support that this association is mediated via increased energy intake, suggesting that alternative biologic explanations should be also explored [29]. In view of the expansive growth of the fast-food industry in many countries this is a critical issue and may require more intense public discussion on the health consequences of this policy. According to a recent survey, people from the USA obtain one-third of their daily caloric intake from restaurant meals, and one-third of customers of chain restaurants in New York purchased meals containing more than 1000 calories [30]. Thus, there is a growing need to develop new public health policies to limit fast-food consumption and to facilitate a healthier food selection.

Another aspect in the context of high fast-food consumption which may further explain the elevated risk of obesity is the energy density of modern foods. There is convincing evidence that energy density of foods is a key determinant of caloric intake. From an evolutionary point of view, the human regulatory system for energy intake is adapted to starchy foods with low caloric content which requires large volumes to obtain sufficient energy. Today, most fast-foods have a high energy density which may favor a passive overconsumption of calories. A recent study showed that the average energy density of fast-food menus is approximately 1100 kJ/100 g, which is 65% higher than the average British diet (approximately 670 kJ/100 g) and more than twice the energy density of recommended healthy diets (approximately 525 kJ/100 g). It is 145% higher than in traditional African diets (approximately 450 kJ/100 g) which represent the levels against which human weight regulatory mechanisms have evolved. The authors concluded that the high energy density of many fast foods challenges human appetite control systems with conditions for which they were never developed [31].

Another determinant of the obesity epidemic may be the persistent trend over the last decades towards increasing portion sizes. A study from the USA demonstrated that the average portion size for many food items increased markedly between 1977 and 1998, with greatest increases for food consumed at fast-food restaurants and at home [32]. Similar trends have been documented in other countries. Experimental human studies have clearly established that both increasing the portion size and the energy density of food is associated with an increase in caloric intake and, in the long run, may therefore promote weight gain and obesity [33].

Finally, socioeconomic status is a strong determinant of obesity and of T2DM. In most countries there is a gradient between education and household income and the prevalence of obesity. A low socioeconomic status is associated with an unfavorable lifestyle including poor nutrition, low leisure-time physical activity and low health consciousness. This gradient is usually greater in females than males. Thus, the association between low household income and obesity may be mediated by the low costs of energy-dense foods, whereas prudent healthy diets based on lean meats, fish, vegetables and fruit may be less affordable for those of lower socioeconomic status [34].

**Table 14.3** Environmental factors promoting the development of obesity.

Ready availability of food
High palatability of food
High energy density
Relatively low cost of foods
High consumption of sugar-sweetened beverages
Aggressive commercial food promotion
Low physical activity

## Pathophysiologic links between obesity and type 2 diabetes

T2DM is characterized by an impaired insulin action or a defective secretion of insulin or both. Both defects are thought to be required for the manifestation of the disease and both are present many years before the clinical onset of the disease. To date, the mechanisms by which obesity increases the risk of developing T2DM are only partly understood and the evolving picture is getting more and more complex. The main adverse effect of obesity is on the action of insulin, particularly in liver, muscle and adipose tissue, but obesity also affects insulin secretion. Substantial advances have been made over recent years in our understanding how an excessive fat mass, but also chronic over-nutrition, may cause metabolic disturbances resulting in overt T2DM in those with a genetic predisposition for the disease.

### Lipids and insulin resistance

The earliest hypothesis to explain the relationship between obesity and T2DM is the “glucose–fatty acid cycle” which is based on the observation of a competition between glucose and fatty acid oxidation in the heart muscle and was introduced by Randle *et al.* [35]. The increased supply of non-esterified fatty acids from expanded adipose tissue depots competes with glucose utilization, particularly in muscle, which represents the organ that oxidizes the largest proportion of glucose. The proposed mechanism is an inhibition of the glycolytic enzymes pyruvate dehydrogenase, phosphofructokinase and hexokinase. As a consequence, the rate of glucose oxidation is reduced and glucose concentrations rise. The concomitant increased fatty acid turnover is accompanied by an increased release of glycerol from adipose tissue which is reutilized for hepatic glucose production, further augmenting the imbalance of glucose metabolism. Increased hepatic glucose output is another early disturbance contributing to glucose intolerance.

In addition, it was reported that elevated free fatty acids can directly impair insulin action. Recent studies suggested that obese subjects and those with T2DM have a high intramyocellular lipid accumulation which is an important feature of the insulin-resistant state. Exposure of skeletal muscle to an excessive lipid supply may lead to intramuscular accumulation, not only of neutral fatty acids, but also of lipid-derived metabolites such as ceramide, diacylglycerol and fatty acyl coenzyme A (CoA). This lipid accumulation is associated with coincident disturbances in insulin action mediated by an activation of a serine–threonine kinase cascade leading to serine–threonine phosphorylation of insulin receptor substrate 1 (IRS-1) and IRS-2 which may cause an impairment of insulin signaling including an impaired activation of phosphoinositol-3 kinase and other downstream elements [36]. This condition is also caused and exacerbated by chronic overnutrition with a high dietary fat intake. Thus, the increased availability of fatty acids may be the single most critical factor in disturbing insulin action in obesity.

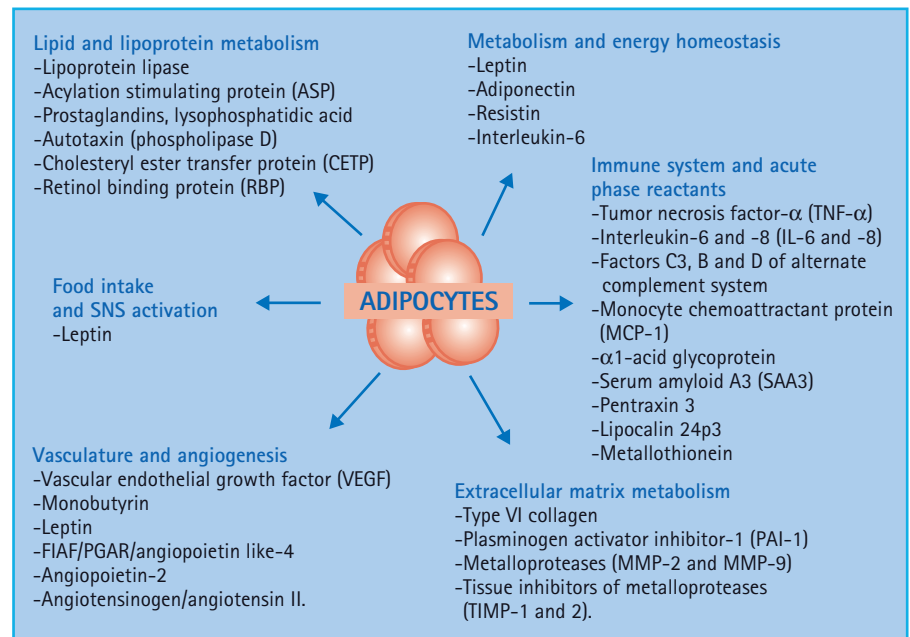

**Figure 14.2** Hyperbolic relation between  $\beta$ -cell function and insulin sensitivity. IGT, impaired glucose tolerance; NGT, normal glucose tolerance; T2DM, type 2 diabetes mellitus. ### Lipids and $\beta$ -cell function

Obesity is characterized by an elevated insulin secretion and a decreased hepatic insulin clearance. Human studies suggested that the  $\beta$ -cell volume is increased by about 50% in healthy obese subjects, probably because of hypertrophy of existing  $\beta$ -cells. Insulin release and insulin sensitivity are closely reciprocally related in a non-linear manner (Figure 14.2). Failure of this feedback system is known to result in a progressive decline in  $\beta$ -cell function and to underlie the development of T2DM. In addition to glucose, long-chain fatty acids may also exert a stimulatory effect on insulin secretion from the pancreatic  $\beta$ -cells via generation of fatty acyl CoA and activation of protein kinase C [36]. Another effect of fatty acids on insulin secretion is via binding to the G-protein-coupled receptor GPR 40 on the  $\beta$ -cell membrane which may result in a subsequent increase in intracellular calcium and secretory granule exocytosis [37]. Although fatty acids are critical for normal insulin secretion, a chronic exposure of  $\beta$ -cells to excessive fatty acids is associated with marked impairment of glucose-stimulated insulin secretion and decrease in insulin biosynthesis [38]. Another mechanism by which elevated fatty acids may impair insulin secretion in response to glucose is via an increased expression of uncoupling protein 2 (UCP-2) in  $\beta$ -cells. UCP-2 was found to be upregulated under glucolipotoxic conditions and mitochondrial superoxide has been identified as a post-translational negative regulator of UCP-2 activity in islets [39].

Glucose sensing of the pancreatic  $\beta$ -cells requires an intact oxidative mitochondrial metabolism to generate ATP. The resulting high ATP:ADP ratio is a prerequisite for normal insulin secretion. Studies in humans suggest that insulin resistance may

**Figure 14.3** Secretory products from adipose tissue and functional relationship. Reproduced from Lafontan M. Fat cells: afferent and efferent messages define new approaches to treat obesity. *Annu Rev Pharmacol Toxicol* 2005; **45**:119–146, with permission from *Annual Reviews*.

also arise from defects in mitochondrial fatty acid oxidation which may lead to increased intracellular fatty acid metabolites (fatty acid CoA, diacylglycerol). It was recently shown that young insulin-resistant offspring of parents with T2DM have features of impaired mitochondrial function [40]. Furthermore, it was reported that obese individuals have smaller mitochondria with reduced bioenergetic capacity than lean controls [41]. Although studies on this topic are still limited, there is growing evidence that a defective mitochondrial function could be a prominent feature of disturbances in both insulin secretion and action [42].

### Adipose tissue as a secretory organ

Another hypothesis that may explain the association between obesity and T2DM is the observation that adipose tissue is a secretory organ that produces and releases a variety of factors that may contribute to the development of insulin resistance and other health risks (Figure 14.3; Table 14.4). Among these factors most data have been collected for a mediator role of tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ). TNF- $\alpha$  is a multifunctional cytokine which was the first found to be expressed in adipose tissue [43]. It was subsequently shown that TNF- $\alpha$  exerts a variety of catabolic effects in adipose tissue. In addition to TNF- $\alpha$ , it was reported that its two receptor subtypes are overexpressed in adipose tissue from obese subjects [44–46]. The upregulated TNF- $\alpha$  system induces multiple adverse effects at the local organ level such as inhibition of glucose uptake because of an impairment of insulin signaling and suppression of GLUT 4 expression, a reduction of lipoprotein lipase expression and activity, and an increase in lipolysis [47]. Moreover, TNF- $\alpha$  activates the NF- $\kappa$ B pathway in adipose tissue which leads to an increased expression of many proinflammatory proteins such as interleukin 6 (IL-6), IL-8 and monocyte chemotactic protein 1 (MCP-1) among others. Finally,

**Table 14.4** Secretory function of adipose tissue in obesity and potential clinical consequences.

Product	Secretion	Consequence
Free fatty acids	↑	Dyslipidemia (TG ↑), insulin resistance
TNF- $\alpha$ , IL-6, MCP-1 and other cytokines/chemokines	↑	Insulin resistance, type 2 diabetes
Angiotensinogen, angiotensin II and other vasoactive factors	↑	Hypertension
PAI-1	↑	Thrombotic complications
CETP	↑	Low HDL cholesterol
Adiponectin	↓	Insulin resistance, atherosclerosis
Estrogens	↑	Endometrial and breast cancer

CETP, cholesterol ester transfer protein; HDL, high density lipoprotein; IL, interleukin; MCP, monocyte chemotactic protein; PAI, plasminogen activator inhibitor; TG, triglycerides; TNF, tumor necrosis factor.

TNF- $\alpha$  was demonstrated to reduce the expression of adiponectin, a protein that is abundantly expressed in fat cells and exerts direct antidiabetic and anti-atherosclerotic actions. A key mechanism by which TNF- $\alpha$  causes insulin resistance may be that this cytokine stimulates the phosphorylation of IRS-1 at the serine residue 307 which inhibits the transduction of the insulin signal to downstream elements [48].

Using an *in vitro* co-culture model of human adipocytes and muscle cells it was recently demonstrated that other fat cell secre-

tory products, in addition to TNF- $\alpha$ , are also involved in the development of muscle insulin resistance [49]. Thus, it is likely that the negative effect on muscle insulin action is brought about by a combination of adipokines. Although we have currently little information on the nature and the complex interplay of such proinflammatory and anti-inflammatory factors, a few relevant players have been identified. One such element may be MCP-1 [50]. Other potential candidates with a prodiabetic action may include plasminogen activator inhibitor 1 (PAI-1), but also lipid metabolites such as ceramide. Retinol-binding protein 4 (RBP-4) was also shown to contribute to insulin resistance via reduced PI<sub>3</sub> kinase signaling and enhanced hepatic expression of the gluconeogenic enzyme phosphoenolpyruvate carboxykinase. An interesting observation in this context is that adiponectin may be able to antagonize the insulin resistance-promoting activity of proinflammatory cytokines released from adipose tissue in an autocrine fashion [51].

Adipocytes are also able to release products with anti-inflammatory properties including factors such as adiponectin, IL-1 receptor antagonist and IL-10. By far the most interesting component is adiponectin, which is the most abundantly expressed protein in adipose tissue. It was shown in a number of clinical studies that circulating adiponectin levels are inversely associated with BMI and that low concentrations predict the development of T2DM [52,53]. Adiponectin is now known to exert a variety of antidiabetic and anti-atherosclerotic effects (e.g. adiponectin stimulates fatty acid oxidation in an AMP-activated protein kinase-dependent manner) [54].

### Signaling pathways of inflammation in adipose tissue

Current research has shown that the inflammatory response in human obesity is mediated via activation of the c-Jun N-terminal kinase (JNK) and IKK $\beta$ -NF- $\kappa$ B pathways. Both pathways are simultaneously stimulated by cytokines such as TNF- $\alpha$  and IL-6, but also by lipids. It has been convincingly demonstrated in experimental studies that genetic or chemical inhibition of these pathways can reduce inflammation and improve insulin resistance (for review see [55]) (Figure 14.4). In obesity, JNK activity is elevated not only in adipose tissue, but also in liver and muscle. Loss of JNK1 prevents the development of insulin resistance and diabetes in both genetic and dietary mouse models of obesity [56]. IKK $\beta$  can act on insulin signaling through at least two pathways. First, it can directly phosphorylate IRS-1 on serine residues and, second, it can phosphorylate the inhibitor of NF- $\kappa$ B (I $\kappa$ B) thus activating NF- $\kappa$ B, a transcription factor that stimulates the production of many proinflammatory mediators including TNF- $\alpha$  and IL-6 [57]. Mice heterozygous for IKK $\beta$  are partially protected against insulin resistance caused by lipid infusion, high-fat diet or genetic obesity [58]. Both the JNK and the IKK $\beta$ -NF- $\kappa$ B pathways are activated via pattern recognition receptors that function as membrane receptors for a variety of external signals. It is interesting to note that endogenous lipids and lipid conjugates were found to activate toll-like receptors (TLRs) in obesity. It was recently reported that saturated fatty

**Figure 14.4** Potential cellular mechanisms for inflammation and development of insulin resistance. acids bind and activate TLR-4 on adipocytes, thereby suggesting a direct link between exogenous nutrients that are redundant in the obese state and inflammation [59]. Mice with a loss-of-function mutation of TLR-4 were found to be protected from diet-induced obesity and insulin resistance. These mice also showed a reduced NF- $\kappa$ B and JNK activity under a high-fat diet compared to wild-type control mice [60]. In a similar model, markedly lower circulating levels of MCP-1 were measured. TLR-4 deficiency, however, did not attenuate the induction of TNF- $\alpha$  and IL-6 expression [61].

It is noteworthy that most proteins released from adipose tissue are not produced by fat cells but rather by pre-adipocytes and invading immune cells such as activated macrophages. While leptin and adiponectin are true adipokines which are almost exclusively produced by adipocytes, TNF- $\alpha$ , IL-6, IL-8, MCP-1,

visfatin, PAI-1 and others are mainly expressed by pre-adipocytes, macrophages resident in adipose tissue and possibly other cells. The relative contributions of the various cellular components in adipose tissue to the secretion of these products remains unknown and may vary substantially according to depot and model. Nevertheless, all these locally secreted factors appear to participate in the induction and maintenance of the subacute inflammatory state associated with obesity. It is also important to mention that the invading macrophages release factors that substantially augment adipocyte inflammation and insulin resistance [62]. Another interesting observation in this context is that pre-adipocytes and macrophages share many common features [57].

The regulation and biologic functions of the secretory products are diverse and only poorly understood. In addition to the direct effects of fatty acids and their intracellular products, other factors may also contribute to the chronic inflammatory state in adipose tissue. It was recently shown that fat cell size may be a critical determinant of the production of proinflammatory and anti-inflammatory factors. Enlarged hypertrophic fat cells are characterized by a shift towards a proinflammatory state [63], thereby promoting insulin resistance. This is in agreement with clinical data showing that fat cell hypertrophy is associated with an increased risk of developing T2DM [64].

### Obesity and endoplasmic reticulum stress

A recent observation suggests that obesity and chronic overnutrition overload the functional capacity of the endoplasmic reticulum (ER) and that the resulting ER stress contributes to the activation of the inflammatory signaling pathways including the JNK pathway. In both high-fat diet induced and genetic obesity models, obesity was shown to cause ER stress with inositol-requiring kinase-1 $\alpha$  (IRE-1 $\alpha$ ) having a crucial role in insulin receptor signaling as a mediator of JNK activation [65]. In a mouse model of type 2 diabetes, systemic overexpression of 150-kDa oxygen-regulated protein (ORP150), a molecular chaperone located in the ER, improved insulin intolerance and enhanced glucose uptake indicating that this chaperone has an important role in insulin sensitivity and is a potential target for the treatment of T2DM [66].

### Obesity and oxidative stress

A study from Japan demonstrated that fat accumulation is associated with systemic oxidative stress in humans and mice [67]. There was a selective production of reactive oxygen species (ROS) in adipose tissue of obese mice, accompanied by an increased expression of NADPH oxidase and a decreased expression of anti-oxidative enzymes. The authors also showed that fatty acids increased oxidative stress in cultured adipocytes via NADPH oxidase activation which was followed by dysregulated production of adipokines such as adiponectin, PAI-1, IL-6 and MCP-1. In addition, treatment with an NADPH oxidase inhibitor reduced ROS production, restored the dysregulation of adipokines in adipose tissue and improved diabetes, dyslipidemia and hepatic

steatosis, indicating that the redox status in adipose tissue is a critical factor in the development of the metabolic syndrome [67].

### Adipose tissue hypoxia

An expansion of the adipose tissue mass leads to fat cell hypertrophy and subsequent hypoxia of the tissue. Recent studies convincingly support the concept that hypoxia has an important if not central role in the development of chronic inflammation, macrophage infiltration, impaired adipokine secretion, ER stress and mitochondrial dysfunction in white adipose tissue in obesity [68,69]. These consequences are also accompanied by an inhibition of adipogenesis and triglyceride synthesis and elevated circulating free fatty acid concentrations. Measurement of the interstitial partial oxygen pressure (PO<sub>2</sub>) in adipose tissue showed a reduction of up to 70% leading to oxygen levels of about 2% in obese animals compared to lean controls [69]. This observation was further substantiated by the determination of hypoxia response genes such as hypoxia-inducible factor 1 $\alpha$  (HIF-1 $\alpha$ ), vascular endothelial growth factor (VEGF), heme oxygenase 1 (HO-1) and others. The low oxygen pressure may also contribute to a reduced mitochondrial respiration with a consecutive increase in lactate production. In humans, HIF-1 $\alpha$  was also shown to be increased in white adipose tissue of obese patients and its expression was reduced after surgery-induced weight loss [70]. Hypoxia was also demonstrated to decrease adiponectin expression in adipocytes [71].

The physiologic basis of adipose tissue hypoxia may be related to a reduction in adipose tissue blood flow and capillary density which has been reported in both obese humans and animals. Although the hypoxic state leads to an increased production and release of pro-angiogenic factors from adipose tissue such as VEGF and others, this compensatory mechanism may not be sufficient to keep the PO<sub>2</sub> at a normal level as the free diffusion of oxygen in the adipose tissue may be limited [69].

### Accumulation of immune cells

Leptin, TNF- $\alpha$ , MCP-1 and other chemokines have an essential role in the recruitment of macrophages to adipose tissue. The secretory profile of both pre-adipocytes and adipocytes includes a variety of chemoattractants for immune cells. It was recently reported that the attraction of T-lymphocytes possibly caused by stromal cell-derived factor 1 (SDF-1) represents the initial step which subsequently leads to the invasion and activation of circulating monocytes–macrophages resembling the scheme originally described for atherosclerosis [72]. Such accumulation of immune cells and inflammation of adipose tissue has been shown in obese humans [73] and appears to be more pronounced in omental than subcutaneous adipose tissue [74], which would also fit with the concept that the amount of visceral fat is the culprit for the metabolic and cardiovascular complications of obesity.

### Role of body fat distribution pattern

Another important issue in this context is the distribution of body fat. It has long been known from early clinical studies that

**Figure 14.5** Nutrition and obesity-induced inflammation and development of systemic insulin resistance. Reproduced from De Luca C, Olefsky JM. Stressed out about obesity and insulin resistance. *Nat Med* 2006; **12**:41–42, with permission from Nature Publishing Group.

subjects with a more abdominal type of body fat distribution are at increased risk of developing T2DM and other metabolic and cardiovascular complications [75–77]; however, the underlying cause has only recently become evident. Intra-abdominal fat cells exhibit a differing expression profile and are lipolytically more active than subcutaneous adipocytes. Moreover, they show a greater accumulation of lymphocytes and macrophages, indicating greater proinflammatory activity. Visceral adipose tissue also has a much higher blood vessel and nerve density leading to a much greater metabolic activity. Visceral adipose tissue drains into the portal vein and thus the liver is directly exposed to fatty acids and proteins released from this active fat depot promoting insulin resistance in the liver. Thus, the inflammatory process is detected, not only at the level of adipose tissue, but may also affect the liver and possibly other organs. As enlarged visceral fat depots are frequently associated with fat accumulation in the liver, it was also hypothesized that secretory products from the visceral adipose tissue may directly cause hepatic insulin resistance.

In summary, a variety of data suggests that chronic overnutrition with a high-fat, high-sugar diet and as a consequence an accumulation of body fat is the primary cause of chronic inflam-

mation in obesity and may promote the development of systemic insulin resistance which affects many tissue including liver, muscle and the brain (Figure 14.5). It should not be neglected that apart from an unhealthy diet, other lifestyle factors such as lack of physical activity may substantially contribute to these pathologic processes.

### Treatment of obesity in the context of the metabolic syndrome and type 2 diabetes

The fact that obesity is the most powerful driving force for the development of T2DM provides the rationale to consider weight management as the most important initial treatment step. Numerous studies have consistently shown that weight loss is not only an effective means to prevent the development of T2DM in those at increased risk, but may also improve the metabolic disturbances and associated risk factors in those with overt T2DM. In addition, weight reduction facilitates reaching the primary treatment goal of a metabolic control close to normal. Interestingly, almost all disturbances mentioned above are potentially reversi-

ble by weight loss. This was particularly demonstrated for elevated circulating adipokines. A modest to moderate weight reduction was found to reduce significantly the concentrations of circulating factors such as leptin, C-reactive protein, PAI-1, IL-6, IL-8, MCP-1 and others by 10–50%. By contrast, adiponectin levels are known to rise in relation to weight reduction. In a recent study in surgically treated morbidly obese subjects a significant reduction in macrophage infiltration was documented in adipose tissue samples after a mean weight loss of 22 kg within 3 months [70].

### Management of obesity in subjects with type 2 diabetes

For the reasons outlined, management of obesity should represent a central component in the treatment strategy for T2DM. Although currently available weight reduction programs for patients with diabetes have only limited success rates, particularly in the long run, in contrast to previous beliefs, recent studies show that obese subjects with T2DM can achieve clinically significant weight loss. In the prospective Look AHEAD study, the average weight loss in obese subjects with T2DM in the intensive lifestyle intervention group after 1 year of treatment was 8.6% of the initial body weight and was accompanied by substantial improvements of all weight-associated risk factors. Mean HbA<sub>1c</sub> fell from 7.3% (56 mmol/mol) to 6.2% (44 mmol/mol) despite reductions in the dosage of glucose-lowering agents [78].

Despite this positive development, treatment of obese subjects with T2DM is usually considered to be more difficult than treating obese subjects without diabetes for several reasons. People with T2DM are usually older than obese subjects without diabetes, which may mean a smaller weight loss as energy expenditure decreases with age. Another reason is that subjects with diabetes focus more on blood glucose control which could result in neglecting other health problems. Finally, the effect of various antidiabetic agents to increase weight or prevent weight loss has to be considered [79].

### Dietary approaches

The cornerstones of a weight reduction program for obese patients with diabetes include a moderately hypocaloric diet, an increase in physical activity and behavior modification, very similar to the recommendations for obese subjects without diabetes. Numerous studies have applied and examined such concepts and have been critically evaluated in reviews [80–82].

The gold standard in the dietary treatment of obese patients with T2DM is a balanced moderately energy-restricted diet with an energy deficit of at least 500 kcal/day (see Chapter 22). The most important single measure is the reduction in fat intake, particularly in saturated fatty acids. A low-fat, high carbohydrate diet is generally recommended. As shown recently, a diet rich in fiber and complex carbohydrates has some beneficial effects on measures of glucose and lipid metabolism but these effects may be small and possibly of limited clinical importance [83]. The concept of a high-carbohydrate, low-fat diet was challenged by clinical studies showing that replacement of saturated fat by monounsaturated fat compared to high-carbohydrate intake is equally favorable or even has advantages with regard to glycemic

response and lipids [84]. More importantly, recent studies using a low-carbohydrate, high-protein diet were at least equally effective. In a recent meta-analysis of such studies, HbA<sub>1c</sub>, fasting glucose and some lipid fractions improved with lower carbohydrate content diets [85]. In a study from Israel, a Mediterranean type of weight loss diet showed small advantages in comparison to the classic low-fat, low-carbohydrate diet in a subgroup of overweight participants with diabetes [86]. The message from this and other studies [87,88] is that the macronutrient composition of the diet is secondary for weight reduction. In patients with nephropathy, however, protein intake remains a critical issue and should be limited in accordance with current recommendations [89].

From a practical point of view it is extremely important to assess the habitual diet of patients with T2DM and to focus counseling on timely changes of their eating habits in order to approach current dietary recommendations [89]. It should be stressed that all efforts for dietary changes should be made as simple as possible for patients as they may also be burdened by many requirements to manage their diabetes. For obese subjects with T2DM the frequent recommendation to distribute their allowed calories over 5–6 meals is difficult to meet and may even hinder weight loss without being of any advantage for metabolic control [90]. Therefore, in patients without insulin, three meals a day may be more appropriate and advantageous to reach the individual dietary and weight goals.

Another possible dietary approach is the use of a very low calorie diet (VLCD) for initial weight loss. This option may be particularly valuable for patients with poor metabolic control. Dietary restriction is known to be associated with a rapid improvement of insulin resistance and glycemic control after even short periods of VLCD. There is also evidence that the pattern of adipokines and macrophage-associated gene expression can change dramatically under such conditions [91]. This approach, however, can only be applied for a limited period of time and requires intensive medical surveillance. The long-term results of VLCD are moderately better than those of conventional diets, although there is considerable weight regain under the former [92]. Therefore, there is need for new sophisticated solutions such as intermittent VLCD in combination with conventional hypocaloric diets to obtain better long-term results [93]. Another possibility is to change the pattern of nutrient intake to modify adipose tissue inflammation. To date, there is little practical information available to indicate whether specific effects of single components in the diet can ameliorate adipose tissue inflammation independent of calorie restriction. There is no doubt that more research is urgently required to explore the potential of dietary components and to develop novel strategies that may help to provide better dietary solutions for the management of obesity.

### Antidiabetic drugs and body weight

It has long been recognized that antidiabetic drugs can promote weight gain in subjects with T2DM (see Chapters 27 and 29). The strongest weight-promoting effect is exerted by insulin. In the Diabetes Control and Complications Trial (DCCT), intensified

insulin treatment was associated with substantial weight gain that resulted in unfavorable changes of lipid levels and blood pressure similar to those seen in the insulin resistance syndrome [94]. In the UK Prospective Diabetes Study (UKPDS), insulin treatment caused a mean weight gain of approximately 7 kg over 12 years of treatment in newly diagnosed subjects with T2DM [95]. In addition, sulfonylureas are known to promote weight gain because of their action to promote insulin secretion. In the UKPDS, the average weight gain under glibenclamide treatment amounted to about 5 kg [95].

Administration of glitazones, a relatively new class of PPAR- $\gamma$  agonists with insulin sensitizing activity, leads to substantial weight gain of 4–5 kg on average. There is growing evidence, however, that weight gain under glitazone treatment occurs mainly in subcutaneous depots, not in the visceral depot, which should have less deleterious metabolic consequences. Furthermore, weight gain under administration of glitazones is not only caused by an increase in fat mass, but also by enhanced fluid retention. In contrast, metformin and  $\alpha$ -glucosidase inhibitors have a modest weight lowering potential [79].

Recent data for the DPP-4 inhibitors show that these new drugs are weight neutral, whereas the administration of GLP-1 mimetics, such as exenatide, results in a substantial weight loss in a high proportion of patients [96].

### Weight lowering drugs

Another component in the treatment of obesity is the adjunct administration of weight lowering drugs. As the efficacy of currently approved drugs is limited, drug treatment is only recommended if the non-pharmacologic treatment program is not sufficiently successful and if the benefit:risk ratio justifies drug administration [97]. At present, only two compounds are available that have demonstrated efficacy and safety in obese subjects with and without T2DM.

Orlistat is a gastric and pancreatic lipase inhibitor that impairs the intestinal absorption of ingested fat. In a recent systematic review of clinical studies over at least 12 weeks in obese subjects with T2DM, orlistat treatment produced a greater weight loss than placebo treatment by 2.0 kg on average, associated with a small improvement in HbA<sub>1c</sub> compared with controls [98]. Furthermore, orlistat moderately decreases low density lipoprotein (LDL) cholesterol concentrations.

Sibutramine is a selective serotonin and noradrenaline reuptake inhibitor that enhances satiety and slightly increases thermogenesis.\* The same systematic review showed an average weight loss of 5.1 kg in obese patients with T2DM, also accompanied by

improvements of glycemic and lipid measures [98]. As sibutramine is known to activate the sympathetic nervous system, this drug should not be used in patients with diabetes and poorly controlled hypertension or coronary artery disease.

### Bariatric surgery

Bariatric surgery is now an established method to reduce body weight in subjects with extreme obesity ( $\geq 40$  kg/m<sup>2</sup>), but there is growing consensus that this method can also be applied in subjects with T2DM at a BMI  $\geq 35$  kg/m<sup>2</sup>. In this group of patients surgery is by far the most effective treatment mode with excellent long-term results compared to all other methods. In the Swedish Obese Subjects study, a large prospective trial comparing bariatric surgery with conventional dietary treatment, sustained weight loss  $\geq 20$  kg was achieved in the surgically treated subjects with practically no significant weight change in the control group. The surgical intervention not only reduced the incidence of T2DM, but also significantly reduced total mortality [99]. A recent meta-analysis of studies on the effect of bariatric surgery in obese patients with T2DM demonstrated that 78% had a complete remission of diabetes. Weight loss and diabetes resolution was greatest in patients undergoing combined restrictive and malabsorptive surgical methods [100]. The majority of insulin-treated patients can stop insulin treatment within a few months after surgery and all other medications for diabetes and other cardiovascular risk factors can be considerably reduced or discontinued. There are also many studies indicating how rapidly most circulating adipokines are normalized in relation to the degree of weight loss in these patients.

---

## Conclusions

There is now growing information on how obesity is increasing the risk of developing T2DM. It is apparent that an excess of body fat promotes insulin resistance and impairs insulin secretion. As most patients with T2DM are overweight or obese, weight management must be a central component of any treatment strategy, as weight loss has been convincingly shown to provide a marked improvement in metabolic control. In parallel, most if not all underlying disturbances benefit from weight loss or dietary interventions. As conventional concepts combining an energy-reduced diet and an increase in physical activity frequently have poor long-term results, however, more effective weight loss strategies should be developed and evaluated.

\*The marketing authorization for sibutramine has recently been withdrawn in Europe following the publication of the SCOUT trial. In this trial which included 9,800 overweight or obese individuals at high risk of CVD events, treatment with sibutramine was associated with a 16% increased risk of non-fatal MI, non-fatal stroke, resuscitated cardiac arrest or CVD death. This result was driven by an increased incidence of non-fatal MI and stroke.

## 4 Other Types of Diabetes

# 15

## Monogenic Causes of Diabetes

Angus Jones & Andrew T. Hattersley

Diabetes and Vascular Medicine, Peninsula Medical School, Exeter, Devon, UK

### Keypoints

- Monogenic diabetes results from single-gene mutations that cause  $\beta$ -cell dysfunction or, less commonly, insulin resistance.
- Approximately 1–2% of diabetes is monogenic, but this is frequently misdiagnosed.
- Monogenic diabetes should be suspected where: presentation is atypical for type 1 or 2 diabetes; there is an autosomal dominant (or maternally inherited in mitochondrial disorders) family history; there are characteristic associated features such as deafness in mitochondrial diabetes or fat loss in lipodystrophy; or diabetes has been diagnosed within the first 6 months of life.
- Mutations in the glucokinase gene, which is important in “sensing” blood glucose levels in the pancreas, result in resetting of fasting glucose to a higher level (5.5–8.0 mmol/L). Patients have dominantly inherited mild fasting hyperglycemia with only modest changes in glycated hemoglobin. Complications are rare and no treatment is needed.
- Mutations in the transcription factor genes *HNF1A* and *HNF4A* result in dominantly inherited progressive hyperglycemia with symptomatic diabetes in adolescence or young adulthood. Patients with *HNF1A* or *HNF4A* diabetes are very sensitive to sulfonylurea treatment and may not require insulin until middle or old age.
- Mitochondrial mutations can result in maternally inherited diabetes often with sensorineural hearing loss and a range of other disorders.
- Diabetes diagnosed before 6 months is unlikely to be type 1 diabetes and a genetic cause should be sought even where the patient is now an adult. High dose sulfonylurea treatment is often more effective than insulin where mutations affecting Kir6.2 and SUR1 subunits of the  $\beta$ -cell potassium channel are identified.
- Acanthosis nigricans is the key feature of insulin resistance and a genetic cause should be considered where this is seen in non-obese patients. Partial lipodystrophy results in thin muscular limbs with hypertriglyceridemia and insulin resistance and suggests a mutation in *LMNA* or *PPARG*. In the absence of lipodystrophy an insulin receptor mutation is the most common cause.

### Introduction

Monogenic diabetes results from inheritance of one or more mutations in a single gene and accounts for 1–2% of diabetes cases. Mutations may be inherited in a dominant or recessive fashion. The majority (90%) of monogenic diabetes cases are initially misdiagnosed as type 1 (T1DM) or type 2 diabetes (T2DM).

Correct genetic diagnosis is important to predict clinical course, explain other associated clinical features, enable genetic counseling and diagnose family members, and most importantly guide appropriate treatment.

Monogenic diabetes where the primary disorder affects the  $\beta$ -cell has four main clinical presentations: familial mild fasting hyperglycemia (glucokinase maturity-onset diabetes of the young [MODY]), familial young-onset diabetes (transcription factor MODY), neonatal diabetes and diabetes with extrapancreatic fea-

tures. Clinical and biochemical features that help differentiate the common forms of monogenic diabetes that result in  $\beta$ -cell dysfunction from T1DM and T2DM are summarized in Table 15.1. Clinical features and management of monogenic diabetes without extrapancreatic features are further summarized in Figure 15.1. Single-gene mutations may also cause diabetes through insulin resistance as occurs in the inherited lipodystrophies and insulin receptor mutations. A number of monogenic multisystem diseases (e.g. hemochromatosis and cystic fibrosis) may cause diabetes; these are beyond the scope of this chapter and are discussed elsewhere (see Chapter 18).

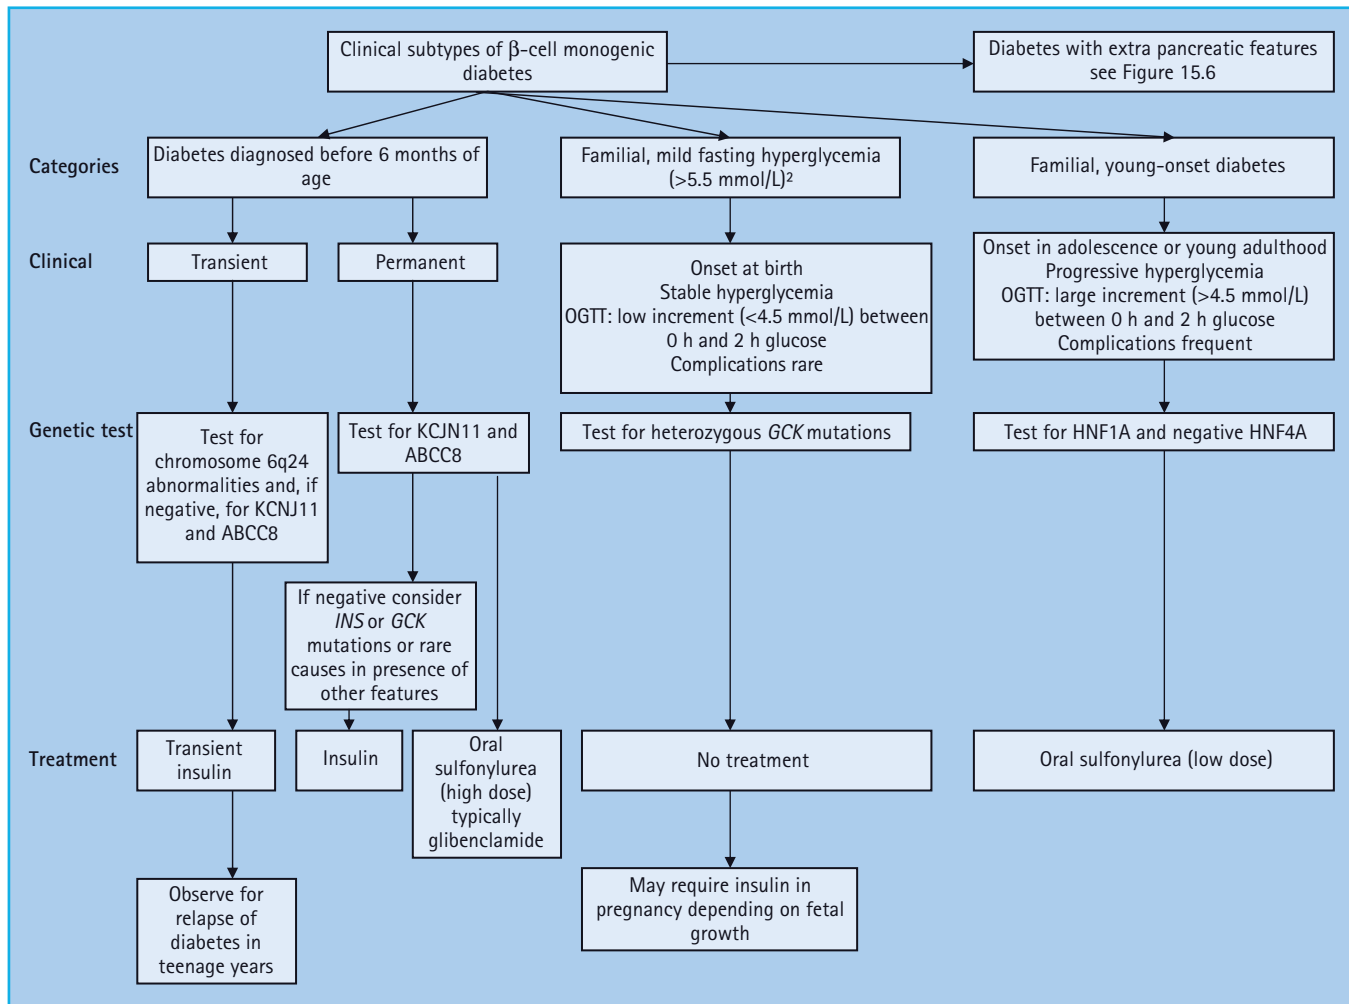

### Maturity-onset diabetes of the young

Maturity-onset diabetes of the young (MODY) is autosomal dominantly inherited diabetes that, despite a young age of onset, is not insulin dependent [1,2]. It results from  $\beta$ -cell dysfunction rather than insulin resistance [1]. The underlying genetic etiology has now been defined that allows MODY to be subclassified according to the gene involved [3,4]. Mutations in at least eight genes have been linked to MODY [5,6]. These include mutations

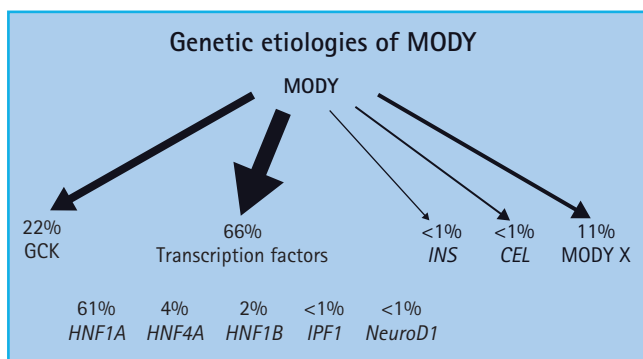

**Table 15.1** Differentiating  $\beta$ -cell monogenic diabetes from type 1 and 2 diabetes.

Features	Type 1 diabetes	Young type 2	GCK MODY	HNF1A MODY	MIDD	K <sub>ATP</sub> PNDM
Insulin dependent	Yes	No	No	No	+/-	Yes
Parent affected	2–4%	Usually	Yes	Yes	Mother	15%
Typical age of onset	6 months – young adult	Adolescent and young adult	Birth (may be diagnosed at any age)	Teens – young adult	Young adult	Under 6 months
Obesity	Pop freq	Yes	Pop freq	Pop freq	Rare	Pop freq
Acanthosis nigricans	No	Yes	No	No	No	No
Glycemia	High	Variable	Mild	High	Variable	High
$\beta$ -Cell autoantibodies	Usually	Sometimes	No	No	No	No
Typical C peptide (pmol/L)	<200 Outside honeymoon period	500–>1000	100–900	100–700	<100–700	<200

DM, diabetes; GCK, glucokinase; HNF1A, hepatocyte nuclear factor 1A (HNF4A is similar); MIDD, maternally inherited diabetes and deafness; PNDM, permanent neonatal diabetes; Pop freq, population frequency (frequency of obesity seen in the general population).

**Figure 15.1** Clinical subtypes and management of monogenic  $\beta$ -cell diabetes without extrapancreatic features. To convert plasma glucose measurements to mg/dL multiple by 18. ABCC8, ATB binding cassette subfamily C; GCK, glucokinase gene; HNF, hepatocyte nuclear factor; INS, insulin gene; KCNJ11, potassium inwardly rectifying channel, subfamily J, member 11 gene; OGTT, oral glucose tolerance test.

**Figure 15.2** The different genetic etiology in a UK maturity-onset diabetes of the young (MODY) series. MODY X denotes dominantly inherited young-onset non-insulin dependent diabetes fitting clinical criteria for maturity-onset diabetes of the young where mutations in known MODY genes have not been identified. Adapted from McCarthy & Hattersley [6].

in the gene encoding the glucose sensing enzyme glucokinase (*GCK*) and mutations in several transcription factors that affect  $\beta$ -cell development and function, the frequencies of which are summarized in Figure 15.2. Clinical presentation varies greatly depending on the underlying genetic mutation. Table 15.2 summarizes the clinical features of glucokinase and transcription factor diabetes. The strikingly different subtypes of MODY mean it is important to define the underlying genetic etiology. We recommend the use of clinical categories based on underlying genetic cause – familial mild fasting hyperglycemia resulting from glucokinase gene mutations (*GCK* MODY), familial young-onset progressive diabetes resulting from *HNF1A* and *HNF4A* mutations (transcription factor MODY) and renal cysts and diabetes syndrome (RCAD) resulting from *HNF1B* mutations.

Mutations in the genes associated with MODY should be sought in patients with diabetes diagnosed under 25 years of age, who do not fully fit the phenotypes of T1DM or T2DM and who have a strong family history of diabetes (Table 15.1). Differentiating from apparent T1DM is particularly important as these patients can often be most effectively treated without the use of injected insulin.

## Glucokinase MODY

Glucokinase catalyzes the phosphorylation of glucose to glucose-6-phosphate, the first and rate-limiting step in intracellular glucose metabolism in both  $\beta$ -cells and hepatocytes (Figure 15.3). Owing to the unique catalytic properties of the enzyme, the rate of glucose phosphorylation is proportional to the glucose concentration, thus allowing  $\beta$ -cells and hepatocytes to respond to changes in glycemia. In the  $\beta$ -cell, glucokinase acts as a glucose sensor ensuring insulin release is appropriate to the glucose concentration [7]. Heterozygous loss-of-function mutations in *GCK* result in a shift of the dose–response curve to the right [8].

**Table 15.2** Comparison of the clinical characteristics of glucokinase and transcription factor maturity-onset diabetes of the young (MODY).

	Glucokinase MODY	Transcription factor MODY
Onset of hyperglycemia	Birth	Adolescence/early adulthood
Presentation	Usually asymptomatic, detected by screening or on routine testing	Usually symptomatic
Nature of hyperglycemia	Minimal increase in glycemia with age Mild (FPG usually 5.5–8 mmol/L) HbA <sub>1c</sub> usually close or just above upper limit of normal	Progressive deterioration of glycemia with age May be severe (FPG frequently >14 mmol/L off treatment) HbA <sub>1c</sub> variable depending on age and treatment, may be high
Pattern in an oral glucose tolerance test	FPG >5.5 mmol/L (2 hour – FPG) usually <3.5 mmol/L	FPG often <5.5 mmol/L (2 hour – FPG) usually >3.5 mmol/L
Microvascular complications	Rare	Frequent
Pathophysiology	$\beta$ -Cell defect (glucose sensing defect)	$\beta$ -Cell defect (initially insulin secretion maintained at normal glucose values but not increased in hyperglycemia)
Extrapaneatic manifestations	Reduced birth weight	See Table 15.3
Treatment	Pharmacologic treatment rarely needed	Sensitive to sulfonylurea treatment May progress to require insulin

FPG, fasting plasma glucose.

Glycemia is therefore regulated at a higher setpoint but remains tightly controlled. Subjects are still able to stimulate their  $\beta$ -cells maximally [8]. Glucokinase is also present in the liver and as a result patients have reduced hepatic glycogen synthesis [9].

Over 200 loss-of-function mutations in *GCK* have been identified, all causing a similar clinical picture. Homozygous loss-of-function glucokinase mutations are a rare cause of insulin-requiring diabetes presenting in the neonatal period [10]. Gain-of-function mutations cause congenital hyperinsulinism [11].

## Clinical features

Patients have mild fasting hyperglycemia from birth, usually 5.5–8.0 mmol/L. There is only minor deterioration in fasting glucose with age (Figure 15.4) [12]. Patients do not have symptoms of hyperglycemia. Post meal glucose values are only mildly raised and there is frequently only a small increase (<3 mmol/L in 70% of patients) seen at 2 hours on an oral glucose tolerance test [13] which may explain the near normal HbA<sub>1c</sub> and rarity of complications [14]. Glycated hemoglobin values above 7.5% would be suggestive of an alternative diagnosis. Marked worsen-

**Figure 15.3** Glucokinase and its role within the  $\beta$ -cell. Glucokinase is the rate determining step in glucose metabolism, and therefore in the rate of production of ATP, which leads ultimately to insulin secretion.

**Figure 15.4** Variation of blood glucose concentration with age in patients with glucokinase and transcription factor MODY.

ing of the glycemia suggests that the patient has developed T1DM or T2DM in addition to their *GCK* mutation. Microvascular and macrovascular complications are rare even when no treatment is given [14]. Glucokinase MODY is asymptomatic and, although it is autosomal dominantly inherited, there may be no known family history of diabetes. Testing of apparently unaffected

parents can reveal that one parent has mildly raised fasting plasma glucose.

### Differentiating from type 1 and 2 diabetes

Diagnosis of glucokinase MODY is most important in young patients who may otherwise be thought to have T1DM and treated with insulin [15]. Unlike T1DM, hyperglycemia remains mild,  $\beta$ -cell antibodies are usually negative and (if tested) one parent is likely to have mild hyperglycemia. Fasting C-peptide will remain detectable and the post meal rise in glucose concentration will be far less than in T1DM. Differentiating glucokinase MODY from T2DM can be more difficult as both conditions can cause mild hyperglycemia with a strong family history. Lack of obesity and features of insulin resistance, a small increment on oral glucose tolerance testing and non-progression all suggest glucokinase MODY.

### Management

Outside of pregnancy, hypoglycemic medication is not recommended as hyperglycemia is mild, complications are rare and medication appears to have minimal effect because the regulation of glycemia is preserved [16]. Once diagnosis is confirmed, treatment can usually be discontinued; however, this should be done with caution as it is possible for T1DM or T2DM to coexist with a *GCK* mutation.

**Figure 15.5** The centile birth weight of children in families with glucokinase mutations. The weight is increased by the presence of a maternal mutation and decreased by the presence of a fetal mutation. Data from Hattersley *et al.* [18].

### Glucokinase MODY and pregnancy

#### Clinical features

Patients with *GCK* mutations are frequently found to have hyperglycemia during screening in pregnancy and represent approximately 3% of Caucasian patients with gestational diabetes [17]. Their identification is important because they have a different clinical course, both within and outside pregnancy, than other subjects with gestational diabetes. The birth weight of the newborn infant will depend on the mutation status of both the mother and the fetus (Figure 15.5). Where only the mother carries the mutation, maternal hyperglycemia may result in increased fetal insulin secretion and growth causing the fetus to be large for gestational age [18]. If the fetus inherits the mutation from the father, however, birth weight is reduced by approximately 500 g as a result of reduced fetal insulin secretion and insulin-mediated fetal growth [18]. If both mother and fetus have the *GCK* mutation the two opposing effects are cancelled out and the newborn infant is of normal weight.

#### Genetic testing for *GCK* mutations in pregnancy

We recommend testing for *GCK* mutations when a pregnant patient is found to have persistently raised fasting plasma glucose 5.5–8 mmol/L and an increment of <4.6 mmol/L on at least one oral glucose tolerance test (either during or outside pregnancy). An absence of family history should not exclude the diagnosis as asymptomatic hyperglycemia in a parent may not have been detected.

#### Management

Patients with hyperglycemia resulting from glucokinase mutations are often treated with insulin during pregnancy in an attempt to correct the fasting hyperglycemia. Fetal genotype, however, is a far greater determinant of fetal birth weight than treatment of the mother and insulin treatment appears to have little effect on fetal growth [19]. This probably reflects the difficulty in lowering the blood glucose in glucokinase patients

because of increased counter-regulation [20]. Patients stop producing their own insulin and produce counter-regulatory hormones if blood glucose is reduced to normal levels, making successful control of blood glucose with insulin difficult. This results in frequent hypoglycemic symptoms at non-hypoglycemic blood sugar levels and means that large doses of insulin may be required to reduce fasting hyperglycemia to normal levels [20,21]. In some cases where the fetus has inherited the mutation, intensive insulin treatment has resulted in a low birth weight child [21]. This is to be expected as a small baby is seen when the fetus inherits a mutation from the father and is born to a normoglycemic mother [18,22]. Testing fetal genotype *in utero* is not without risk. Treatment decisions in glucokinase gestational diabetes should therefore be related to fetal growth as shown by scans rather than being made solely on maternal glycemia [21]. If the abdominal circumference is greater than the 75th centile insulin may be used but early delivery is the most successful strategy.

### *HNF1A* and *HNF4A* (transcription factor MODY)

Transcription factors are proteins that bind to DNA and form part of a complex regulatory network controlling gene expression. The majority of patients with MODY have a heterozygous mutation in a transcription factor gene, by far the most common being mutations in the hepatic nuclear factors 1A and 4A (*HNF1A* and *HNF4A*). Diabetes resulting from mutations in other transcription factor encoding genes including *HNF1B*, insulin promoter factor 1 (IPF-1) and *NEUROD1* are discussed elsewhere in this chapter.

Transcription factor mutations alter insulin secretion in the mature  $\beta$ -cell as well as altering  $\beta$ -cell development, proliferation and cell death. Mutations in the hepatic nuclear factors appear to alter levels of proteins critical in metabolism including the GLUT-2 glucose transporter and key enzymes in the mitochondrial metabolism of glucose [23–25]. Reduced  $\beta$ -cell proliferation and preserved or increased apoptosis could explain the progressive deterioration in  $\beta$ -cell function seen in these patients [25–28].

Mutations in *HNF1A* account for up to 70% of cases of MODY with nearly 200 different mutations reported. *HNF4A*, the next most common, accounts for approximately 3% of cases [29].

#### Clinical features

Heterozygous transcription factor mutations cause autosomal dominant diabetes presenting in adolescence or early adulthood resulting from progressive failure of insulin secretion. While diabetes is similar in *HNF1A* and *HNF4A* mutation carriers as a result of a common pattern of  $\beta$ -cell dysfunction, a number of differences in extrapancreatic features occur (Table 15.3).

#### Diabetes

Patients are usually born with normal glucose tolerance and then show progressive  $\beta$ -cell dysfunction until they develop diabetes,

**Table 15.3** Extrapancreatic features assisting in the differential diagnosis of transcription factor maturity-onset diabetes of the young (MODY).

Transcription factor	Extrapancreatic clinical features
<i>HNF1A</i>	Low renal glucose threshold (glycosuria) Raised HDL Raised cardiovascular risk (in excess of type 2 diabetes)
<i>HNF4A</i>	Increased birth weight/macrosomia Low HDL, low lipoprotein A1 and A2, raised LDL
<i>HNF1B</i>	Renal cysts and renal development disorders and multiple others. See Table 15.5
NeuroD1	None described

HDL, high density lipoprotein cholesterol; LDL, low density lipoprotein cholesterol.

usually between 10 and 30 years of age (Figure 15.4). Sixty-three percent of *HNF1A* carriers are diagnosed with diabetes by the age of 25 years and 79% by the age of 35 years; the age of diagnosis is partly related to the location of the underlying mutation within the gene [30–32]. Patients show deteriorating glycemia with age and require pharmacologic treatment. In the oral glucose tolerance test, in contrast to patients with glucokinase mutations, the fasting glucose is often normal initially but there is marked elevation of glycemia at 2 hours and consequently a large 2-hour increment (>5.0 mmol/L) [13]. This occurs because insulin secretion rates in early *HNF1A* MODY remain appropriate, with blood glucose values less than 8.0 mmol/L but are reduced significantly in comparison to non-diabetic non-mutation carriers above this level [33]. Microvascular complications are frequent particularly when hyperglycemia is inadequately treated [34]. Patients tend to be lean and insulin-sensitive. Obesity occurs at similar levels to the normal population.

#### Extrapancreatic clinical features

These are summarized in Table 15.3 and discussed in more detail below.

#### *HNF1A*

Patients with *HNF1A* mutations have elevated levels of high density lipoprotein cholesterol (HDL) which contrasts with the reduced HDL levels seen in T2DM [35]. Despite this they appear to have a greater risk of coronary heart disease than patients with T1DM [34]. Frequency of microvascular complications is similar to that seen in T1DM and T2DM and relates to degree of glycemic control [34]. Patients have a reduced renal threshold for glucose. Mutation carriers without diabetes may develop glycosuria after a glucose challenge even if glycemia remains within normal limits [36].

#### *HNF4A*

*HNF4A* mutations are associated with an 800 g increase in birth weight compared with non-mutation carrying siblings [37]. This

means the offspring of *HNF4A* mutation carrying fathers, as well as the offspring of *HNF4A* mothers, are at risk of marked macrosomia. There is also an increased risk of hypoglycemia in affected neonates. These features appear to relate to increased insulin secretion *in utero* and in early infancy which evolves into reduced insulin secretion and diabetes in later life [37]. *HNF4A* mutation carriers have reduced levels of HDL (and lipoprotein A1 and A2) and frequently have raised LDL, while triglyceride levels are similar to population norms [38].

#### Differentiating from type 1 diabetes

These patients are usually diagnosed as having T1DM as they have symptomatic diabetes occurring in adolescence or young adulthood. We recommend genetic testing for *HNF1A* mutations in any young adult with apparent T1DM, a parent with diabetes, and who is antibody-negative at diagnosis. Evidence of non-insulin dependence increases the likelihood of a positive result; this would include no ketosis in the absence of insulin treatment, good glycemic control on low doses of insulin, or detectable C peptide with plasma glucose >8 mmol/L 3–5 years after diagnosis (outside the honeymoon period) [39]. While glutamine acid decarboxylase (GAD) antibodies are usually negative, positive GAD antibodies may be expected in up to 1–2% of the non-diabetic normal population, and therefore positive antibodies (particularly at low titer) may not exclude monogenic diabetes; testing should be considered where clinical suspicion is high [40,41]. *HNF4A* testing should be performed in any patient with a high suspicion of having *HNF1A* who tests negative for *HNF1A* mutations, particularly where there is evidence of increased birth weight and/or neonatal hypoglycemia.

#### Differentiating from type 2 diabetes

*HNF1A* should be suspected and mutation screening performed in patients otherwise suspected to be have T2DM where the following features are present ([39] and [www.diabetesgenes.org](http://www.diabetesgenes.org)):

- 1 Young-onset diabetes – typically before 25 years old in at least one family member;
- 2 Family history of diabetes – at least two generations and ideally two individuals diagnosed in their twenties or thirties), particularly where affected individuals are non-obese;
- 3 Absence of obesity, acanthosis nigricans or other evidence of insulin resistance.

In addition, a large increment in the glucose tolerance test (>5 mmol/L), presence of glycosuria with blood glucose less than 10 mmol/L, marked sensitivity to sulfonylureas and a lipid profile showing normal or raised HDL and normal or low triglycerides (atypical for T2DM) would all be supportive of a diagnosis of *HNF1A* instead of T2DM [35]. *HNF4A* should be suspected and tested in those patients who are suspected to have *HNF1A* mutations but test negative on *HNF1A* screening. These patients have a normal renal glucose threshold and frequently have a personal and/or family history of high birth weights and/or neonatal hypoglycemia.

## Management

Patients with both *HNF1A* and *HNF4A* mutations are sensitive to sulfonylurea therapy which we recommend as first line treatment [38,42]. Glycemic control with sulfonylureas is often better than with insulin and the fasting glucose lowering effect is 4 times greater than that seen in T2DM [42,43]. Transfer to sulfonylurea treatment is successful in the majority of patients although insulin therapy may be required as diabetes progresses [44]. Even very low sulfonylurea doses may cause hypoglycemia. The starting dose should therefore be low – we use a starting dose of 40 mg/day gliclazide or 2.5 mg/day glibenclamide in adults. If there is hypoglycemia with low doses of standard agents, a short-acting agent such as nateglinide may be appropriate [45]. Because of the apparent increased risk of cardiovascular disease in *HNF1A*, statin therapy should be considered and we suggest it for all patients aged over 40 years.

## Management in pregnancy

Evidence to support management strategies for *HNF1A* and *HNF4A* in pregnancy is very limited. Our current practice is to continue sulfonylureas if glycemic control is good before pregnancy but otherwise institute treatment with insulin. Consideration should be given to switching to glibenclamide in the prepregnancy period as this sulfonylurea has the most evidence for safety in pregnancy [46,47]. If a fetus carries *HNF4A*, the risk of macrosomia and neonatal hypoglycemia is high whether the mutation comes from the mother or father [37]. If either parent is known to carry a *HNF4A* mutation, we recommend:

- 1 Very tight glucose control in mothers with diabetes to attempt to minimize macrosomia;
- 2 Serial antenatal ultrasound scans to look for macrosomia with early delivery if this is marked; and
- 3 Early measurement of neonatal glucose and consideration of diazoxide treatment if hypoglycemia persists.

## Other transcription factor MODY

Other transcription factor mutations causing autosomal dominant  $\beta$ -cell diabetes have been identified in the genes *IPF1*, *NEUROD1*, *KLF11* and *PAX 4* but all are very rare [48–53].

## Neonatal diabetes and diabetes diagnosed within 6 months of life

Children diagnosed with diabetes within the first 6 months of life (referred to as neonatal diabetes) are likely to have monogenic diabetes and not T1DM [54–57]. These patients commonly present with ketoacidosis and absent C-peptide. Neonatal diabetes is rare, affecting 1 in 100 000–200 000 live births [58]. Approximately half of cases remit spontaneously and are therefore termed transient neonatal diabetes mellitus (TNDM) as opposed to permanent neonatal diabetes mellitus (PNDM) where diabetes persists. TNDM often recurs in later life [59]. Neonatal diabetes results from mutations of key genes involved in  $\beta$ -cell development or function. Table 15.4 summarizes the known genetic causes of neonatal diabetes.

**Table 15.4** Causes of neonatal diabetes.

Pancreatic pathophysiology	Protein, chromosome or gene affected	Prevalence	Inheritance	Features in addition to neonatal diabetes and low birth weight
Reduced $\beta$ -cell function	$K_{ATP}$ channel ( <i>KCNJ11</i> and <i>ABCC8</i> )	50% of permanent neonatal diabetes, 25% of transient neonatal diabetes	85% spontaneous. Remainder autosomal dominant or recessive	Developmental delay and epilepsy. Sulfonylurea responsive
	Chromosome 6q24	70% of transient neonatal diabetes	Variable	Macroglossia and umbilical hernia
	Glucokinase (homozygous for mutation)	Rare	Autosomal recessive	Both parents have heterozygous glucokinase associated hyperglycemia
	<i>SLC2A2</i>	Rare	Autosomal dominant	Hypergalactosemia, hepatic failure
Reduced pancreatic mass	<i>GLIS3</i>	Rare	Autosomal recessive	Congenital hypothyroidism, glaucoma, liver fibrosis and cystic kidney disease
	<i>PTF1A</i>	Rare	Autosomal recessive	Pancreatic and cerebellar agenesis
	<i>PDX1</i>	Rare	Autosomal recessive	Pancreatic agenesis
Increased $\beta$ -cell destruction	<i>HNF1B</i>	Rare	Autosomal dominant	Exocrine pancreas insufficiency and renal cysts
	<i>EIF2AK3</i>	Rare	Autosomal recessive	Spondyloepiphyseal dysplasia, renal failure, recurrent hepatitis and mental retardation
	<i>FOXP3</i>	Rare	X-linked	Immune dysregulation, intractable diarrhoea, eczematous skin rash and elevated IgE
	<i>INS</i>	12% of permanent neonatal diabetes	Autosomal dominant	None

### Permanent neonatal diabetes

Approximately half of PNDM is caused by mutations in the genes *KCNJ11* and *ABCC8* which encode the Kir6.2 and SUR1 subunits, respectively, of the  $\beta$ -cell ATP-sensitive potassium channel ( $K_{ATP}$  channel) [60–63]. This channel is constitutively open and regulates insulin secretion by closing in response to the raised intracellular ATP levels that occur as a consequence of hyperglycemia. Channel closure triggers depolarization of the  $\beta$ -cell membrane which leads to insulin secretion. Activating mutations in *KCNJ11* and *ABCC8* prevent closure of the potassium channel in response to increased ATP so the  $\beta$ -cell remains hyperpolarized and unable to secrete insulin [64]. Sulfonylureas close the  $\beta$ -cell  $K_{ATP}$  channel by an ATP independent route and they have been used successfully in the management of the majority of patients with neonatal diabetes resulting from *KCNJ11* and *ABCC8* mutations [65]. The  $K_{ATP}$  channel is also present in the brain, nerves and muscles. Reflecting this distribution of channels, 20% of patients with *KCNJ11* mutations (and occasional patients with *ABCC8* mutations) have associated neurologic features [57,60,61,64].

Heterozygous mutations in the insulin gene (*INS*) have been identified in 12% of cases of isolated PNDM and insulin treatment is required [66,67]. A number of other genetic causes have been found which all appear to be relatively rare [58] as outlined in Table 15.4.

The majority (85%) of PNDM resulting from  $K_{ATP}$  channel mutations arise spontaneously from *de novo* heterozygous mutations, with the remainder being familial and inherited mainly in an autosomal dominant pattern. About 40% of neonatal diabetes resulting from *ABCC8* mutations, however, are inherited in an autosomal recessive fashion [63].

#### Clinical features

Diabetes caused by *KCNJ11* mutations typically present in the first 26 weeks of life (median 4–6 weeks) with marked hyperglycemia often accompanied by ketosis. C-peptide is usually undetectable and islet cell antibodies negative [60]. As with all neonatal diabetes subtypes, infants are often small for gestational age as a result of reduced fetal insulin secretion with consequent decreased insulin mediated growth. About 20% of patients with PNDM and *KCNJ11* mutations have neurologic features, the most common being developmental delay, sometimes with muscle weakness and/or epilepsy. The most severe form where neonatal diabetes is accompanied by developmental delay and epilepsy has been named developmental delay, epilepsy and neonatal diabetes (DEND). “Intermediate DEND” refers to neonatal diabetes with less severe developmental delay and no epilepsy. The severity of the clinical condition relates closely to the underlying mutation and its effect on  $K_{ATP}$  channel ATP sensitivity [64,68].

Neonatal diabetes caused by *ABCC8* mutation has a similar phenotype but leads to transient neonatal diabetes more commonly than PNDM and has associated neurologic features only rarely [61–63]. Patients with neonatal diabetes and *INS* mutations present at a median age of 9 weeks and are also often small for gestational age but do not have extrapancreatic features [66].

#### Management

Although insulin therapy is commonly used in the initial period after diagnosis, the majority of patients with *KCNJ11* and *ABCC8* mutations can successfully transfer from insulin to sulfonylurea therapy, usually with significant improvements in glycemic control [62,65]. Ninety percent of those with *KCNJ11* mutations are able to discontinue insulin, while HbA<sub>1c</sub> appears to improve in all patients with a mean drop from 65 to 46 mmol/mol (8.1 to 6.4%) after 12 weeks [65]. Glibenclamide was initially selected as it is non-selective and widely available; it has been used in the majority of cases and may be more effective than other sulfonylurea agents [69]. The doses needed are often higher than those needed for the treatment of T2DM: a median dose of 0.45 mg/kg/day is required with doses up to 1.5 mg/kg/day needed in some cases [65,70]. Diarrhoea is a possible side effect but this usually only lasts 1–3 days [71]. Sulfonylurea therapy may result in some improvement in neurologic features even where they are commenced in adulthood [69,72,73]. Further information on transferring patients from insulin to sulfonylureas can be found at [www.diabetesgenes.org](http://www.diabetesgenes.org).

Neonatal diabetes resulting from *INS* mutations requires insulin treatment [66]. Affected individuals with a heterozygous *KCNJ11* mutation contemplating parenthood should be counseled that they have a 50% chance of passing on the mutation to their offspring. Where unaffected parents whose child is affected by a heterozygous mutation are planning further pregnancies, the risk of further affected children is low because of the possibility of a germline mutation is approximately 5–10% [74]. Where parents have a child with neonatal diabetes caused by a recessive *ABCC8* mutation, there is a 25% chance of each further offspring being affected but the risk is low for subsequent generations.

### Transient neonatal diabetes

The genetic etiology of more than 90% of transient neonatal diabetes has been established. The majority (70%) of cases result from abnormalities the q24 region of chromosome 6 (6q24) affecting imprinted genes [58,75]. Genetic imprinting occurs when only the maternal or paternally inherited allele of a gene is expressed. In TNDM paternal uniparental disomy, paternal duplication of 6q24 or abnormal methylation of the maternal copy of the chromosome causes overexpression of the paternal copies of the genes *PLAGL1* (also known as *ZAC*) and *HYMAI* [75,76]. Paternal duplication of 6q24 can be inherited, therefore this abnormality causes the majority of inherited TNDM cases. Uniparental disomy causes sporadic TNDM; cases resulting from abnormal methylation of the maternal copy of chromosome 6 may be sporadic or inherited [75,76]. The majority (90%) of TNDM not associated with 6q24 abnormalities are caused by mutations in *KCNJ11* and *ABCC8* [57,59,62,77–81].

#### Clinical features

6q24 diabetes usually presents in the first week of life often with severe hyperglycemia and dehydration but usually without ketosis

[75]. Islet cell antibodies are usually negative and C-peptide is low or negligible [75]. Low birth weight is common (mean birth weight 2.1 kg), and there may be associated macroglossia and/or umbilical hernia. Insulin treatment is required for a median of 12 weeks before the patient goes into remission. Diabetes recurs later in life in 50–60% of patients as a result of  $\beta$ -cell dysfunction. The average age of recurrence is 14 years. In some cases hyperglycemia may be intermittent and seen only at times of stress [75,82]. Where TNDM is caused by *KCNJ11* and *ABCC8* mutations, diabetes tends to present later (median 4 weeks), takes longer to remit and is associated with less intrauterine growth restriction (median birth weight 2.6 kg) [59].

### Management

Insulin is required in the neonatal period whereas treatment requirements following relapse vary from diet to oral hypoglycemics or insulin [82]. In TNDM cases resulting from *KCNJ11* and *ABCC8* mutations, diabetes may be successfully managed with sulfonylureas [59,62].

Genetic counseling depends on the underlying genetic etiology. Cases caused by uniparental disomy are sporadic and therefore have low risk of occurrence in either siblings or offspring of the affected child. Methylation defects often result from homozygous mutations in the transcription factor gene *ZFP57* and therefore may be inherited in an autosomal recessive manner [76]. Offspring of males with 6q24 duplication have a 50% chance of developing TNDM whereas if the abnormality is inherited from the mother they will not be affected but the TNDM may occur in the following generation [82].

### Genetic testing in neonatal diabetes

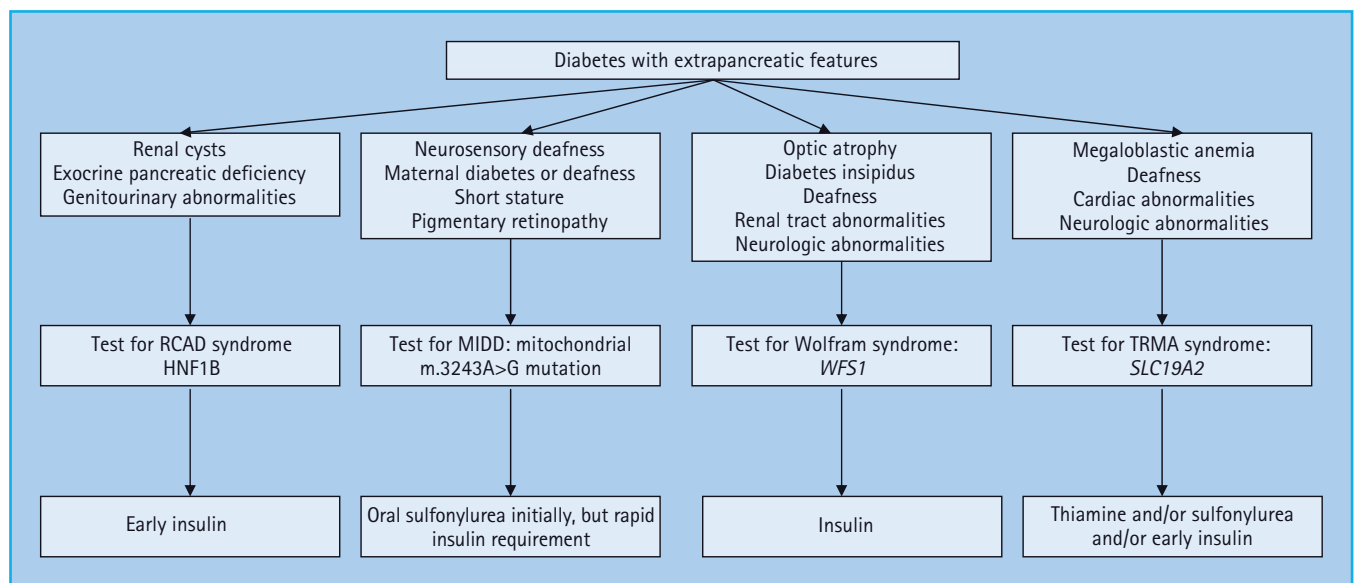

At the time of diagnosis of neonatal diabetes it is not known whether the diabetes will be transient or permanent. We recommend testing for 6q24 abnormalities, *KCNJ11*, *ABCC8* and *INS* mutations at diagnosis in all diabetes diagnosed before 6 months. Identifying mutations in these genes is important as it will influence treatment. An early diagnosis and very low birth weight make 6q24 most likely. A genetic cause (*KCNJ11* or *INS*) can be established in approximately 7% of diabetes diagnosed between 6 months and 1 year of age so consideration should be given to testing this age group, especially where autoantibody tests are negative [56].

### Diabetes with extrapancreatic features

A number of monogenic causes of diabetes are associated with distinct features occurring outside the pancreas. In many cases extrapancreatic disease may be the presenting feature, for example in cystic fibrosis and hemochromatosis (see Chapter 18). Clinical subtypes and management of monogenic  $\beta$ -cell diabetes that have extrapancreatic features are summarized in Figure 15.6.

#### Maternally inherited diabetes and deafness

Maternally inherited diabetes and deafness (MIDD) results from a mutation in mitochondrial DNA and causes maternally inherited diabetes with sensorineural deafness that may be accompanied by a wide range of other features. It affects up to 1% of patients with diabetes but is frequently undiagnosed [83].

**Figure 15.6** Clinical subtypes and management of monogenic  $\beta$ -cell diabetes that has extrapancreatic features. *HNF1B*, hepatocyte nuclear factor 1B; MIDD, maternally inherited diabetes and deafness; RCAD, renal cysts and diabetes; *SLC19A2*, solute carrier family 19, member 2 gene; TRMA, thiamine responsive megaloblastic anemia; *WFS1*, Wolfram syndrome 1 gene.

**Figure 15.7** Phenotypes of: (a) renal cysts and diabetes syndrome due to *HNF1B* mutation or deletion; (b) maternally inherited diabetes and deafness caused by mitochondrial m.3243A>G mutation. Adapted from Murphy *et al.* [181].

**Pathogenesis**

The vast majority of mitochondrial diabetes results from the m.3243A>G point mutation in mitochondrial DNA. Other mitochondrial DNA mutations have been implicated but are rare [84].

The m.3243A>G mutation affects the mitochondrial respiratory chain and therefore may result in cellular energy deficiency. Organs that are most affected are those with high metabolic activity which include the endocrine pancreas, cochlea and in some cases the retina, muscle, kidney and brain. Mitochondrial dysfunction in pancreatic islets results in abnormal  $\beta$ -cell function, loss of  $\beta$ -cell mass and insulin deficiency while insulin sensitivity is usually normal although can be reduced (reviewed in [83]). As mitochondria are only inherited from the mother, the maternal line in a family is affected, and children of a male patient are not at risk. Although all children of an affected female are likely to carry the mutation, phenotype can vary widely in the same family because of heteroplasmy. Offspring inherit a mix of mutant and

wild-type mitochondrial DNA – the proportion of mitochondria carrying the mutation will vary in offspring of an affected mother as will subsequent segregation of mitochondria to different tissues.

**Clinical features**

The characteristic clinical features of MIDD are summarized in Figure 15.7. The majority of mutation carriers develop diabetes (over 85%) and sensorineural hearing loss (over 75%) [85–88]. There is usually a family history of diabetes and/or hearing loss in maternal relatives but clinical features can vary greatly even within the same pedigree [89]. Diabetes is progressive and usually presents with insidious onset similar to T2DM but may present acutely, with ketoacidosis occurring in approximately 8% of cases [85,86,90]. Mean age at diagnosis of diabetes is 37 years but age of diagnosis can range from early adolescence to old age [86,90,91].

Hearing loss typically develops in early adulthood but again may occur in children as well as the elderly; it is more common and often more severe in men [86,88]. Patients with the m.3243A>G mutation have a high prevalence of renal failure with focal segmental glomerular sclerosis (FSGS) found more frequently than diabetic nephropathy on renal biopsy [86,92]. Diabetic retinopathy may be less prevalent than in other forms of diabetes; macular retinal dystrophy is frequent but rarely causes visual symptoms [83,86,92]. Cardiac abnormalities include left ventricular hypertrophy, heart failure (which can progress rapidly), cardiac autonomic neuropathy and cardiac arrhythmias [93–97]. Other possible clinical manifestations of the m.3243A>G mutation include short stature, MELAS (mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes), psychiatric disorders, proximal myopathy and gastrointestinal symptoms [83].

### Differentiating from type 1 and 2 diabetes

Diabetes caused by the m.3243A>G mutation may present like T1DM or T2DM [85,86,90]. GAD antibodies are usually but not always negative [98–100]. The presence of deafness in the patient or clustering of diabetes and/or deafness in maternal relatives should prompt investigation for the m.3243A>G mutation. Short stature, early-onset cardiomyopathy, myopathy, early-onset stroke or macular retinal dystrophy on retinal screening may all raise suspicion of MIDD [83].

If there is clinical suspicion of MIDD, the diagnosis can be confirmed by testing for the m.3243A>G mutation, usually in blood leukocytes. In rare cases the result may be negative on blood-derived DNA testing despite the presence of the mutation in other tissues as a result of heteroplasmy. Testing of other samples (e.g. urine or mouthwash) may be more appropriate than blood [83].

### Management

Diabetes usually requires early insulin treatment (mean 2 years post diagnosis) [85,86,90,100]. There is a theoretical basis for avoiding metformin in view of the risk of lactic acidosis [83,85]. There may be some benefit in co-enzyme Q10 supplementation although randomized double-blind control trials have yet to be performed [101,102]. Monitoring for cardiac manifestations should be considered from a young age, particularly if there are clinical features or family history of early cardiomyopathy. Aggressive blood pressure management and early angiotensin-converting enzyme (ACE) inhibitor treatment may be appropriate in view of the high risk of renal complications. Renal biopsy to exclude FSGS may be necessary in those who develop renal failure [83]. Management of hearing loss involves avoidance of exacerbating factors, prompt treatment of ear infections, hearing aids if necessary and consideration of cochlear implants where there is profound hearing loss [83,103,104].

Maternal relatives of affected patients and children of female patients should be assumed to carry the m.3243A>G mutation. Therefore, periodic screening for the features and complications

of MIDD may be advisable. In contrast, paternal relatives and children of an affected male are not at risk of carrying the mutation.

### Renal cysts and diabetes (*HNF1B* MODY)

*HNF1B* is a transcription factor with a role in regulating gene expression in a number of tissues including the pancreas, kidneys, liver genital tract and gut [105]. Heterozygous deletions or mutations in *HNF1B* can cause developmental abnormalities in all these organs although the most common phenotypes are renal abnormalities and diabetes. *HNF1B* abnormalities may show autosomal dominant inheritance, although 32–58% of cases arise spontaneously and there is a wide variation in phenotype even with identical mutations [106–110].

### Clinical features

The clinical features are summarized in Table 15.5 and Figure 15.7. Developmental renal disease is the most consistent feature with renal cysts being the most common manifestation [106]. Other possible renal abnormalities include glomerulocystic kidney disease, cystic renal dysplasia and morphologic abnormalities such as horseshoe kidney. Renal function can range from

**Table 15.5** Features of patients with *HNF1B* mutations causing RCAD (renal cysts and diabetes) in a UK cohort. Adapted from Bingham & Hattersley [108].

Clinical features	Subjects with <i>HNF1B</i> mutations and details (%)
<b>Renal phenotype</b>	
Renal cysts	66%
Renal impairment	86% (15% dialysis/transplantation)
Morphologic renal abnormalities	Horseshoe kidney Single kidney
Renal histology (includes)	Glomerulocystic kidney disease Cystic renal dysplasia Oligomeganephronia
Diabetes	58% Mean age of diagnosis 26 years, range 10–61 years Insulin treatment common
<b>Other features</b>	
Hypomagnesemia	40%
Short stature	20% <2 SD below mean height
Hyperuricemia and gout	20% (clinical gout)
Uterine abnormalities	17%
Hypospadias	17%
Joint laxity	Rare
Hearing loss	Rare
Prognathism	Rare
Pyloric stenosis	Rare
Learning difficulties	Rare
Chromophobe renal cell carcinoma	Rare

normal to dialysis dependent [111,112]. Half of *HNF1B* mutations carriers have early-onset diabetes caused by both insulin deficiency as a result of reduced  $\beta$ -cell number and increased hepatic insulin resistance. The sensitivity to sulfonylureas found with *HNF1A* and *HNF4A* mutations is absent [113]. Diabetes is usually associated with pancreatic hypoplasia and may be associated with exocrine dysfunction although this is rarely symptomatic [114–116]. Low birth weight is common and transient neonatal diabetes may occur [115]. Other clinical manifestations include abnormal liver function tests, genital tract malformations, hypomagnesemia, hyperuricemia and familial hyperuricemic nephropathy [114,117]. An association with chromophobe renal cell carcinoma has been reported reflecting a probable role for *HNF1B* as a tumour suppressor gene [118,119].

#### Differentiating from type 1 and 2 diabetes

Approximately 50% of *HNF1B* mutations and deletions are spontaneous and so patients may not have a family history. Testing for *HNF1B* abnormalities should be considered where there is unexplained cystic renal disease, glomerulocystic disease or other renal developmental abnormalities with or without a past medical or family history of diabetes. It should also be considered in individuals with genital tract abnormalities associated with renal abnormalities. Both simple renal cysts and diabetes are common in the general population and should not lead to testing for *HNF1B* abnormalities. Testing for *HNF1B* should always include dosage analysis to detect gene deletions as these are common and will be missed if the laboratory performs sequencing only [120].

#### Management

Early insulin therapy is usually required for management of diabetes. The sulfonylurea sensitivity seen in other transcription factor diabetes is not seen in *HNF1B*. Renal management is similar to management of other chronic progressive renal diseases. Our recommendation is to repeat renal ultrasound imaging every 2 years in view of the possible increased risk of chromophobe renal carcinoma and to screen for diabetes yearly in non-diabetic mutation carriers.

#### Other monogenic $\beta$ -cell diabetes with extrapancreatic features

##### Wolfram syndrome

Wolfram syndrome (also known as DIDMOAD [diabetes insipidus, diabetes mellitus, optic atrophy and deafness]) is a rare recessive neurodegenerative disorder characterized by diabetes insipidus, diabetes mellitus, optic atrophy deafness and a variety of central nervous system abnormalities. Consideration should be given to this diagnosis where there is a combination of diabetes and optic atrophy [121,122].

##### Thiamine responsive megaloblastic anemia

Thiamine responsive megaloblastic anemia is a rare autosomal recessive condition characterized by megaloblastic anemia (which may be mild), non-autoimmune diabetes mellitus and sen-

sorineural hearing loss. Treatment with high dose thiamine can improve some features including diabetes [123].

##### Wolcott–Rallison syndrome

Wolcott–Rallison syndrome is a rare autosomal recessive condition characterized by early-onset diabetes, spondyloepiphyseal dysplasia, acute hepatic failure, renal impairment and developmental delay. Diabetes usually presents in infancy and requires insulin treatment [124].

##### Monogenic diabetes with pancreatic exocrine dysfunction

Mutations in the carboxyl ester lipase (*CEL*) gene have recently been identified as a rare cause of monogenic diabetes with pancreatic exocrine dysfunction [125].

---

### Insulin resistance

Monogenic causes of diabetes resulting from insulin resistance include the inherited lipodystrophies, mutations affecting the insulin receptor or post receptor signaling and other monogenic syndromes associated with insulin resistance where abnormalities of insulin action are not the primary disorder. There can be considerable clinical overlap in clinical presentation between these conditions [126]. The presence of acanthosis (Figure 15.8) in a thin patient with diabetes should prompt consideration of underlying monogenic causes of insulin resistance.

---

### Insulin receptor gene mutations

Insulin exerts its effects through binding to a transmembrane receptor, consisting of two alfa and two beta subunits, present on the surface of target cells. Binding of insulin to the alfa subunit activates beta subunit tyrosine kinase activity triggering protein

**Figure 15.8** Acanthosis nigricans affecting the neck of a 26-year-old woman with severe insulin resistance. Reproduced from Moller & O’Rahilly [182] with permission.

activation cascades which lead to insulin's intracellular effects [127,128]. Mutations in the insulin receptor gene lead to inherited insulin resistance syndromes. The severity of the resulting clinical phenotype depends on the extent of impairment of signal transduction resulting from the underlying mutation [129].

### Clinical features

Individuals with severe insulin resistance resulting from insulin receptor mutations may have a number of common features including hyperinsulinemia, acanthosis nigricans, ovarian hyperandrogenism and disturbances of glucose homeostasis which can include hypoglycemia as well as impaired glucose tolerance and diabetes [129]. Three main syndromes resulting from insulin receptor mutations resulting in severe insulin resistance have been described: Type A insulin resistance syndrome, Rabson–Mendenhall syndrome and leprechaunism (Donohue syndrome). There may be considerable clinical overlap and these syndromes may simply represent varying clinical features from a continuum of severity of receptor dysfunction rather than completely distinct syndromes [129]. Many patients with insulin receptor defects and severe insulin resistance (adult males in particular) may not fit into the syndromic descriptions below.

Features of the Type A insulin resistance syndrome include severe insulin resistance, acanthosis nigricans, polycystic ovarian disease, hirsutism and signs of virilization occurring in young females (often termed HAIR-AN syndrome). The patients with an underlying insulin receptor mutation are usually slim [130,131]. The most severe syndrome seen with insulin receptor mutations is leprechaunism (Donohue syndrome), a rare autosomal recessive disorder in which patients have low birth weight, growth restriction, disordered glucose homeostasis, characteristic dysmorphic features and usually do not survive infancy [131,132].

Rabson–Mendenhall syndrome is an autosomal recessive disorder that is between leprechaunism and Type A insulin resistance in terms of the severity of insulin resistance. Patients present in childhood with acanthosis nigricans, extreme growth retardation, dysplastic dentition, coarse facial features, lack of subcutaneous fat and pineal hyperplasia [131,133,135]. Reported renal abnormalities include medullary sponge kidney and nephrocalcinosis [133,135]. Patients may have paradoxical fasting hypoglycemia at diagnosis but develop frank diabetes (occasionally with ketoacidosis) in later years [134]. Life expectancy is markedly reduced, early death often occurring from complications of diabetes or intractable ketoacidosis.

### Differentiating from type 1 and 2 diabetes

The presence of features of insulin resistance in a thin but not an obese individual is suggestive of an underlying insulin receptor gene mutation. Serum adiponectin levels are typically high in patients with insulin receptor mutations whereas they are low in other forms of insulin resistance. It has been suggested that adiponectin levels could be used as a screening test with sequencing of the insulin receptor gene reserved for those case where adiponectin levels are raised [126,136,137].

Unlike T2DM and the lipodystrophies, triglyceride levels in patients with insulin resistance caused by insulin receptor mutations are typically normal [131].

### Management

While insulin sensitizers such as metformin and the thiazolidinediones may have a role in management their effect is often limited and insulin therapy is required as  $\beta$ -cell function declines [131]. Glycemic control is often poor despite very high doses of insulin (doses in excess of 500 units/kg/day have been reported). U500 insulin has a role in reducing the insulin volumes required [131,138]. Insulin-like growth factor I (IGF-I) is capable of stimulating glucose uptake and glycogen storage *in vivo* and has therefore been used in treatment of diabetes caused by insulin receptor mutations. Side effects were frequent in early studies but tolerability may be increased by combining IGF-I with its principal binding protein IGFBP-3 [139].

## Inherited lipodystrophies

Lipodystrophies are clinically heterogeneous disorders that are characterized by the selective loss of adipose tissue. They are associated with insulin resistance and other features such as diabetes mellitus, acanthosis, dyslipidemia, hepatic steatosis and (in female patients) hyperandrogenism, oligomenorrhoea and polycystic ovaries [140]. Lipodystrophies may be inherited or acquired. The inherited subtypes (all of which are rare) are described below.

### Familial partial lipodystrophy

Familial partial lipodystrophies are autosomal dominant disorders associated with the loss of peripheral subcutaneous fat. The two main subtypes result from mutations in *LMNA* and *PPARG*.

Familial partial lipodystrophy associated with *LMNA* mutations (also known as Dunnigan lipodystrophy) results in gradual peripheral subcutaneous fat loss from puberty. This, and the associated muscle hypertrophy, gives a muscular appearance of the arms and legs (Figure 15.9). There may be fat loss from the anterior abdomen and chest and excess fat deposition in the face, neck and intrabdominally [141,142]. Diabetes is common, particularly in female patients [143]. Hypertriglyceridemia may be marked and associated with pancreatitis. Acanthosis and polycystic ovarian syndrome are relatively uncommon. Although hepatic steatosis may develop cirrhosis appears rare [144,145]. Cardiovascular mortality is high.

Familial partial lipodystrophy associated with *PPARG* mutations appears to be phenotypically similar to that caused by *LMNA* mutations although hypertension is more common [146–155].

Diagnosis may be obvious in women but more difficult in males where a muscular appearance of limbs is more common. Early-onset diabetes in a non-obese patient with hypertriglyceridemia should raise suspicion of lipodystrophy particularly if there is marked peripheral fat loss [156].

**Figure 15.9** Familial partial lipodystrophy in a 46-year-old woman. There is truncal and limb lipodystrophy, preserved facial and neck adipose tissue, muscle hypertrophy and acanthosis apparent in the groin regions.

### Congenital generalized lipodystrophy (Berardinelli–Seip syndrome)

This is a rare (estimated prevalence 1 in 10 million) autosomal recessive disorder characterized by a near complete absence of subcutaneous fat from birth, giving a muscular appearance [140]. Because of the absence of functioning adipocytes, lipids are stored in metabolically active tissues. Those affected have features of severe insulin resistance including often widespread acanthosis, hypertriglyceridemia and low HDL cholesterol [157]. Hepatic steatosis occurs early and may lead to cirrhosis; hepatomegaly is

seen frequently [158–160]. Childhood growth is accelerated and bone age advanced. Diabetes commonly develops during adolescence [160]. Other associated features include acromegaloid features, hypertrophic cardiomyopathy, skeletal muscle hypertrophy, bone cysts and intellectual impairment [160]. Serum leptin and adiponectin levels are markedly reduced [161].

Three molecularly distinct forms have been identified: congenital generalized lipodystrophy types 1, 2 and 3 resulting from mutations in 1-acylglycerol 3-phosphate-O-acyltransferase 2 (*AGPAT2*), Berardinelli–Seip congenital lipodystrophy 2 (*BSCL2*) and Caveolin-1 (*CAV1*). *AGPAT2* and *BSCL2* account for the majority of cases and have some difference in phenotype. Some patients with this phenotype do not have mutations in any of these genes and so it is likely there are further genetic etiologies to be discovered [140,162,163].

### Other inherited forms of lipodystrophy

Rare subtypes of lipodystrophy associated with dysmorphic features include mandibuloacral dysplasia (lipodystrophy with characteristic skeletal abnormalities), SHORT syndrome (short stature, hyperextensibility of joints, ocular depression, Reiger anomaly, teething delay) and neonatal progeroid syndrome [156].

### Management of lipodystrophy

Management should address insulin resistance and the main causes of morbidity and mortality in lipodystrophy which include diabetes and its complications, cardiovascular and cerebrovascular disease, recurrent pancreatitis (as a result of severe hypertriglyceridemia), cirrhosis and psychologic distress related to appearance [140].

Lifestyle changes are important and should include an extremely low fat diet (<15% total energy from fat) and increased physical activity [140]. Hypertriglyceridemia that does not respond to lifestyle changes and control of hyperglycemia may require treatment with fibrates and high doses of fish oils. Estrogen replacement including contraceptive pills may exacerbate hypertriglyceridemia and is best avoided.

Glycemic control requires a combination of oral treatments and high dose insulin in the majority of patients. Metformin is commonly used to improve insulin sensitivity although there are no available trial data in inherited lipodystrophies [156]. Response to thiazolidinediones appears to vary with significant improvements in glycemic control and insulin resistance in some but not in all reported cases [155,164–169]. Where insulin is required dose requirements may be very high and U500 insulin appropriate [138,140]. Where proteinuric renal disease develops the threshold for renal biopsy should be low as non-diabetic renal disease (e.g. membranoproliferative glomerulonephritis and focal segmental glomerulosclerosis) appears to be more common than diabetic nephropathy [170].

Levels of the adipocytokine leptin are markedly reduced in severe lipodystrophies. Leptin replacement has been associated with marked improvements in glycemic control and hypertriglyceridemia in a number of cases of both generalized and partial

inherited lipodystrophy [171–177] and may also improve hepatic steatosis [178,179].

### Other monogenic conditions associated with insulin resistance

Other monogenic conditions associated with insulin resistance either have marked obesity (e.g. Alström and Bardet–Biedl syndromes); neurologic disease including myotonic dystrophy and Friedreich ataxia or rapid aging (e.g. Werner syndrome) [180].

### Use of diagnostic and predictive molecular testing in monogenic diabetes

Diagnostic testing for the major causes of monogenic diabetes is now widely available. Specific recommendations for the different forms of monogenic diabetes are discussed in the relevant sections of this chapter. As molecular testing remains relatively expensive and time-consuming it is recommended that testing is restricted to those individuals with a moderate to high possibility of a positive result. The molecular genetic testing performed should be guided by the clinical phenotype and also the relative prevalence of mutations within that population. As many of these conditions are familial, the characteristics of other family members should also be considered. There should be some caution, however, as monogenic diabetes can occur in families that also have T1DM or T2DM. For similar reasons the results of molecular testing should be interpreted in the context of the clinical findings. For example, a patient with glucokinase diabetes could also develop T1DM or T2DM.

Where a family member has a confirmed genetic diagnosis, phenotypically unaffected relatives should be tested to assess whether they will be at risk of developing diabetes in the future. Where the main mutation phenotype is diabetes, regular urine or blood testing may be preferable as there is little clear extra benefit from prospective testing. Where families do request predictive testing, they should receive full counseling on the potential benefits and disadvantages and be allowed to make their own decisions on this.

### Conclusions

Monogenic diabetes results from single gene changes that affect  $\beta$ -cell function or insulin sensitivity. Correct diagnosis can help define prognosis and the best treatment and allow screening of family members. Diagnostic testing is now widely available and should be considered where presentation is atypical for T1DM or T2DM, where there is an autosomal dominant family history, where there are characteristic associated features and in all cases where diabetes has been diagnosed within the first 6 months of life.

### Keypoints

- Many commonly used drugs interfere with glucose homeostasis and can provoke hyperglycemia in subjects without diabetes or worsen glycemic control in patients with diabetes.
- Glucocorticoids act on post insulin-receptor mechanisms to induce dose-dependent insensitivity to insulin in its target tissues.
- Glucocorticoid-induced diabetes often requires treatment with oral hypoglycemic agents or insulin while glucocorticoid treatment continues.
- Oral contraceptive pills rarely cause hyperglycemia, although it can occur with combined pills that contain high-dose estrogen or the progesterone levonorgestrel, and in women with a history of gestational diabetes.
- Estrogen replacement therapy in postmenopausal women does not affect glycemic control.
- Thiazide diuretics impair insulin secretion when given at high dosages. Impairment of insulin secretion is related to potassium depletion.
- Loop diuretics such as furosemide (frusemide) are less likely to cause hyperglycemia.
- Non-selective  $\beta$ -adrenoceptor antagonists inhibit insulin secretion and can impair glucose tolerance. Cardioselective  $\beta_1$ -adrenoceptor blockers have much less pronounced effects.
- Other drugs that can precipitate or aggravate hyperglycemia include:
  - Streptozocin (streptozotocin), pentamidine and ciclosporin (cyclosporine) via  $\beta$ -cell toxicity;
  - Diazoxide via inhibition of insulin secretion;
  - $\beta_2$ -Receptor agonists (salbutamol and ritodrine), which increase hepatic glucose production;
  - Growth hormone in supraphysiologic doses;
  - Protease inhibitors (indinavir, nelfinavir, ritonavir, saquinavir) by inducing insulin resistance; and
  - Antipsychotics via weight gain and insulin resistance.

Many drugs can cause or worsen pre-existing hyperglycemia – a problem recently recognized by the World Health Organization (WHO) and the American Diabetes Association (ADA) with the identification of drug-induced diabetes as a separate etiologic category (see Chapter 2). The diabetogenic properties of drugs are important for two main reasons. First, polypharmacy is an unfortunate but common necessity in managing patients with diabetes; clear understanding of the potential hyperglycemic effects of drugs is therefore helpful in anticipating and avoiding deterioration in glycemic control. Secondly, various drugs can induce diabetes in previously normoglycemic individuals; this state is usually reversible and not insulin-dependent, but can become permanent.

Drugs can raise blood glucose concentrations through two broad mechanisms: by reducing insulin biosynthesis or secretion, or by reducing tissue sensitivity to insulin (Figure 16.1). Some important examples are listed in Table 16.1. Of particular note are the glucocorticoids, which are used in many diseases,

and certain commonly used antihypertensive drugs [1–7]. Hypertension commonly accompanies diabetes, and most patients require more than one antihypertensive agent to meet the increasingly stringent targets for blood pressure control (see the first part of Chapter 40).

This chapter describes the drugs that can induce or aggravate hyperglycemia, together with a strategy for managing patients with drug-induced diabetes.

### Glucocorticoids

Glucocorticoids were named for their hyperglycemic effects [8] and have by far the most powerful adverse effect on glycemic control of all the commonly prescribed drugs. During the 1930s, it became apparent that diabetic symptoms improved following either adrenalectomy [9] or hypophysectomy [10], indicating that glucocorticoids have important influences on glucose homeostasis. This fact was recognized in clinical practice [11–15], soon after the landmark discovery in 1949 by Hench *et al.* [16] that glucocorticoids had potent anti-inflammatory effects. Since then,

**Figure 16.1** Mechanisms of drug-induced hyperglycemia.

therapeutic use of these agents has escalated; recent data from the General Practice Research Database suggest that nearly 1% of the UK population may be using oral glucocorticoids at any time, increasing to 2.5% in subjects aged 70–79 years [17]. Inhaled corticosteroid use is even more widespread, with more than 6% of the UK population currently using an inhaled corticosteroid [18].

Glucocorticoids worsen hyperglycemia in patients with diabetes, but can also cause significant increases in blood glucose (and insulin) concentrations in previously normoglycemic individuals when given in high doses (i.e. equivalent to 30 mg/day or more of prednisolone) [19]. Impaired glucose tolerance or diabetes mellitus have been reported in 14–28% of subjects receiving long-term glucocorticoids [20,21], and subjects who have an intrinsically low insulin response (e.g. in response to glucose loading) are particularly susceptible [22]. These subjects are thought to be at greater risk of developing type 2 diabetes (T2DM) in the future, compared to the general population [23]. Using data from the Health Improvement Network, Gulliford *et al.* [24] found that in a large primary care population, drawn from 114 family practices, orally administered glucocorticoids were associated with up to 2% of incident cases of diabetes mellitus.

Glucocorticoids reduce hepatic and peripheral tissue sensitivity to insulin through post-receptor mechanisms (Fig. 16.1). In adipocytes, dexamethasone inhibits the expression of the insulin-signaling intermediate protein, insulin receptor substrate 1 (IRS-1) [25], and this may contribute to insulin resistance (see Chapter 7). These effects may be partly offset by glucose-independent stimulation of insulin secretion [26].

All glucocorticoids cause dose-dependent insulin resistance at dosages greater than the equivalent of 7.5 mg/day prednisolone [21]. The duration of exposure to glucocorticoids does not appear to be important, and hyperglycemia is generally reversible on withdrawing the drug.

Most problems have been reported with oral glucocorticoids, but those administered topically can also induce severe hyperglycemia, especially if given at high dosage over large areas of damaged skin and under occlusive dressings [27]. This is more likely to occur in children because of their higher ratio of total body surface area to body weight [28]. Although inhaled corticosteroids do not cause significant hyperglycemia, there has been a single case report of deteriorating glycaemic control in a patient with T2DM who was prescribed high-dose fluticasone propionate [29]. The hyperglycemic potency of glucocorticoids does not follow the hierarchy of their anti-inflammatory or immunosuppressive activities. For example, deflazacort, which has similar immunomodulating effects to other glucocorticoids, produces less hyperglycemia than prednisone or dexamethasone [30].

Other commonly encountered adverse effects of glucocorticoids are hypertension and sodium and water retention. Thiazide diuretics should not be used to treat these complications, as their own hyperglycemic action synergizes with that of glucocorticoids [31].

Corticotropin (adrenocorticotrophic hormone [ACTH]) or tetracosactide (tetracosactrin), previously given as an alternative to glucocorticoid therapy (e.g. in exacerbations of multiple sclerosis), is no longer recommended for therapeutic use. It can cause hyperglycemia and hyperinsulinemia in rodents [32,33].

**Table 16.1** Drugs that cause or exacerbate hyperglycemia.

Potentially potent effects	Minor or no effects
Glucocorticoids	Oral contraceptives
Oral contraceptives	Progestogen-only pills
High-dose estrogen	Levonorgestrel in combination pills
Thiazide diuretics (especially high dosages)*	Loop diuretics
Non-selective $\beta$ -adrenoceptor antagonists	Calcium-channel blockers
$\beta_2$ -adrenoceptor agonists	$\alpha_1$ -adrenoceptor antagonists
Salbutamol	Growth hormone (physiologic doses)
Ritodrine	Somatostatin analogs†
Antipsychotics	Androgen deprivation therapy for prostate cancer
HIV protease inhibitors	Selective serotonin reuptake inhibitors
Indinavir, nelfinavir, ritonavir and others	Nicotinic acid
	Lamivudine
	Isoniazid
Others	
Pentamidine	
Gatifloxacin	
Streptozocin (streptozotocin)	
Diazoxide	
Ciclosporin (cyclosporine)	
Tacrolimus	
Temsirolimus	
Interferon- $\alpha$	
L-asparaginase	

HIV, human immunodeficiency virus.  
 \* "High" dosages of thiazides correspond to  $\geq 5$  mg/day bendroflumethiazide.  
 † Somatostatin analogs may induce hyperglycemia in type 2 but not type 1 diabetes.

The metabolic adverse effects of glucocorticoids have stimulated the development of selective glucocorticoid receptor ligands with similar anti-inflammatory efficacy to glucocorticoids currently in use but with fewer adverse effects. A number of these compounds have been developed and shown in animal studies not to induce hyperglycemia [34]. These agents are likely to be tested clinically in humans in the near future.

### Oral contraceptive pills and estrogen replacement therapy

Estrogens and some progestogens used in contraceptive agents are potentially diabetogenic. This is not surprising, as endogenous sex steroids have been shown to affect glucose homeostasis in women without diabetes: insulin sensitivity rises during the follicular phase of the menstrual cycle and falls during the luteal

phase [35]. As with glucocorticoids, post-receptor insulin resistance appears to be responsible; *in vivo* studies have demonstrated a decrease in insulin sensitivity in women without diabetes taking certain contraceptive pills [36,37], and a number of implantable hormonal contraceptives have been linked to alterations in carbohydrate metabolism, including impaired glucose tolerance and increased insulin resistance [38,39]. The tendency to cause hyperglycemia was particularly marked with the early pills, which had a relatively high estrogen content; the overall risk of developing impaired glucose tolerance was 35% [40], and even greater in women with a history of diabetes during pregnancy [41,42]. Impaired glucose tolerance during pregnancy remains a potent risk factor, even with the newer oral contraceptives; these women are three times more likely to develop diabetes with a progestogen-only pill than with a low-dose combined pill [43].

Most currently available combined oral contraceptives contain low estrogen dosage (25–50  $\mu\text{g/day}$ ). In 1992, Rimm *et al.* [44] reported the metabolic effects of oral contraceptives in a large prospective survey of healthy volunteers, and found transient rises in serum insulin concentrations and impairment of glucose tolerance with all formulations. Consistent with this, metabolic studies have demonstrated fasting hyperinsulinemia and reduced insulin sensitivity [36,37,45]. Reassuringly, however, recent studies, including a massive prospective follow-up of almost 99 000 non-diabetic participants [46], found no appreciable increase in the incidence of diabetes among users of current oral contraceptives [46,47]. The authors of a recent Cochrane review [48] concluded that hormonal contraceptives have little clinical impact on carbohydrate metabolism. Low-dose combined oral contraceptives are safe in younger women with uncomplicated well-controlled diabetes [49].

In contrast to the older high-estrogen pills, the effect on glucose homeostasis of low-estrogen combination pills is determined mainly by the type and dosage of progestogen, with monophasic levonorgestrel combinations having the most deleterious effect. Oral progestogen-only formulations cause only minor hyperglycemia in healthy subjects, although diabetes may develop in women who had hyperglycemia during previous pregnancies [43]. The long-acting progestogens, such as depot medroxyprogesterone (Depo-Provera) and sustained-release low-dose levonorgestrel, cause a statistically but not clinically significant deterioration in glucose tolerance in healthy women [39,50]. There is little evidence, however, to suggest that this translates into clinical harm, and the WHO medical eligibility criteria for contraceptive use do not restrict the use of progestogen-only contraceptives in women with diabetes unless diabetes has been present for over 20 years or complications are present [51]. A primary care study in the UK found that progestogen-only methods of contraception, including the injectable contraceptive Depo-Provera and progestogen-only pills, are significantly more likely to be prescribed for women with diabetes than for those without diabetes [52]. There is no convincing evidence that the Mirena coil is associated with any change in glucose metabolism.

Hyperglycemia induced by hormonal contraceptives is usually reversible on withdrawal of the contraceptive pill. The current low-dosage contraceptive pills do not apparently predispose to the subsequent development of T2DM, although there is some evidence that this is a hazard in patients previously exposed to high-dosage pills [53].

#### Estrogen replacement therapy in women with diabetes

A number of observational studies of hormone replacement therapy (HRT) use in T2DM have demonstrated an association between HRT use and reduced cardiovascular risk [54,55]. This is in contrast to the general population, where HRT is not associated with a reduction in the incidence of cardiovascular disease in postmenopausal women [56]. HRT preparations differ with regard to type and dose of estrogen, type of combination progestogen and route of administration, and it is likely that these differences may be important in determining the overall balance of cardiovascular risk and benefit in specific patient subgroups such as those with diabetes. One placebo-controlled randomized study in 25 postmenopausal women with T2DM found that conjugated equine estrogen therapy (0.625 mg/day) had beneficial effects on blood glucose and lipid profiles [57]. A further study in 28 postmenopausal women with T2DM using continuous oral 17 $\beta$  estradiol (1 mg) and norethisterone (0.5 mg) had similar findings [58]. In the Women's Health Initiative study, involving over 160 000 postmenopausal women aged 50–79 years, those randomized to HRT had a lower incidence of self-reported diabetes than those randomized to placebo. This was true both for women taking conjugated equine estrogen alone and those taking a combination of conjugated equine estrogen plus medroxyprogesterone acetate [59,60]. The results of these studies, along with the findings of a meta-analysis quantifying the effect of HRT on components of the metabolic syndrome in postmenopausal women [61], provide some reassurance that postmenopausal estrogen replacement therapy can be offered to patients with diabetes.

---

### Antihypertensive and cardiovascular agents

#### Thiazide diuretics

Hyperglycemia was recognized as an adverse effect of chlorothiazide (the first marketed thiazide diuretic) within a year of its introduction in 1957 [62]. Thiazides can induce adverse biochemical changes, including hyperglycemia, hypokalemia and dyslipidemia [63–68]. The overall frequency of impaired glucose tolerance is around 3–6 cases per 1000 patient-years when high dosages of thiazides ( $\geq 5$  mg/day bendroflumethiazide (bendroflumethiazide) are used. With low dosages ( $\leq 2.5$  mg/day bendroflumethiazide) and the correction of any fall in plasma potassium concentration, the problem is far less common [69–74].

Long-term studies show that impaired glucose tolerance usually develops slowly, with a lag period of 2 years after starting the thiazide [66,67]. The precise mechanism by which thiazide

diuretics impair glucose tolerance has not been elucidated. It was previously thought to be secondary to both reduced glucose-stimulated insulin release and to insulin resistance (Figure 16.1), but some recent evidence suggests the mechanism involves reduced pancreatic insulin release alone and not reduced insulin sensitivity [75]. The severity of glucose intolerance is strongly correlated with the degree of hypokalemia [67]; the impairment of insulin secretion is secondary to potassium depletion, which appears to inhibit the cleavage of proinsulin to insulin and is reversible on restoring normokalemia [73,76,77]. The result is post-prandial hyperglycemia, with elevated proinsulin concentrations between meals that may downregulate insulin receptors in peripheral tissues. This phenomenon affects people without diabetes and those with T2DM, but not patients with type 1 diabetes (T1DM) receiving exogenous insulin replacement.

#### $\beta$ -Adrenoceptor antagonists

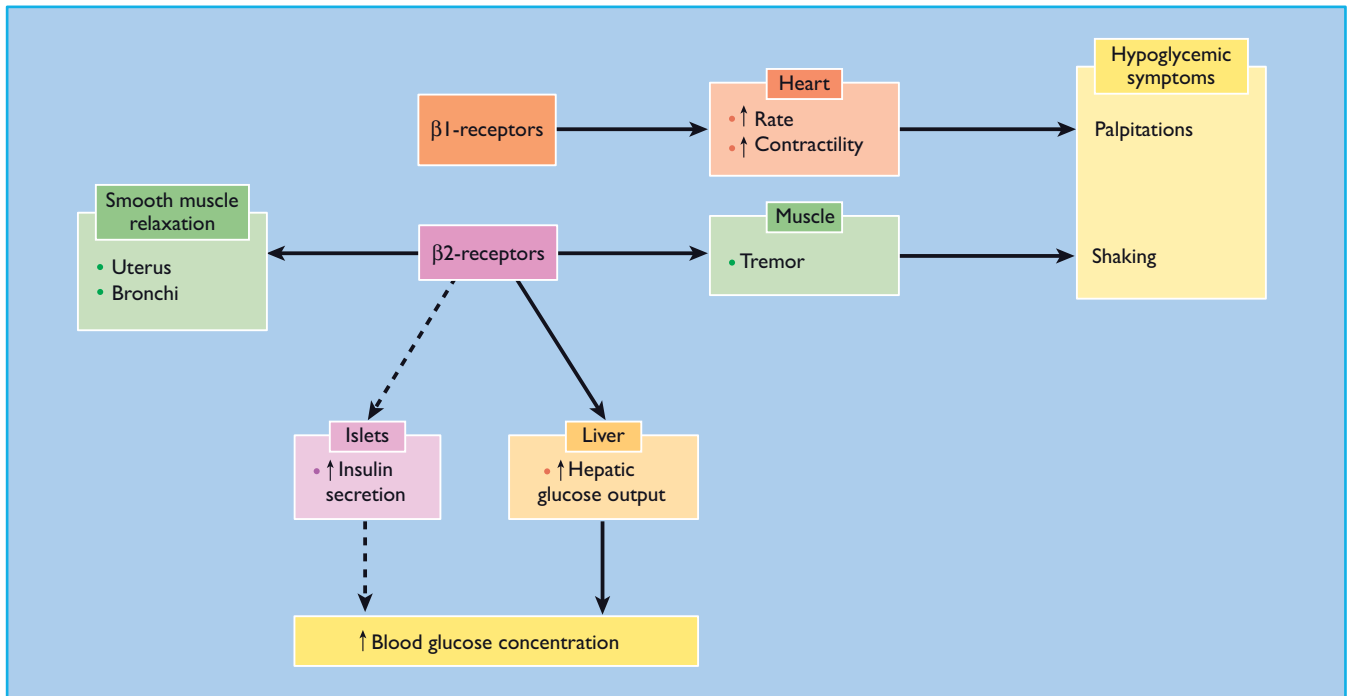

$\beta$ -Adrenoceptors modulate glucose homeostasis at several different points (Figure 16.2). Long-term studies suggest that  $\beta$ -adrenoceptor antagonists induce insulin resistance, possibly partly through weight gain [78]. This diabetogenic effect is amplified if high-dose thiazides are also given [79]. The authors of a recent meta-analysis of 94 492 patients with hypertension concluded that treatment with  $\beta$ -adrenoceptor antagonists is associated with a 22% increased risk for new-onset diabetes [80]. The risk was greater in patients with higher baseline body mass indexes and higher baseline fasting glucose concentrations.

$\beta$ -Adrenoceptor antagonists differ in their diabetogenic potential; in the meta-analysis, the risk for new-onset diabetes was 30% greater for atenolol and 34% greater with metoprolol than other agents [80]. In contrast, there was no increase in the risk for new-onset diabetes with propranolol compared with placebo. In fact, in the GEMINI trial, carvedilol stabilized glycated hemoglobin and improved insulin resistance in patients with diabetes and hypertension [81].

The possible importance of  $\beta$ -adrenoceptor antagonists in masking hypoglycemic symptoms is discussed in Chapter 26.

#### Calcium-channel blockers

*In vitro* and *in vivo* studies have demonstrated that calcium-channel blockers can impair glucose metabolism. Very few cases of clinically significant hyperglycemia have been reported, however, [82–88], and most were associated with excessive dosage of these drugs. Verapamil inhibits the second phase of glucose-stimulated insulin release by blocking the uptake of calcium into the cytosol of  $\beta$ -cells [89]; it also inhibits sulfonylurea and glucagon-induced insulin secretion [90]. Hyperglycemia and metabolic acidosis are well described in verapamil poisoning, and *in vivo* animal studies suggest that hyperglycemia may be caused by a combination of impaired insulin release and insulin resistance, causing a fall in insulin-mediated glucose clearance, together with increased action of circulating catecholamines [91]. Serum glucose concentrations have been found to correlate directly with the severity of the calcium-channel blocker intoxication.

**Figure 16.2** Effects mediated by  $\beta_1$ - and  $\beta_2$ -adrenoceptors.

**Figure 16.3** Plasma glucose and insulin concentrations during an oral glucose tolerance test, in 20 healthy controls (red) and in four dysglycemic subjects treated with intravenous pentamidine (yellow). Data are mean  $\pm$  SEM. \*  $P < 0.05$ , \*\*  $P < 0.01$  vs baseline. Reproduced from Assan *et al.* [100] with permission from the American Diabetes Association.

tion [92]. Nonetheless, calcium-channel blockers used appropriately can be regarded as safe in patients with diabetes [82,93–96].

## Other drugs

### $\beta$ -Cell toxins

A few drugs act directly as  $\beta$ -cell toxins and can cause permanent diabetes, often insulin-dependent. A classic example is the nitro-sourea, streptozocin (streptozotocin), which has long been used to induce experimental insulin-dependent diabetes in rodents; in humans, it is employed as chemotherapy for inoperable or metastatic insulinoma.

Pentamidine, used to treat *Pneumocystis jirovecii* infection in patients with AIDS [97], is closely related to another experimental diabetogenic drug, alloxan. It causes destruction of  $\beta$ -cells and may initially induce insulin release and transient hypoglycemia [98], followed subsequently by diabetes [99]. This effect is predominantly seen when pentamidine is given intravenously (Figure 16.3), but can also follow inhalation of an aerosol [100]. In one series of 128 patients with AIDS treated with pentamidine for *Pneumocystis jirovecii* infection, nearly 40% developed significant abnormalities of glucose homeostasis: hypoglycemia (5%), hypoglycemia followed by diabetes (15%) and diabetes alone (18%) [100]. Higher doses of pentamidine, higher plasma creatinine concentration and more severe anoxia were risk factors for the development of these glucose abnormalities.

## Part 4 Other Types of Diabetes

The rodenticide pyriminil (Vacor) has also caused irreversible diabetes in humans when ingested accidentally or with suicidal intent.

### HIV protease inhibitors

The treatment of HIV infection has evolved dramatically during the last decade, with the wide introduction of protease inhibitors such as indinavir, nelfinavir, ritonavir and saquinavir. In general, these drugs are well tolerated, but worsening of pre-existing diabetes or the new onset of T2DM has been reported in 2–6% of patients receiving them [101–103]. Transient elevations in glucose concentrations are common in these patients, and there is a fivefold increase in the incidence of sustained glucose intolerance [101]. Because of similarities to the pathogenesis and clinical

presentation of T2DM, it has been advised that treatment of protease inhibitor-associated hyperinsulinemia and hyperglycemia should follow the recommendations of the American Diabetes Association for the management of T2DM [104].

A striking syndrome of peripheral lipodystrophy, hyperlipidemia and insulin resistance has also been described in patients receiving HIV protease inhibitors, especially long term (Figure 16.4). This suggests that the underlying cause of hyperglycemia is insulin resistance [103]. The mechanism is not fully understood; Carr *et al.* [103] propose that protease inhibitors may bind to as yet uncharacterized target proteins that regulate lipid metabolism, leading to elevated circulating fatty acids that could interfere with insulin signaling or enter the fatty acid cycle and compete with glucose cycle intermediates. Recent

**Figure 16.4** Protease inhibitor-induced lipodystrophy. (a,b) "Buffalo hump" caused by nuchal fat deposition. (c,d) Facial fat atrophy. Courtesy of Professor Munir Pirmohamed, University of Liverpool, UK.

studies indicate that these drugs have direct effects on adipocytes, including resistance to insulin's actions in promoting glucose uptake and inhibiting lipolysis [105], as well as impairment of differentiation from pre-adipocytes to mature fat cells [106].

### **$\beta_2$ -Adrenoceptor agonists**

$\beta_2$ -Adrenoceptor agonists stimulate insulin secretion, but this effect is overwhelmed by increased hepatic glucose output, and the usual net effect is hyperglycemia (Figure 16.2). High dosage of  $\beta_2$ -agonist drugs (e.g. salbutamol, ritodrine and terbutaline) is commonly used to treat asthma and premature labor. Hyperglycemia often results [107], and diabetic ketoacidosis has even been induced in previously non-diabetic pregnant women [108]. Continuous nebulization of  $\beta_2$ -agonist drugs for status asthmaticus can also result in hyperglycemia [109]. The effects of  $\beta_2$ -agonists are most pronounced in patients with T1DM. When dexamethasone is administered together with a  $\beta_2$ -agonist, as in the treatment of preterm labor, the resulting hyperglycemia can be severe, even in previously normoglycemic patients. In view of this, current guidance from the National Institute for Health and Clinical Excellence (NICE) recommends that when tocolysis is indicated in women with diabetes, an alternative to  $\beta_2$ -adrenoceptor agonists should be used to avoid hyperglycemia and ketoacidosis [110].

Epinephrine (adrenaline) [111], dopamine [112] and theophylline can also cause hyperglycemia through similar mechanisms.

### **Diazoxide**

Diazoxide is a non-diuretic benzothiadiazine derivative with potent vasodilator properties, which was previously used to treat hypertensive crises; it is now rarely used for this indication, but is sometimes helpful in cases of inoperable insulinoma and to treat profound hypoglycemia following sulfonylurea overdose. The dose used for treatment of patients with insulinoma ranges between 100 and 600 mg/day, often in divided doses [113]. It acts on the  $\beta$ -cell membrane to open the ATP-dependent potassium channel, thus hyperpolarizing the membrane and inhibiting insulin secretion (see Chapter 6). Diazoxide can cause hyperglycemia after only two or three doses.

### **Somatostatin analogs**

Somatostatin suppresses insulin secretion but also inhibits the release of the counter-regulatory hormones, growth hormone and glucagon; the net effect in subjects without diabetes is usually to maintain euglycemia. Octreotide, a somatostatin analog used to treat neuroendocrine tumors, has different metabolic effects in T1DM and T2DM [114]. In patients with T1DM treated with exogenous insulin, suppression of glucagon and growth hormone decreases hepatic glucose production and can lower blood glucose and/or insulin requirements. In patients with T2DM, inhibition of endogenous insulin can predominate, leading to hyperglycemia. There is some evidence that treatment with octreotide,

lanreotide and the long-acting preparations of both drugs can impair glucose tolerance and occasionally cause diabetes, notably in people with acromegaly whose glucose homeostasis is already impaired (see Chapter 17) [115–117]. The effect of long-acting somatostatin analogs on glucose metabolism in patients with acromegaly is complex; they reduce the insulin resistance caused by elevated growth hormone concentrations, but also suppress insulin secretion from islet  $\beta$ -cells. The net balance between the two effects determines whether long-acting somatostatin analogs improve or worsen glucose metabolism [118]. These effects are inconsistent and unpredictable, with worsening glucose metabolism occasionally seen in the presence of improving growth hormone concentrations [119].

Utilizing its suppressive effect on insulin release, octreotide has been used effectively to manage refractory hypoglycemia caused by acute sulfonylurea poisoning or quinine treatment [120–123].

### **Recombinant human growth hormone**

Biosynthetic growth hormone (GH), now widely used to treat growth failure, is an insulin antagonist that can cause reversible mild glucose intolerance [124]. A recent large study of over 23 000 children treated with human recombinant human growth hormone (hGH) showed a sixfold higher frequency of T2DM than expected [125], although the incidence of T1DM was not increased. These data from a young cohort suggest that GH probably accelerates the development of the disease in individuals who may have a genetic predisposition to T2DM.

Increasingly, hGH has become accepted as long-term therapy in adults with GH deficiency (GHD) (see Chapter 17); as yet, no significant adverse effects on glycemic control have been reported. Fasting plasma glucose and glycated hemoglobin usually increase, but remain within the reference range, in subjects without diabetes during prolonged hGH replacement; in subjects with pre-existing impaired glucose tolerance, they tend not to rise further above pretreatment baseline values [126]. This probably reflects the complex interaction between hGH, insulin-like growth factor I (IGF-I) and body composition. Many people with adult GHD have abnormal body composition with central adiposity and decreased lean body mass. In the short term, rhGH acts as an insulin antagonist but in the longer term leads to increases in IGF-I and decreased fat mass, which tend to improve insulin sensitivity (see Chapter 17). It is recommended, however, that overdosing be avoided and glycemic control be monitored [127].

New-onset diabetes mellitus has been described in patients with the HIV wasting syndrome (AIDS cachexia) treated with hGH in supraphysiological doses [128].

### **Antirejection drugs**

Post-transplantation diabetes mellitus (PTDM) has been reported in non-diabetic adult transplant recipients taking ciclosporin (cyclosporine) [129,130]. Animal studies have implicated reversible  $\beta$ -cell damage [131], causing reduced insulin secretion [132–

134]. In addition, pancreas allograft biopsies from transplant patients receiving ciclosporin show histologic changes compatible with islet cell damage, including cytoplasmic swelling, vacuolization and apoptosis [135]. Recent studies suggest that the risk of PTDM increases progressively with time after transplantation. Newer preparations of ciclosporin which are better absorbed from the gastrointestinal tract achieve higher blood concentrations and thus higher cumulative exposure, and increase the incidence of diabetes [136].

PTDM is also commonly observed in up to 28% of adults receiving tacrolimus (FK506), a newer and more potent immunosuppressive agent [137–139]. More recent trials, however, suggest the risk of developing PTDM can be reduced by the use of low-dose tacrolimus (0.15–0.2 mg/kg/day) [140]. Altered insulin and glucagon responses to arginine in patients treated with these drugs suggest a defect in the  $\beta$ -cell– $\alpha$ -cell axis within the islet (see Chapter 6) [141]. The diabetogenic effects of both ciclosporin and tacrolimus are largely reversible with appropriate reductions in the drug dosage.

Recently developed immunosuppression protocols aiming to minimize the use of steroids and nephrotoxic immunosuppressants have resulted in the extensive use of potent non-nephrotoxic immunosuppressants, such as mycophenolate mofetil and sirolimus. The incidence of PTDM associated with these agents is uncertain. Study results with sirolimus have been inconsistent, with some suggesting an increased risk of developing PTDM [142,143] and others not [144].

$\alpha$ -Interferon therapy has been associated with the development of both T1DM and T2DM, sometimes with ketoacidosis; autoimmune mechanisms have been implicated [145].

## Drugs used in psychiatric disorders

### Antipsychotic agents

Hyperglycemia occurs occasionally with conventional antipsychotic drugs, but the use of the newer atypical antipsychotics, especially clozapine and olanzapine, have been widely reported to be associated with the development of *de novo* diabetes mellitus and exacerbation of pre-existing diabetes [146–148]. A causative relationship between antipsychotic and diabetes has not been established beyond doubt because many patients receiving these drugs who develop diabetes have traditional risk factors for diabetes. Indeed, the rates of diabetes in people with severe mental illness were reported to be higher in the pre-antipsychotic era (see Chapter 55). Possible underlying mechanisms linking antipsychotics and the development of diabetes include hepatic dysregulation caused by antagonism of hepatic serotonergic mechanisms [149]. Weight gain, associated with fasting hyperglycemia and hyperinsulinemia, point to insulin resistance as the underlying mechanism although some *in vitro* studies suggest that the antipsychotics may have a direct effect on insulin secretion. In a few cases, blood glucose concentrations may return to normal once the drug is discontinued. Despite a wealth of evidence from a number of sources (anecdotal case reports, drug safety studies, pharmacoepidemiologic studies, prospective studies) linking

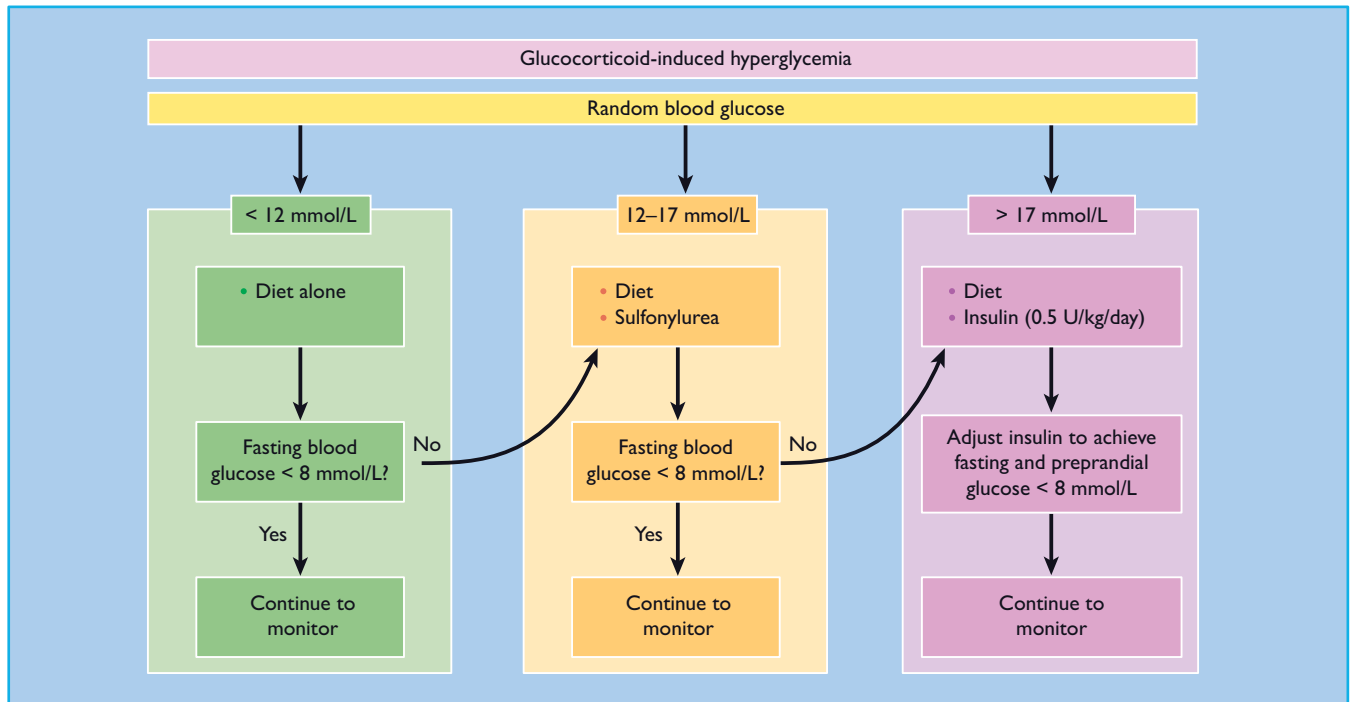

glucose intolerance to the use of atypical antipsychotics, one estimate of the attributable risk of diabetes associated with atypical antipsychotics ranged from 0.05% for risperidone to 2.03% for clozapine, suggesting that the absolute excess risk associated with atypical antipsychotics is probably low [150]. Consequently, most individuals receiving antipsychotics will not develop diabetes and for those who do, the cause is unlikely to be related to their treatment. When prescribing atypical antipsychotic medication, however, baseline screening and follow-up monitoring is recommended.

### Antidepressants

Depression is an important problem among people with diabetes (see Chapter 55), and various antidepressant drugs can affect plasma glucose and insulin concentrations [151,152]. The tricyclic antidepressant, nortriptyline, worsens glycemic control [153], and has been shown to reduce insulin concentrations in animal studies [152]. There is also a single case report in the literature of another tricyclic agent, clomipramine, causing significant symptomatic hyperglycemia which resolved when the drug was discontinued and recurred when the patient was rechallenged with the drug [154]. The selective serotonin reuptake inhibitors (SSRIs), fluoxetine and fluvoxamine, cause hyperglycemia in mice, apparently because increased serotonergic neurotransmission enhances catecholamine release from the adrenal medulla while suppressing insulin release [151]. This does not, however, appear to be a significant problem in humans; indeed, various antidepressant drugs, including SSRIs, have been shown to improve glycemic control in patients with diabetes by decreasing appetite while relieving depression and helping to improve compliance with antidiabetic treatment [155].

### Other drugs

- *Asparaginase* (crisantaspase), an anticancer drug used to treat acute lymphoblastic leukemia, causes predictable impairment of glucose tolerance which is secondary to insulin resistance. In one trial in children, 10% of cases developed hyperglycemia, and all showed glycosuria [156].
- *Oxymetholone* and *danazol*, certain synthetic steroid derivatives with androgenic properties, impair glucose tolerance, probably by inducing insulin resistance at a post-receptor site [157]; stimulation of glucagon secretion may also contribute [158].
- *Nicotinic acid*, used to treat dyslipidemia, is reported to cause hyperglycemia which is occasionally severe [118,159], although no such deleterious effect was observed in a recent trial in people with diabetes [160]. Its analog, acipimox, does not have adverse effects on glycemic control in people with diabetes [161].
- *Phenytoin* can cause hyperosmolar hyperglycemic syndrome or overt diabetes by interfering with calcium ion entry into  $\beta$ -cells, thus inhibiting insulin secretion [162].
- *Gatifloxacin* is a broad-spectrum 8-methoxyfluoroquinolone antibacterial agent previously used to treat a variety of infections. There have been several postmarketing reports of dysglycemia, both hypoglycemia and hyperglycemia, associated with the use of

**Figure 16.5** Treatment algorithm for glucocorticoid-induced hyperglycemia.

gatifloxacin [163,164]. The incidence of gatifloxacin-induced hyperglycemia is estimated at around 1%, and reported cases have involved both new-onset diabetes and worsening of glycemic control in patients with existing diabetes. The exact underlying mechanism is unknown, but data from animal studies point towards possible inhibition of insulin secretion [164] or increased secretion of epinephrine [165].

Transient hyperglycemia has been described following treatment or overdose with a number of commonly prescribed drugs such as non-steroidal anti-inflammatory drugs [166] and isoniazid. There are also anecdotal reports of drug-induced hyperglycemia associated with nalidixic acid [167], carbamazepine [168], encainide [169], benzodiazepines [170] and mianserin [171].

### Treatment of drug-induced hyperglycemia

Clinically relevant hyperglycemia occurs most commonly with high doses of glucocorticoids. If hyperglycemia occurs during thiazide treatment, the need for the drug should be reassessed. If a diuretic is required, then a small dose of furosemide or bumetanide may be substituted. If an antihypertensive agent is needed, it may be possible to reduce the dosage of bendroflumethiazide (e.g. to 2.5 mg/day), or to replace it with another class of drug.

### Steroid-induced diabetes

It may not be possible to withdraw glucocorticoid therapy, although “steroid-sparing” immunosuppressive drugs such as

azathioprine can sometimes be introduced for certain indications. Other measures are often needed to control hyperglycemia. Management depends primarily upon the severity of hyperglycemia (Figure 16.5). Random blood glucose measurements provide only an approximate guide, and therapy should be adjusted by frequent blood glucose monitoring; simple relief of symptoms alone is inadequate. A target fasting blood glucose concentration of <8 mmol/L may be suitable in the short term, and the usual criteria for good control should be applied if long-term glucocorticoid therapy is undertaken (see Chapter 20).

If significant hyperglycemia develops with high-dose glucocorticoid therapy (e.g. prednisolone 40 mg/day or more), insulin therapy may be started at 0.5 U/kg bodyweight per day, divided between morning and evening doses of short- and intermediate-acting insulin. This dosage is unlikely to produce hypoglycemia and indeed may need to be increased progressively, as dictated by blood glucose monitoring. If the patient presents as a hyperglycemic emergency, standard therapy with intravenous insulin should be started; because steroids induce insulin resistance, insulin delivery rates of 6–8 U/hour may be required initially (see Chapter 34).

Patients with diabetes who are to begin high-dosage glucocorticoid therapy must be warned that their glycemic control will worsen, and treatment for their diabetes should be adjusted prospectively. Those with T2DM treated by diet alone and whose fasting blood glucose concentration is 7–10 mmol/L will require addition of a sulfonylurea or insulin, while those poorly controlled with high dosages of oral agent will need insulin therapy. For patients already taking insulin, the dosage may need to be

increased by 50% initially, starting on the same day as steroid therapy. Further adjustments will be based upon results of blood glucose monitoring.

---

## Conclusions

Many drugs can cause hyperglycemia and diabetes, or worsen blood glucose control in patients with diabetes. The possible contribution of diabetogenic drugs should be considered in newly diagnosed patients with diabetes, or if hyperglycemia develops in subjects with previously well-controlled diabetes. Drug effects are often reversible and there are often alternative treatments to achieve the same therapeutic goals. Where the prescription of diabetogenic drugs is inevitable, careful monitoring of glycemic control and prudent use of suitable antidiabetic treatment can mitigate their effects.

## Endocrine Disorders that Cause Diabetes

**Neil A. Hanley**

Endocrine Sciences Research Group, University of Manchester, Manchester, UK

### Keypoints

- Endocrine causes of diabetes are mainly a result of an excess of hormones that are counter-regulatory to insulin, and act by inhibiting insulin secretion and/or action.
- Acromegaly is almost always secondary to growth hormone-secreting adenomas of the anterior pituitary somatotrophs and disturbs glucose homeostasis in up to approximately 50% of patients.
- Cushing syndrome is caused by excessive levels of glucocorticoids and disturbs glucose homeostasis to some degree in over 50% of cases.
- Pheochromocytoma is a tumor of the chromaffin cells, which in 90% of cases is located in the adrenal medulla and causes hyperglycemia in approximately 50% of cases.
- Glucagonoma and somatostatinoma are rare islet cell tumors that produce hormones that inhibit the secretion and action of insulin.
- Thyrotoxicosis commonly causes mild glucose intolerance, but overt diabetes only occurs in a tiny minority.
- Other endocrinopathies such as primary aldosteronism and primary hyperparathyroidism can disturb glucose homeostasis.
- Polycystic ovarian syndrome occurs in 5–10% of women of reproductive age and associates with some degree of glucose intolerance or diabetes resulting from insulin resistance in approximately 50% of cases.

### Introduction

The primary focus of this chapter is on those endocrine disorders that cause hyperglycemia and where effective treatment of the endocrinopathy can be expected to normalize the blood glucose concentration. These conditions mostly reflect excessive secretion of “counter-regulatory” hormones, the metabolic actions of which oppose those of insulin by inhibiting its secretion, action, or both.

### Acromegaly

#### Etiology, incidence and clinical features of acromegaly

Acromegaly comprises a constellation of symptoms and signs caused by excessive growth hormone (GH) secretion that leads to bony and soft tissue overgrowth accompanied by cardiovascular and metabolic pathology (Figure 17.1a; Table 17.1) [1]. It affects approximately 60 people per million [2] and, in 99% of cases, is caused by a pituitary adenoma, most commonly larger than 1 cm in diameter (a “macroadenoma”; Figure 17.1b). A tiny minority of cases are caused by excessive secretion of GH-releasing hormone (GHRH) from a hypothalamic gangliocytoma

or a carcinoid tumor of the lung or pancreas [1]. A small percentage of acromegaly occurs within the wider endocrine syndrome of multiple endocrine neoplasia type 1 (MEN1) caused by mutations in the tumor suppressor gene, *MEN1* [3]. MEN1 can also include glucagonomas and somatostatinomas, both of which are separately capable of causing secondary diabetes. Commonly, acromegaly has been present for a decade prior to diagnosis [4]. This long-standing hypersecretion of GH provides the time necessary for the characteristic external features of the disorder to develop (Figure 17.1a; Table 17.1).

#### Features of disturbance to glucose tolerance in acromegaly

Glucose intolerance or overt diabetes is common in acromegaly because of the direct hyperglycemic effects of GH excess (Figure 17.2). Overt diabetes has been reported in a range of 19–56% of patients with acromegaly, while impaired glucose intolerance (IGT) affects 16–46% [5–8]. Diabetes is most frequent in patients with higher GH levels [9,10]. There is also a correlation between serum insulin-like growth factor I (IGF-I), and both fasting and post-prandial glucose. In fact, placing age-adjusted IGF-I values into rising quartiles correlated very accurately to decreasing insulin sensitivity such that serum IGF-I levels could predict insulin sensitivity more accurately than either random GH levels or the nadir value following glucose tolerance testing [11].

Clinically, diabetes in acromegaly usually resembles the type 2 form (T2DM), with most patients not needing insulin therapy but being maintained with oral hypoglycemic agents or diet alone

**Figure 17.1** Acromegaly in a patient found to have a random blood glucose level of 13 mmol/L during preparation for sinus surgery. Features included: (a) the characteristic facial appearance; (b) a large adenoma (arrow) extending up to but not in contact with the optic chiasm demonstrated by magnetic resonance imaging (R, right; L, left). Following successful trans-sphenoidal removal of the tumor, glucose tolerance returned to normal.

[9]. GH can induce insulin resistance when infused into normal subjects [12,13], and insulin resistance is a consistent feature of people with acromegaly [14,15]. Insulin action is impaired in both the liver and extrahepatic tissues, with decreases in both the suppression of hepatic glucose production and in insulin-dependent glucose disposal [13,15]. For instance, impairment of insulin-mediated activation of glycogen synthase has been demonstrated in skeletal muscle [16–18]. Insulin resistance may also be exacerbated by the lipolytic action of GH, generating non-esterified fatty acids (NEFAs) which act on the liver to increase glucose production and in muscle to inhibit glucose utilization (via the “glucose–fatty acid” cycle) (Figure 17.2). Where pancreatic compensation is adequate, an exaggerated insulin secretory response creating hyperinsulinemia can counterbalance the insulin resistance and maintain euglycemia. Similar to the natural history of deteriorating blood glucose control in T2DM, eventually  $\beta$ -cell compensation fails, the insulin response is impaired and hyperglycemia ensues [14]. This has been termed the Starling curve of the pancreas (see Figure 11.1).

### Diagnosis and treatment of acromegaly

GH release is normally pulsatile with intervening periods of low level or undetectable hormone, whereas secretion from pituitary adenomas is autonomous. Therefore, the diagnosis can be deduced from a series of random serum measurements where GH is consistently detected. An alternative, better diagnostic test takes advantage of the negative feedback on GH secretion by glucose. A failure of serum GH to suppress to below 2 mU/L (approximately 1  $\mu$ g/L) within 3 hours of 75 g oral glucose is diagnostic of acromegaly. A further option, particularly suited as the initial screening test of outpatients, is measurement of serum IGF-I, which if raised above sex- and age-matched controls is diagnostic of acromegaly, unless there is a possibility of GH abuse [1]. It is noteworthy that the diagnosis of acromegaly can be difficult in patients with type 1 diabetes mellitus (T1DM) where GH hypersecretion is observed. Whereas this might compromise the use of serum GH as a diagnostic biomarker of a somatotroph adenoma, IGF-I values tend to be low in poorly controlled T1DM indicative of the state of GH resistance. Thus, raised serum IGF-I values

**Table 17.1** Clinical features of acromegaly.

**Musculoskeletal**

Protruding mandible (prognathia) with lower teeth separation  
 Big tongue (macroglossia)  
 Enlarged forehead (frontal bossing)  
 Large hands and feet (carpal tunnel syndrome, tight rings, increasing shoe size)  
 Osteoarthritis from abnormal joint loading  
 Increased stature (gigantism; if GH excess occurs prior to epiphyseal closure)

**Skin**

Irritating, thickened, greasy (increased sebum production)  
 Excessive sweating

**Cardiovascular**

Dilated cardiomyopathy causing cardiomegaly and cardiac failure  
 Hypertension

**Metabolic**

Impaired glucose tolerance or potentially diabetes

**General**

Headaches  
 Tiredness, often very disabling and lowers quality of life/ability to work

**Local tumor effects**

Compression of the optic chiasm (superior tumor growth) or cranial nerves III, IV and/ or VI (lateral tumor growth into cavernous sinus)

GH, growth hormone.

remain a confident predictor for a diagnosis of acromegaly in people with T1DM. Having diagnosed acromegaly, magnetic resonance imaging (MRI) of the anterior pituitary defines the extent of the adenoma (Figure 17.1b).

Based on this investigation, symptoms, patient wishes and comorbidity, and GH levels, treatment can be either surgical, medical or radiotherapy (Table 17.2) [1,19]. When the tumor is a macroadenoma, especially if it extends beyond the pituitary fossa, curative surgery becomes unlikely or impossible; however, surgery can be useful for “debulking” and rapid lowering of serum GH levels in patients who are highly symptomatic, or where the tumor has encroached upon the optic chiasm and affected visual fields. The standard approach is trans-sphenoidal, either via the nostril or from behind the upper lip. Once the sphenoid sinus has been traversed and midline access to the sella turcica gained, tumor is removed from the anteroinferior aspect causing the residual tissue to drop back down into or towards the pituitary fossa. Tumor beyond the fossa, in locations such as the cavernous sinus, cannot be approached directly, hence the reason why surgery for large tumors is not anticipated to be curative [19]. Conversely, cure can be commonly achieved for over 50% of microadenomas (<1 cm diameter). The reported ranges vary widely according to expertise.

Medical therapy, most commonly using somatostatin analogs, is effective at both lowering GH levels and shrinking the tumor volume [1,20,21]. Approximately 60% of patients respond to somatostatin analogs because of the presence of predominantly

**Figure 17.2** Mechanisms of hyperglycemia and diabetes in acromegaly. Diabetes develops if β-cells fail to compensate for the increased demand for insulin. IGT, impaired glucose tolerance; NEFA, non-esterified fatty acid.

**Table 17.2** Treatment of acromegaly (Adapted from Holt and Hanley [130].)

Advantages	Disadvantages
<b>Trans-sphenoidal surgery</b>	
Rapid effect	Invasive and requires general anesthetic
Can restore vision in optic nerve compression	Non-curative for large extrasellar tumors
Might be curative if complete resection	
<b>Somatostatin analog drugs</b>	
Non-invasive	Monthly intramuscular injection
May shrink tumor	Expensive
Decreases GH in ~60% of patients	Gastrointestinal side effects (commonly diarrhea)
	Unlikely to be curative (i.e. continuous therapy needed)
<b>Pegvisomant</b>	
Non-invasive	Expensive
Blocks GH action	GH concentrations remain elevated
<b>Radiotherapy</b>	
Non-invasive	Slow to act – may take up to 10 years
Likely to shrink tumor	Standard external three-beam radiotherapy likely to cause hypopituitarism by destroying other pituitary cell types
Likely to reduce GH levels	
Might be curative	

GH, growth hormone.

type 2 and type 5 somatostatin receptors on the tumor cell surface [1,21]. The analogs can be administered subcutaneously; however, once it is clear that they are tolerated, the most common formulation is month-long intramuscular depot preparations. They can be used either prior to surgery, with the goal of operating on a shrunken tumor, on a long-term basis in place of surgery or post-surgery where GH levels have not been normalized.

Some GH-secreting adenomas co-express dopamine receptors more characteristic of prolactinomas [21]. Indeed, 25% of cases of acromegaly show raised levels of both prolactin and GH possibly indicating a tumor cell phenotype more consistent with the somatomammotroph from which it is thought that somatotrophs (GH secretion) and lactotrophs (prolactin secretion) terminally differentiate. In these instances, dopamine agonists, as used in hyperprolactinemia, can be useful, especially as they can be administered orally, and allow reduction in dosage of the more expensive intramuscular depot somatostatin analogs. This opportunity to use lower doses of somatostatin analogs may also lessen their side-effects, such as gastrointestinal disturbance (most commonly diarrhea) and gallstones. It has recently been questioned, however, whether commonly used ergot alkaloid derived dopamine agonists, such as cabergoline, cause fibrotic side-effects, especially involving heart valves [22,23]. Despite concerns from regulatory agencies, the prevailing view from endocrinologists is that the doses of these agents used to treat endocrine disorders (compared with the therapeutic regimens in Parkinson disease) are not problematic. In any case, alternative non-ergot derived agents, such as quinagolide, are available. Bromocriptine is less commonly used because of the almost inevitable side-effects of nausea. Responsiveness to both dopamine and somatostatin analog therapy can be easily assessed at the start of treatment by hourly measurement of serum GH over 8 hours following the administration of a test dose of each agent given sequentially on two consecutive days.

The last decade has seen the appearance of a new clinical agent that blocks GH action. GH induces signal transduction via binding to its receptor as a dimer. Pegvisomant has been developed as a GH antagonist by preventing this dimerization and thus inhibiting GH action. This leaves elevated GH levels from the somatotroph adenoma but, nevertheless, pegvisomant is effective at reversing the clinical features of acromegaly [1,24]. The major problem with its use in many countries has been its prohibitive cost. Concern over tumor growth because of loss of negative feedback (a scenario akin to Nelson syndrome following bilateral adrenalectomy in Cushing disease) seems unfounded [1,24].

Radiation therapy is most commonly administered as conventional three-field external beam radiotherapy [1]. It is effective at lowering GH and IGF-I levels [25]. This approach delivers approximately 4500 Gy to the pituitary region with the total dose calculated such that the optic chiasm receives less than 8 Gy. An alternative is stereotactic radiotherapy (also known as  $\gamma$ -knife therapy or radiosurgery), which by using more sources can focus a higher concentration of radiation to a defined area of tumor. Whereas the latter modality allows greater preservation of adja-

cent normal pituitary tissue, the former approach is a more all-encompassing strategy to ensure tumor destruction, albeit with a higher post-therapy incidence of hypopituitarism. The choice is important as there is evidence that pituitary radiotherapy is associated with increased morbidity and mortality from subsequent cerebrovascular disease meaning that repeat therapy is not undertaken lightly [26].

### Outcome of acromegaly and disturbance to glucose tolerance

Unless there are cogent reasons against, attempts should be made to normalize GH excess in acromegaly to decrease the morbidity and mortality associated with the disorder [1,26]. Curative treatment is best defined by a nadir serum GH of less than 2 mU/L upon 75 g oral glucose challenge. Glucose tolerance improves and insulin levels decrease after successful treatment by pituitary surgery and irradiation [27,28]. Hyperglycemia may worsen in a few patients, presumably those with a stronger underlying tendency to T2DM, when treated with somatostatin analogs because these drugs also suppress insulin secretion [29,30]. In the longer term, somatostatin analogs tend to improve glucose tolerance [31,32]. Insulin sensitivity is also improved with pegvisomant therapy in patients with both glucose intolerance and diabetes [33–36]. If hyperglycemia persists after serum GH levels have been normalized then the patient should be considered as having T2DM. One caveat to this is the possibility of GH deficiency as part of hypopituitarism post-surgery or radiotherapy [14]. GH deficiency causes centripetal fat deposition, which would itself cause or accentuate insulin resistance and potential loss of euglycemia.

Generally, diabetic complications are considered rare in acromegaly. Nevertheless, it is worth considering GH action in the context of both macrovascular and microvascular diabetic complications. Untreated GH excess increases cardiovascular morbidity and mortality and, potentially, abnormalities of glucose metabolism occurring in acromegaly could contribute to hypertension which affects over 50% of patients with acromegaly [5]. GH has been linked to proliferative diabetic retinopathy ever since resolution of diabetic retinopathy was noted in a woman who developed rapid-onset pan-hypopituitarism [37,38], so much so that hypophysectomy was used as treatment prior to the advent of laser photocoagulation [38]. This view is supported by the observations that patients with diabetes who are GH-deficient rarely develop retinopathy [39], and an experimental study in mice demonstrated that inhibition of GH secretion ameliorated diabetic retinopathy [40]. Patients with diabetes who are acromegalic, however, do not show an increased incidence of diabetic retinopathy [41,42]. Data on the progression of diabetic retinopathy treated with either pegvisomant or somatostatin analog are contradictory, and the outcome of larger trials are awaited [38].

### Effects of diabetes on GH-IGF-I axis

Dysregulation of the GH-IGF-I axis has been well documented in T1DM. The main disturbances include increased GH secretion (Figure 17.3), paradoxically associated with decreased serum

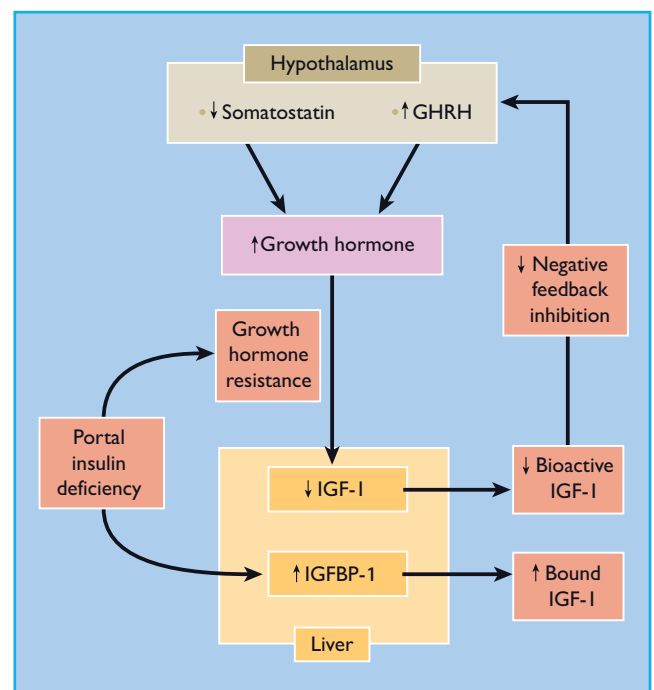

**Figure 17.3** Increased growth hormone (GH) secretion in type 1 diabetes. Note the marked hypersecretion during sleep in the early hours of the morning. Reproduced from Hansen *et al.* [127], with permission from Wiley-Blackwell.

IGF-I levels [43]. GH secretory pulses are larger and more frequent and total 24 hour serum and urinary GH levels are elevated. High circulating GH levels are most obvious during periods of poor diabetic control, and return towards normal with improved control. Pulses of GH secretion during sleep in the early hours of the morning lead to insulin resistance, which manifests itself before breakfast and is largely responsible for the “dawn phenomenon” of fasting hyperglycemia [44]. This physiologic effect, along with that caused by exercise and GHRH, is exaggerated in patients with T1DM, especially those who are poorly controlled. GH secretion accounts for much of the decreased insulin sensitivity observed during normal puberty, as well as the deterioration in glycemic control at this time in adolescents with T1DM. Despite GH hypersecretion, levels of IGF-I – the principal mediator of GH activity – are inappropriately low, indicating a state of GH resistance (Figure 17.4). Hepatic resistance to GH has been attributed both to decreased number of GH receptors and to post-receptor defects [43]. Circulating levels of GH-binding protein (GHBP) are also decreased in T1DM. Administration of recombinant human IGF-I (rhIGF-I) as an adjunct to insulin has been demonstrated to reverse GH hypersecretion and improve glycemic control, while reducing insulin requirements. Co-administration of IGF-binding protein 3 (IGFBP-3) with IGF-I has similar beneficial effects on carbohydrate metabolism, and also avoids side effects of IGF-I, notably edema, headache, retinal edema and jaw pain [45]. Recombinant IGF-I has also been used to treat states of severe insulin resistance in which the insulin receptor is functionally impaired, such as the spectrum from Donohue to Rabson–Mendenhall syndrome (see Chapter 15) [46]. In such patients, rhIGF-I can be used to treat ketoacidosis, which is the major cause of death and may fail to respond even to massive doses of insulin.

Abnormalities of IGFBP may also alter the regulation of the GH–IGF-I axis in diabetes (Figure 17.4). Six IGFBPs have been identified in humans, the two most relevant being IGFBP-1 (molecular weight 25 kDa), whose synthesis by hepatocytes is

**Figure 17.4** Mechanisms of growth hormone (GH) hypersecretion in diabetes. Insulin-like growth factor 1 binding protein 1 (IGFBP-1) binds and reduces the bioavailability of insulin-like growth factor I (IGF-I), which normally decreases GH secretion by negative feedback inhibition on the hypothalamus and pituitary; IGFBP-1 expression is inhibited by insulin.

inhibited by insulin but independently of GH, and IGFBP-3 (molecular weight 44 kDa), which is GH-dependent [47]. IGFBP-1 levels are increased in T1DM as a result of portal and hepatic insulin deficiency (Figure 17.4) [43], and increase with worsening insulin deficiency and rising HbA<sub>1c</sub> concentrations (Figure 17.5). Increased IGFBP-1 levels have been shown to inhibit IGF-I bioactivity. Portal insulin deficiency in T1DM can thus account for

**Figure 17.5** Correlation between serum immunoreactive insulin-like growth factor 1 binding protein 1 (IGFBP-1) and glycated hemoglobin (HbA<sub>1c</sub>) concentrations in 48 patients with type 1 diabetes mellitus. Reproduced from Langford and Miell [128], with permission from the *European Journal of Clinical Investigation*.

GH resistance, through downregulation of hepatic GH receptors and increased IGFBP-1 levels, both reducing IGF-I production and bioactivity [48]. Decreased IGF-I levels in turn cause GH hypersecretion via reduced negative feedback at the hypothalamus and pituitary, and this exacerbates insulin resistance, thus establishing a vicious circle of raised GH and poor glycemic control (Figures 17.2 and 17.3).

Another consequence of IGF-I deficiency is impaired growth at puberty [48]. Paradoxically, children with new-onset diabetes tend to be taller, especially if the disease develops several years before puberty; increased GH and insulin levels during the pre-clinical evolution of the disease are a possible explanation. Once diabetes is established, growth may slow, particularly before the age of 10 years and if glycemia is poorly controlled (Figure 17.6). The pubertal growth spurt may be blunted and/or delayed, especially in girls, and this may lead to a reduction in final height [48]. Growth failure in adolescents with T1DM is rare nowadays, possibly because of improved management and monitoring of diabetes. Indeed, intensified insulin treatment has been shown to raise IGF-I levels, in parallel with an increase in growth velocity [48]. Finally, growth failure may be associated with truncal obesity, hepatomegaly (secondary to glycogen and/or triglyceride deposition) and sexual infantilism in the Mauriac syndrome [49]. This condition was reported in children with poor glycemic control and excessively high insulin dosages, but is now rare.

## Cushing syndrome

### Etiology, incidence and clinical features of Cushing syndrome

Cushing syndrome comprises a constellation of symptoms and signs caused by excessive levels of glucocorticoid that leads to a characteristic appearance accompanied by metabolic and cardio-

**Figure 17.6** Growth failure in a boy with diabetes. Height fell progressively below the centiles (97th centile at diagnosis) and the pubertal growth spurt was delayed, resulting in a lower final height than predicted.

**Table 17.3** Clinical features of Cushing syndrome.

Easily bruised, thin skin; poor wound healing
Striae (purple or "violaceous" rather than white)
Thin (osteoporotic) bones that easily fracture
Glucose intolerance/diabetes mellitus
Central obesity, characteristic rounded facies, "buffalo" hump
Susceptibility to infection
Predisposition to gastric ulcer
Hypertension
Disturbance of menstrual cycle; symptoms overlap with PCOS
Mood disturbance (depression, psychosis)

PCOS, polycystic ovarian syndrome.

vascular pathology (Figure 17.7; Table 17.3) [50–52]. It occurs most commonly as a side effect of synthetic glucocorticoids administered exogenously for conditions such as rheumatoid arthritis or reversible airways disease. Endogenous Cushing syndrome arises in approximately two-thirds of cases from adrenocorticotropic (ACTH) secreting corticotroph adenomas of the anterior pituitary which affect 5–10 individuals per million. In one-fifth of cases, the cause is a glucocorticoid-secreting tumor of the adrenal cortex and in one-tenth of cases is secondary to syndromes of ectopic ACTH secretion, most commonly from small cell carcinoma of the lung or, more rarely, carcinoid tumors [50–52]. Cushing syndrome is more common in women than

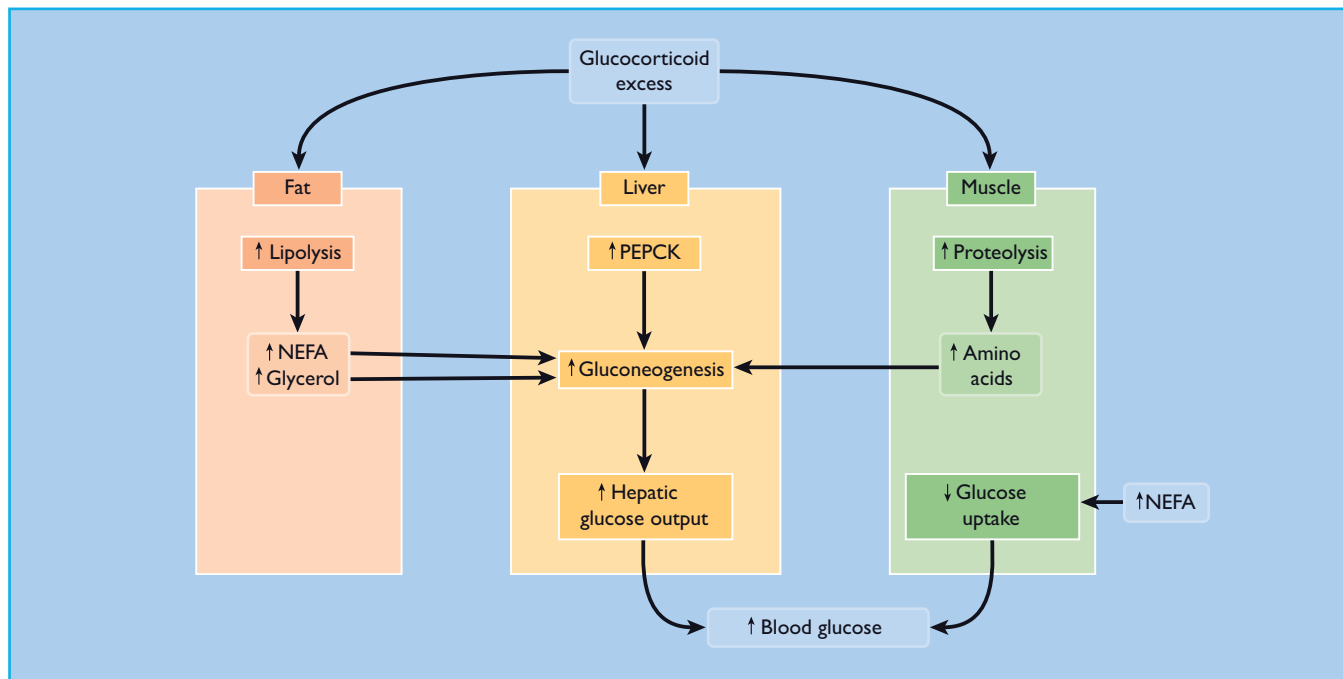

**Figure 17.7** Cushing syndrome in a 53-year-old hypertensive man presenting with diabetes that required insulin to control hyperglycemia. Features included back pain from osteoporotic vertebral collapse, proximal myopathy that prevented him from climbing stairs, characteristic rounded facies (a) and truncal obesity with violaceous striae (c). After removal of the 10-mm corticotroph pituitary adenoma, his facial appearance returned to normal (b), as did blood pressure and blood glucose.

men, with a greater predilection for corticotroph adenomas as the underlying pathology. Prolonged excessive levels of cortisol, the major glucocorticoid in humans, either directly from an adrenocortical tumor or from excessive ACTH causing bilateral hyperfunctional adrenal cortices, causes the characteristic external features of the disorder to develop and results in excess cardiovascular morbidity and mortality (Fig. 17.7a; Table 17.3) [50–52].

#### **Features of disturbance to glucose tolerance in Cushing syndrome**

Impairment of glucose tolerance is observed in 30–60% of cases [7,50,53]. Overt diabetes occurs in 20–50%, arguably in patients

predisposed to diabetes (e.g. those with a family history of the disorder) [7,50,53]. It resembles T2DM because glucocorticoid excess causes hyperglycemia primarily by inducing insulin resistance, reflected by hyperinsulinemia [53]. Insulin-stimulated glucose uptake and utilization by peripheral tissues are both reduced, while hepatic glucose production is greatly increased through stimulation of gluconeogenesis [50,54]. This results from the direct activation of hepatic gluconeogenic enzymes such as phosphoenolpyruvate carboxykinase (PEPCK), and an increasing supply of glucogenic substrates (amino acids and glycerol) generated by muscle proteolysis and peripheral adipose tissue lipolysis (Figure 17.8) [55]. Glucocorticoids also have permissive effects on the gluconeogenesis induced by epinephrine (adrena-

**Figure 17.8** Mechanisms of hyperglycemia and diabetes in Cushing syndrome. NEFA, non-esterified fatty acids; PEPCK, phosphoenolpyruvate carboxylase.

line) and glucagon. Besides enhancing hepatic gluconeogenesis, glucocorticoids also increase hepatic glycogen storage [55].

With endogenous causes of Cushing syndrome, the hyperglycemia can sometimes be effectively treated with sulfonylureas, but many cases require insulin therapy [56]. For Cushing syndrome caused by exogenous drugs, treatment can be tailored from knowledge of the timing and half-life of the glucocorticoid drug as a predictable period of hyperglycemia follows. For instance, prednisolone administered for reversible airways disease at breakfast will generate elevated glucocorticoid levels throughout the remainder of the day with levels falling in the evening. This profile makes the choice of an intermediate acting insulin administered at breakfast appropriate (see Chapter 27).

### Diagnosis and treatment of Cushing syndrome

For exogenously administered glucocorticoids, the diagnosis and treatment of Cushing syndrome are straightforward: wherever possible remove or reduce the offending medication. The major challenge in diagnosing Cushing syndrome resulting from endogenous causes is frequently one of simply considering the condition as the underlying cause of otherwise very common symptoms such as tiredness and weight gain. Avoiding this pitfall is aided by thorough clinical examination when more specific signs may be detected, for instance violaceous stretch marks (called “striae”; Figure 17.7c) or proximal myopathy [50–52]. This issue may be particularly pertinent to the T2DM clinic, with some evidence that occult Cushing syndrome may affect 2% of patients [57].

The first goal is to establish the presence of either autonomous secretion or excessive levels of cortisol [50–52]. Several screening

tests with high sensitivity have been designed (Table 17.4). Circulating cortisol is relatively high during the day and low at bedtime. Maintained daytime levels at night indicate excess. This can be tested by measuring midnight serum cortisol, although this requires prior acclimatization of inpatients for at least 24 hours and quiet surroundings as cortisol levels rise with minimal stress. Where assays have been validated, bedtime salivary cortisol measurement can be very useful as patients can post samples to the laboratory from home. Levels are approximately 10% of those in serum so care must be taken to avoid contamination with blood (e.g. from brushing teeth). The “low dose” dexamethasone suppression tests interrogate the potential loss of physiologic negative feedback at the corticotroph leading to autonomous ACTH secretion. The formal 48-hour test is marginally more specific [51]; however, it is also more inconvenient to perform in the outpatient setting compared with the overnight 1 mg suppression test. Caution needs to be exercised in patients where dexamethasone metabolism is enhanced (e.g. by antiepileptic medication) as this can lead to false-positive results. An alternative screening test examines total excretion of cortisol in a 24-hour urine collection, commonly on several occasions, as an integrated assessment of one day’s adrenocortical function. It is usual for endocrinologists to apply more than one of these various screening tests, which, if failed, provides proof of excess glucocorticoids and a diagnosis of Cushing syndrome.

Several endocrine tests have been developed to differentiate the various etiologies of endogenous Cushing syndrome (Table 17.4) [50–52]. Undetectable serum ACTH indicates an adrenocortical

**Table 17.4** Diagnosis of Cushing syndrome from endogenous causes.

Test	Interpretation
<b>Screening tests to diagnose Cushing syndrome</b>	
Midnight serum cortisol measurement or bedtime salivary cortisol assay	Maintained daytime levels at night-time indicates autonomous cortisol production of Cushing syndrome
1 mg overnight DST. Oral dexamethasone taken at midnight	Serum cortisol >50 nmol/L at following 9 AM consistent with Cushing syndrome
Formal low-dose DST (0.5 mg × 8 doses 6-hourly ending at 3AM)	Serum cortisol >50 nmol/L at following 9 AM consistent with Cushing syndrome
24-hour urinary free cortisol measurement	Elevated values support diagnosis of Cushing syndrome
<b>Tests to localize cause of cortisol excess</b>	
Serum ACTH measurement	If suppressed, indicates autonomous adrenocortical overproduction of cortisol (e.g. an adrenocortical adenoma)
If serum ACTH detectable:	
High dose dexamethasone suppression test (2 mg × 8 doses 6-hourly ending at 3 AM)	>50% suppression of 9 AM serum cortisol from pre- to post-test indicates anterior pituitary source; <50% suppression indicates extrapituitary "ectopic" source of ACTH
Bilateral IPS sampling	Gradient from IPS to periphery of >2:1 supports anterior pituitary source (test can also incorporate CRH administration; see text)
MRI (can include gadolinium enhancement)	Should only be considered once biochemical evidence of pituitary source obtained. Helpful for surgeon in planning trans-sphenoidal surgery
ACTH, adenocorticotrophic hormone; CRH, corticotropin releasing hormone; DST, dexamethasone suppression test; IPS, inferior petrosal sinus; MRI, magnetic resonance imaging.	

source of excessive cortisol causing suppression of ACTH secretion by the anterior pituitary. It can be particularly challenging to distinguish between anterior pituitary and ectopic sources of ACTH causing Cushing syndrome. Corticotroph adenomas, especially intrasellar ones, usually retain a partial capacity for negative feedback; the "high dose" dexamethasone suppression test, administered as eight 2-mg doses every 6 hours, can be expected to reduce cortisol levels by at least 50%. As this cause underlies the original description of the disorder by Harvey Cushing in 1912, pituitary-driven glucocorticoid excess is called Cushing disease. Extrapituitary tumors secreting ectopic ACTH less commonly display this degree of negative feedback such that ACTH levels and consequently cortisol levels are likely to be higher. Although these tumors may be relatively indolent carcinoids, more commonly they are aggressive carcinomas of the

bronchus characterized by a rapid onset of symptoms within a few months, marked hypokalemia and weight loss. The high level of *POMC* gene expression and dysregulated post-translational processing also leads to significant melanocyte stimulating hormone (MSH) secretion resulting in skin pigmentation. Venous sampling of the bilateral inferior petrosal sinuses can distinguish between ectopic or anterior pituitary sources of excessive ACTH. For pituitary sources, a gradient in ACTH levels of at least 2:1 (or 3:1 after the injection of 100 µg corticotropin releasing hormone [CRH] intravenously) should be found between central and peripheral samples. Although it can be very useful, bilateral inferior petrosal sinus sampling (BIPSS) also carries the risk of thrombosis in approximately 1% of cases, meaning that its use by endocrinologists is not always considered warranted. This is especially true where preceding biochemical tests have been conclusive and MRI shows clear radiologic evidence for a tumor. Where biochemistry is supportive of a pituitary source of ACTH excess, but the MRI is equivocal, even after gadolinium enhancement, BIPSS can help to lateralize a corticotroph adenoma by detecting a clear gradient between the right and left sinuses or vice versa. Sources of ectopic ACTH, most commonly in the chest, can be imaged with fine cut computerized tomography (CT), MRI or by using isotope-labeled scintigraphy to detect somatostatin receptors present on approximately two-thirds of ectopic ACTH-secreting carcinoid tumors. Autonomous cortisol-secreting tumors of the adrenal cortex can be imaged satisfactorily by CT or MRI when it can be possible to make assessment of functionality according to lipid content; features of high lipid content implying a tumor with active steroidogenesis.

Wherever possible, curative approaches are undertaken to normalize cortisol secretion as Cushing syndrome carries a high morbidity and markedly increases mortality from cardiovascular causes [50–52,58]. For adrenocortical sources, unilateral adrenalectomy is performed. For ectopic ACTH-secreting tumors, excision of carcinoids is potentially curative, whereas the natural history of carcinoma of the bronchus with ectopic hormone secretion usually makes palliative care more appropriate. Medical therapy to treat corticotroph adenomas remains disappointing. Some excitement was gained for high dose peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ) agonists but larger trials have been disappointing. Pituitary tumors are treated by either trans-sphenoidal surgery or radiotherapy when the indications and complications are largely the same as for those described in the section on acromegaly. The fact that ACTH-secreting adenomas are commonly microadenomas can increase the chances of curative surgery, although this remains heavily operator-dependent. If surgery is delayed, suppressants of adrenocortical steroidogenesis such as ketoconazole or metyrapone can be used temporarily where patients are highly symptomatic [50–52]. In extremis, bilateral adrenalectomy provides a rapid resolution of excessive cortisol secretion, although the total loss of negative feedback to a corticotroph adenoma can result in dangerous pituitary tumor growth that becomes refractory to further treatment, a scenario called Nelson syndrome. In patients where ACTH levels continue

to rise, concomitant radiotherapy to the anterior pituitary can help reduce the risk of this problem arising.

### Outcome of Cushing syndrome and disturbance to glucose tolerance

After successful surgery, the patient is reliant on external glucocorticoid administered as oral hydrocortisone, but a return of cortisol secretion from the adrenal gland(s) can be anticipated over ensuing weeks. Commonly, a physiologic return of diurnal rhythm is never achieved postoperatively [59]. For some, the extensiveness of anterior pituitary surgery, or the long-term suppression either of normal corticotrophs (pituitary or ectopic ACTH secreting tumors) or normal adrenocortical cells (cortisol-secreting tumors) causes a permanent state of hypocortisolism because of underactivity of remaining tissue. This can require continued hydrocortisone administration as for patients with Addison disease, except that mineralocorticoid replacement should not be required.

With successful treatment of Cushing syndrome (Figure 17.7), glucose intolerance may resolve. In such instances, when the patient might be entirely dependent on replacement doses of hydrocortisone, care needs to be taken not to cause hypoglycemia by continued antidiabetes medication. By contrast, persisting abnormalities are relatively common, most likely associated with persistent visceral obesity and metabolic syndrome [59]. On close analysis in one case series, there was a marked persistence of visceral obesity and glucose intolerance in approximately 60% of patients who fulfilled criteria for remission of Cushing syndrome [60].

### Effects of diabetes on hypothalamic–anterior pituitary–adrenal cortex axis

Evidence of overactivity of the hypothalamic–pituitary–adrenal (HPA) axis has been reported in children, adolescents and adults with diabetes, including moderate increases in urinary free cortisol excretion, plasma cortisol and ACTH concentrations [61–64]. These abnormalities have been related to the duration of diabetes [62,63] and to the presence of diabetic neuropathy [64]. Serum cortisol levels fall as metabolic control improves [65].

---

## Pheochromocytoma

### Etiology, incidence and clinical features of pheochromocytoma

Pheochromocytomas are catecholamine-secreting tumors arising from the chromaffin cells of the adrenal medulla (Figure 17.9) [66,67]. Approximately 10% lie in extra-adrenal sites (paragangliomas) along the sympathetic chain in para-aortic or chest regions and approximately 10% are bilateral. Although most pheochromocytomas are sporadic, advances in molecular genetics have demonstrated that a hereditary basis underlies approximately one-fifth to one-quarter of diagnoses, not just in well-known syndromes, such as MEN2, von Recklinghausen

neurofibromatosis and von Hippel–Lindau disease [66]. Such advances have also associated particular genetic defects to tumor type. For instance, succinate dehydrogenase subunit B (*SDHB*) and succinate dehydrogenase subunit D (*SDHD*) mutations are more frequent in extra-adrenal tumors [66]. Mutations in *SDHB* are more commonly associated with a malignant phenotype [68]. The risk of malignancy also increases with tumor size [68].

The clinical manifestations of pheochromocytoma are largely caused by hypersecretion of catecholamines, classically as a triad of symptoms: headaches, sweating and tachycardia [69]. Hypertension is the most common clinical finding and occurs in 80–90% of cases. It can be paroxysmal or sustained, the latter occurring especially in children and in noradrenaline-secreting tumors [66]. Other symptoms may be secondary to the co-secretion of various other peptide hormones such as vasoactive intestinal peptide (VIP), substance P, atrial natriuretic factor, endothelin-1, CRH and GHRH [70]. The normal adrenal medulla predominantly secretes epinephrine, converted from norepinephrine by methylation. This reaction is governed by the enzyme phenylethanolamine-*N*-methyltransferase (PNMT), the expression of which is dependent on high concentrations of cortisol draining centripetally from the outer adrenal cortex towards the adrenal vein [69]. For this reason, larger tumors with more marked disturbance of the normal anatomy or extra-adrenal pheochromocytomas are notable for predominantly secreting norepinephrine as conversion to epinephrine is compromised.

### Features of disturbance to glucose tolerance in pheochromocytoma

Hyperglycemia occurs in up to approximately 50% of patients with pheochromocytoma. The prevalence of diabetes is approximately 35% [71]. Its presence in a young hypertensive person of normal body weight should raise suspicion of pheochromocytoma. The predominant mechanism is catecholamine-mediated reduction in insulin sensitivity and insulin secretion, predominantly caused by epinephrine rather than norepinephrine (Figure 17.10) [72,73]. Epinephrine inhibits  $\beta$ -cell insulin secretion via stimulation of  $\alpha_2$ -adrenergic receptors [74]. In the liver, epinephrine activates  $\beta_2$ -adrenoceptors to enhance glycogenolysis transiently and gluconeogenesis in a more sustained fashion [75–77]. This hepatic gluconeogenesis is fueled by the precursors, lactate, alanine and glycerol, generated by  $\beta_2$ -adrenergic stimulation of muscle glycolysis and adipose tissue lipolysis. Lipolysis in adipose tissue is also stimulated via the  $\beta_1$ - and  $\beta_3$ -adrenoceptors. In addition, epinephrine can impair glucose utilization in muscle through direct  $\beta_2$ -adrenergic effects. The predominance of these  $\beta_2$ -adrenergic effects probably explains why epinephrine, with its higher affinity for  $\beta_2$ -receptors, is more potent than norepinephrine in producing hyperglycemia [75,77]. All these effects are potent mechanisms that raise blood glucose, explaining why epinephrine release is an important component in correcting hypoglycemia after inhibition of insulin and increased glucagon secretion in the hierarchy of counter-regulatory responses (see Chapter 33).

**Figure 17.9** Pheochromocytoma in a 75-year-old man with recent-onset type 2 diabetes treated with a sulfonylurea, who was admitted on an emergency basis with severe chest pain and hypertension (blood pressure 240/130 mmHg). Blood glucose on admission was 27 mmol/L. Urinary catecholamine excretion was greatly increased, and a pheochromocytoma of the right adrenal was demon-

strated by: (a) computed tomography; (b) scanning with  $^{131}\text{I}$ -metaiodobenzylguanidine, which is taken up by catecholamine-synthesizing tissues; and (c) positron emission tomography with  $^{18}\text{F}$ -fluorodeoxyglucose. After laparoscopic removal of the tumor, diabetes and hypertension both resolved.

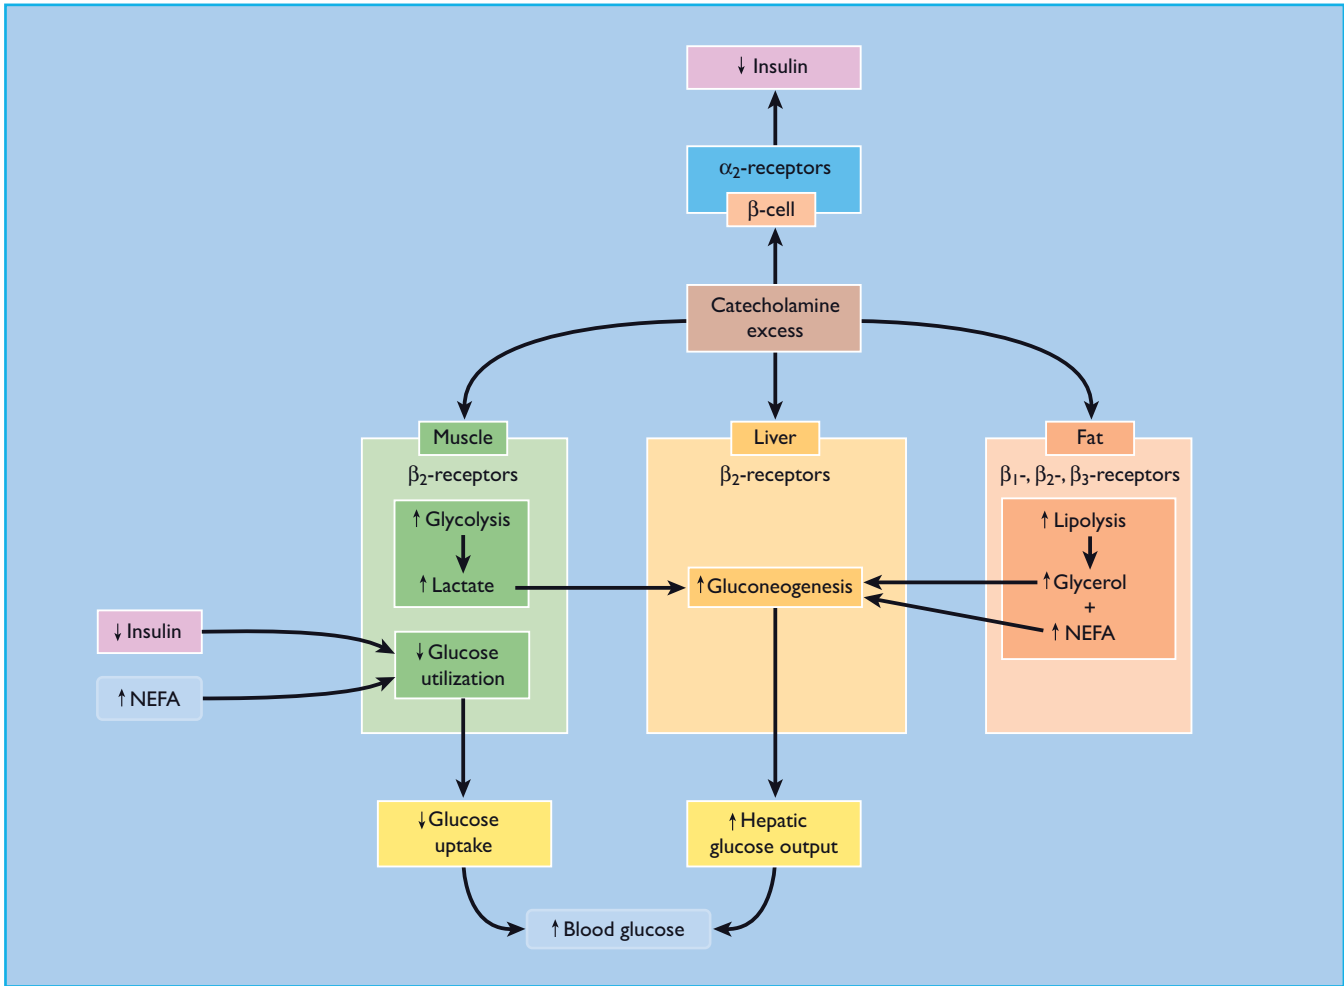

### Diagnosis and treatment of pheochromocytoma

Pheochromocytomas are diagnosed by demonstrating an excess of circulating catecholamines [66–68]. As a proxy marker, this can be achieved by several 24-hour urine collections measuring catecholamines, such as epinephrine, norepinephrine and their metabolites. Assessment of the metabolite vanillylmandelic acid is inadequate as it has a high false-negative rate [66]. Where specific circumstances dictate, for instance in screening those with a genetic predisposition to pheochromocytoma, or where urinary results are equivocal, serum measurement of normetanephrine and metanephrine are very sensitive and specific markers of pheochromocytoma (normetanephrine is the more sensitive) [67]. Imaging the tumor can be performed by either MRI or CT. Treatment is surgical removal of the tumor as an adrenalectomy, increasingly performed laparoscopically unless malignancy is suspected [66–68]. Preoperative preparation must

be meticulous to prevent both a hypertensive crisis during manipulation of the tumor and cardiovascular collapse after its removal. This is achieved by initial  $\alpha$ -receptor blockade followed by beta-blocker. The order of implementation is important to prevent a hypertensive crisis from unopposed  $\alpha$ -adrenoceptor stimulation. The preoperative  $\alpha$ -adrenergic blockade often controls hypertension, but has less effect on glucose intolerance [75,78]. In malignant pheochromocytoma where surgery is not possible, adrenolytic drugs, such as mitotane, can be used palliatively.

### Outcome of pheochromocytoma and disturbance to glucose tolerance

Removal of the tumor corrects the metabolic abnormalities. If presentation, diagnosis and treatment have occurred without undue delay, it also resolves the hypertension [56,75,78,79].

**Figure 17.10** Mechanisms of hyperglycemia in pheochromocytoma. NEFA, non-esterified fatty acid.

Although practice varies, greater understanding of the molecular genetics of pheochromocytoma makes clinical genetics input advisable; some laboratories now undertake germline mutation analyses in seemingly isolated tumors [66]. It is also straightforward to exclude hyperparathyroidism by measuring serum calcium as this simple test, if normal, goes a long way to excluding MEN1. Some clinics offer annual follow-up screening for pheochromocytoma by 24-hour urine collection. Patients with pheochromocytomas caused by identified genetic disorders should be followed up at least annually in dedicated clinical genetics endocrinology clinics.

**Effects of diabetes on adrenal medulla function**

Function of the adrenal medulla may be selectively impaired in patients with long-standing diabetes and hypoglycemia unawareness; attenuation of the epinephrine response to hypoglycemia can delay the restoration of normal serum glucose levels. Epinephrine responses can remain normal to other stimuli, indicating failure of sympathetic activation at a specific, possibly hypothalamic, level (see Chapter 33).

**Other endocrine conditions causing disturbance of glucose tolerance**

**Glucagonoma**

Glucagonoma is a rare tumor of the  $\alpha$ -cell of the pancreatic islet. The first clear-cut case was reported in 1942, but the “glucagonoma syndrome” (in a series of nine patients with similar symptoms) was not described until 1974 [80,81]. It may form part of MEN1 caused by mutations in the tumor suppressor gene, *MEN1* [82]. In a series of 21 patients [83], the syndrome’s most striking clinical features were weight loss (71%), necrolytic migratory erythema (67%) (Figure 17.11a), diabetes (38%), cheilosis or stomatitis (29%) and diarrhea (29%). In this report, patients with the combination of necrolytic migratory erythema and diabetes mellitus were diagnosed more rapidly (after a mean of 7 months), but some cases remain undetected for years. Glucagonoma should always be considered in patients with diabetes and unexplained weight loss or a chronic skin rash.

**Figure 17.11** Glucagonoma showing characteristic necrolytic migratory erythema (a) and multiple hepatic metastases (b). This patient had non-ketotic diabetes, controlled with low dosages of insulin; the rash recurred many times despite treatment with somatostatin analog. He died from pulmonary embolus. Courtesy of Professor Stephen Bloom, Imperial College School of Medicine, London.

Necrolytic migratory erythema (Figure 17.11a) is described in full in Chapter 47. It usually involves the buttocks, groin, thighs and distal extremities, and characteristically remits and relapses [80,81]. Hyperglucagonemia may contribute to the rash, as may hypoaminoacidemia through glucagon's enhancement of amino acid uptake by the liver and zinc deficiency [81]. The glucagonoma syndrome is also characterized by a normochromic normocytic anemia, a tendency to thrombosis (pulmonary embolism is a common cause of death) and neuropsychiatric disturbances [80]. Reporting of the prevalence of diabetes in glucagonoma has been variable but it probably affects approximately three-quarters of individuals [80]. In cohorts with this detection rate, the hyperglycemia has most commonly been mild and may respond to oral hypoglycemic agents. In studies with lower rates of diagnosis, 75% of patients required insulin [80]. The hyperglycemia is largely brought about by the effects of glucagon on stimulating hepatic gluconeogenesis and, in adequately fed individuals, glycogenolysis [81].

The diagnosis is suggested by finding a pancreatic mass and high fasting plasma glucagon concentration in the absence of

other causes of hyperglucagonemia (e.g. severe stress, hepatic and renal failure, poorly controlled diabetes, small-bowel malabsorption and synthetic androgenic drugs) [80,81]. Surgical removal of the tumor is the treatment of choice, but 50% of tumors have metastasized to the liver by the time of diagnosis (Figure 17.11b) [83]. Treatment can then be completed by hepatic artery embolization and/or chemotherapy; somatostatin analogs can also suppress glucagon secretion. The rash may respond to normalization of glucagon levels following removal of the tumor or the use of somatostatin analogs; the administration of zinc, a high-protein diet and control of the diabetes with insulin may also help [80,81,83].

### Somatostatinoma

Somatostatinomas are extremely rare tumors arising in 1 in 40 million individuals from  $\delta$ -cells of the pancreatic islet or enteroendocrine cells of the duodenum and ampulla of Vater [84]. They may be sporadic or as part of genetic syndromes, such as MEN1 [84]. The first two somatostatinomas were found incidentally during cholecystectomy [85,86], but a subsequent case was

diagnosed preoperatively and extensively investigated [87]. The diagnosis was suggested by the triad of diabetes, steatorrhea and gallstones, associated with a tumor of the duodenum [87]. These features, together with hypochlorhydria, are attributable to the widespread inhibitory effects of somatostatin on endocrine and exocrine secretions [84]. Consistent with inhibition of both insulin and glucagon by somatostatin, hyperglycemia is mild, non-ketotic and satisfactorily controlled without insulin [87].

Diagnosis is made by clinical presentation, measuring elevated fasting levels of circulating somatostatin and imaging by CT or MRI. Octreotide scintigraphy can also be used to localize the tumor. Surgical resection is the treatment of choice and can be curative. Where tumors are large and malignant with metastases at the time of diagnosis, debulking, embolization and chemotherapy (including radiolabeled somatostatin analogs) are appropriate [84].

### VIPoma

The first VIP-secreting tumor was recognized by Verner and Morrison in 1958 [88]. Classic features are caused by elevated circulating VIP levels and include watery diarrhea (pancreatic cholera), hypokalemia and achlorhydria [89]. Hypercalcemia and glucose intolerance occur in half of the patients, but overt diabetes is unusual; hyperglycemia is probably secondary to the glycogenolytic effect of VIP and/or to hypokalemia, which can impair both insulin secretion and insulin sensitivity. Diagnosis is aided by serum assay for fasting VIP levels. The tumors are usually large and have metastasized from the pancreatic tail by the time of diagnosis. Debulking surgery forms the mainstay of treatment and 10-year survival is approximately 40% [89].

### Hyperthyroidism

Hyperthyroidism is defined by overproduction of thyroid hormones. Hyperthyroidism leads to thyrotoxicosis; the manifestations of increased circulating thyroid hormones (Table 17.5) [90]. Ignoring the association of autoimmune hyperthyroidism (Graves disease) with T1DM, thyrotoxicosis per se can disturb glucose tolerance in approximately one-third of individuals, with diabetes occurring in a further 8% of patients [91]. There is evidence for insulin resistance as the primary defect [90,91], especially in those who are overweight [92], although insulin secretion may also be impaired [91,93]. Glucose production and expression of the hepatocyte glucose transporter 2 (GLUT-2) protein are enhanced by thyroid hormone excess [94,95]. The insulin resistance is improved with restoration of euthyroidism even if body mass index (BMI) rises [91]. When hyperthyroidism develops in insulin-treated patients with diabetes, glucose control deteriorates and insulin requirements increase in approximately half the patients; these changes are reversed following treatment of hyperthyroidism [96]. In addition to these alterations in insulin secretion and action, the response to oral glucose tolerance testing is also altered in hyperthyroidism because of faster intestinal absorption [97].

**Table 17.5** Clinical features of thyrotoxicosis plus features associated with Graves disease.

Clinical features of thyrotoxicosis
Weight loss despite full, possibly increased, appetite
Tremor
Heat intolerance and sweating
Agitation and nervousness
Palpitations, shortness of breath/tachycardia ± atrial fibrillation
Glucose intolerance
Amenorrhea/oligomenorrhea and consequent subfertility
Diarrhea
Hair loss
Easy fatigability, muscle weakness and loss of muscle mass
Rapid growth rate and accelerated bone maturation (children)
Specific features associated with Graves disease
Bruit in a diffuse, firm goiter
Thyroid eye disease, also called Graves orbitopathy
Pretibial myxoedema – thickened skin over the lower tibia
Thyroid acropachy (clubbing of the fingers)
Other autoimmune features (e.g. vitiligo)

### Primary hyperaldosteronism

Primary hyperaldosteronism was originally described by Conn in 1955 in a patient with hypertension, hypokalemia and neuromuscular symptoms associated with an adrenocortical adenoma secreting aldosterone [69]. A benign adenoma is the most common primary cause (65%) with bilateral hyperplasia accounting for 30% of cases. A handful of cases are brought about by a genetic recombination event between the genes encoding two closely related steroidogenic enzymes. This causes aldosterone secretion under the regulation of ACTH, which is suppressible by glucocorticoids [69]. Although debate is active over whether more subtle normokalemic aldosterone excess is a wider cause of hypertension, the relevance of primary hyperaldosteronism to glucose tolerance relies largely on the hypokalemia, which is part of the classic Conn syndrome as low serum potassium impairs insulin secretion [56,69]. Others have questioned whether aldosterone might exert other diabetogenic effects on glucose metabolism, although this remains unclear [98]. Glucose intolerance has been reported in approximately 50% of patients [99]. This is generally mild and overt diabetes is unusual. Defective insulin release has been implicated with delayed or reduced insulin responses following oral glucose challenge. Removal of the aldosteronoma or potassium loading can correct these defects [99].

### Primary hyperparathyroidism

Primary hyperparathyroidism is secondary to hypersecretion of parathyroid hormone (PTH), usually by a parathyroid adenoma and less commonly by parathyroid hyperplasia [100]. The prevalence of diabetes in primary hyperparathyroidism is approximately threefold higher than in the general population [101–103], with some cases requiring insulin therapy. Insulin resistance with

hyperinsulinemia is generally held responsible, with raised intracellular calcium limiting cellular glucose uptake [103]. It has been debated whether parathyroidectomy for primary hyperparathyroidism improves glucose homeostasis: some reports argue that it is beneficial for both diabetes and impaired glucose tolerance [104,105] while others find less effect [106,107]. Possibly this relates to duration and severity of the calcium disturbance. With the widespread availability of serum biochemistry, hyperparathyroidism is shifting from a symptomatic disorder to an asymptomatic one where serum calcium tends to be only marginally elevated. In the latter scenario, glucose tolerance appears less affected [108].

### Hypopituitarism with growth hormone deficiency

In children, lack of GH increases insulin sensitivity such that young GH-deficient children tend to develop fasting and readily provoked hypoglycemia [109,110]. Using insulin tolerance tests, GH-deficient children were more insulin-sensitive than short children with normal GH secretion [109]. This exaggerated insulin sensitivity attenuates with age and puberty, possibly following increased gonadal steroid production [109] such that adults with GH deficiency demonstrate insulin resistance [12]. Given that GH excess is diabetogenic and acute GH administration raises fasting glucose and fasting insulin levels, and reduces insulin sensitivity [14,17], the value of GH replacement to improve glucose tolerance is likely to be related to whether it can be administered physiologically.

Given this challenge, it is not surprising that the long-term results of GH replacement are somewhat conflicting [12]: a 30-month study showed a deterioration in glucose tolerance and insulin sensitivity despite an increase in lean body tissue and a reduction of fat mass [111]; another study of 6 months' duration found rises in fasting glucose and HbA<sub>1c</sub> without effects on peripheral or hepatic sensitivity [112]; however, a 5-year trial concluded that GH replacement decreased HbA<sub>1c</sub> levels [113]. Another study, evaluating the impact of GH therapy in GH-deficient patients during transition from childhood to adulthood, showed that the beneficial effects of chronic treatment on body composition did not overcome the direct antagonistic effects on insulin action [114]. Insulin secretion may also deteriorate during GH administration [111]. Thus, the replacement of GH in hypopituitary patients with diabetes is contentious: long-term treatment with GH may improve insulin sensitivity via improvements in body composition; however, such patients need to be monitored regularly and overtreatment that might lead to the development of diabetes should be avoided [12,115].

---

## Endocrine disorders that associate with diabetes

Several endocrine disorders that are associated with T1DM because of a common etiology and similar pathology (e.g. autoimmune adrenalitis [Addison disease] or autoimmune thyroid

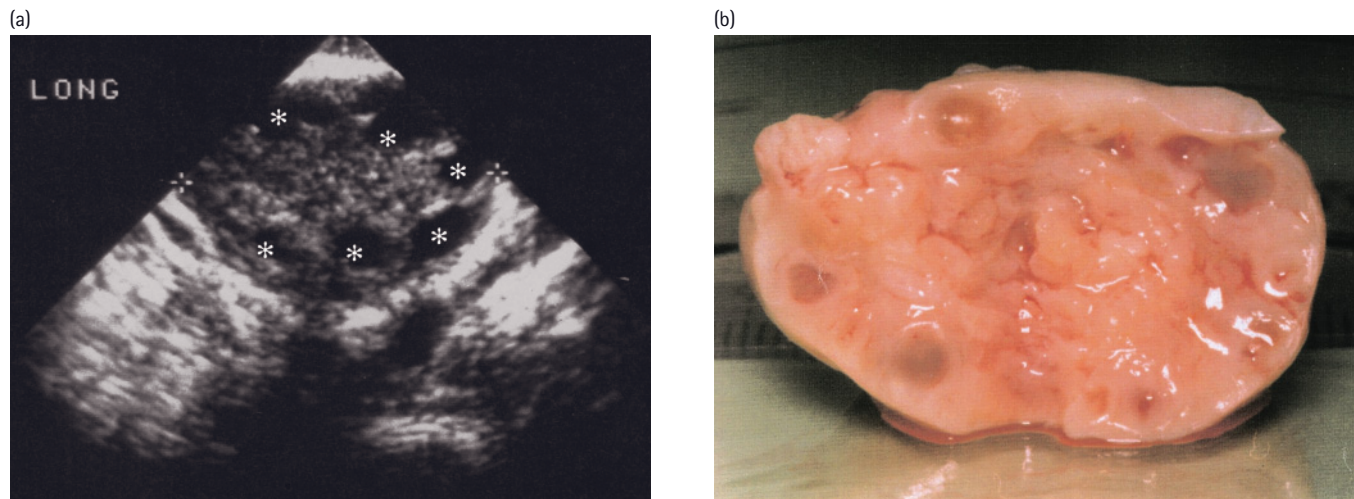

disease). Attention in these disorders is warranted for the onset of new autoimmune pathologies. In patients with T1DM, screening can be justified to exclude hyperthyroidism or hypothyroidism by measuring serum thyroid stimulating hormone (TSH) annually. The development of Addison disease in patients with T1DM markedly increases sensitivity to insulin such that unanticipated hypoglycemic reactions occur as dose requirements fall. Even in the absence of diabetes and insulin therapy, Addison disease can cause hypoglycemia, especially in children. Rare conditions resembling T1DM with associated endocrinopathies, such as the autoimmune polyglandular syndromes or POEMS syndrome may occur. Monogenic causes of diabetes that affect other endocrine organs are covered in Chapter 15. Examples (and their respective endocrine disorder) include the various types of hemochromatosis (primary hypogonadism), Wolfram syndrome (diabetes insipidus) and Kearns–Sayre syndrome (hypoparathyroidism, hypogonadism and hypopituitarism). Here, polycystic ovarian syndrome (PCOS) is addressed as a complex endocrine disorder that includes insulin resistance. The hormonal alterations in PCOS share relevance with some of the mechanisms underlying glucose homeostasis in pregnancy and obesity, covered in Chapters 53 and 14, respectively.

### Polycystic ovarian syndrome

PCOS is defined as clinical or biochemical hyperandrogenism with oligo- or anovulation where other definable causes have been excluded [116–120]. Some definitions incorporate the detection of multiple ovarian cysts into the diagnosis [119,120], although these occur in approximately half of patients with Cushing syndrome and are non-discriminatory (Figure 17.12) [121,122]. PCOS occurs in 5–10% of women of reproductive age and is characterized primarily by insulin resistance although there is also evidence of  $\beta$ -cell dysfunction [123,124]. Impaired glucose tolerance and T2DM are present in nearly 40% and 7.5–10%, respectively, of women with PCOS, with the former having a tendency to progress to T2DM and being associated with an approximate threefold higher risk of gestational diabetes [123,124]. These data are confounded to some degree by the effect of obesity, but the incidence of PCOS remains increased across ethnicities whereas obesity rates vary [124]. Indeed, it can be argued that PCOS in women with normal BMI represents the most severe form of the disorder where genetic screening programs are most likely to identify PCOS susceptibility genes.

The source of the androgens is both the adrenal cortex and the ovary [124]. The raised insulin levels can stimulate androgen production by the ovary and interfere with other aspects of ovarian function. Within the adrenal cortex, where insulin receptors are expressed in the zona fasciculata of the adrenal cortex [125], there is some evidence that insulin can influence glucocorticoid versus sex steroid precursor production [124].

The diagnosis of PCOS is one of exclusion, meaning that clinical and biochemical findings are only supportive of the condition

**Figure 17.12** Polycystic ovary syndrome, showing (a) characteristic ultrasonographic appearance of large, mainly peripheral cysts (asterisks) and (b) the cut surface of a polycystic ovary. [116,121]. Serum estradiol is detectable and usually  $>200$  pmol/L. Endocrine abnormalities include increases in serum luteinizing hormone (LH) leading to a raised LH:FSH (follicle stimulating hormone) ratio, androstenedione and testosterone concentrations. Serum sex hormone-binding globulin (SHBG) levels are commonly low. Ovarian ultrasound is useful to help exclude the presence of a tumor underlying the androgen excess [121].

Further evidence that the condition is caused by insulin resistance comes from its amelioration with exercise and agents that improve insulin sensitivity such as metformin or thiazolidinediones [126]. As well as lowering blood glucose, these agents improve menstrual regularity and increase the chance of ovulatory cycles [126].

## Pancreatic Diseases and Diabetes

### Ranjit Unnikrishnan & Viswanathan Mohan

Dr. Mohan's Diabetes Specialities Centre, Madras Diabetes Research Foundation (WHO Collaborating Centre for Non-communicable Diseases Prevention and Control & IDF Centre of Education), Chennai, India

#### Keypoints

- Pancreatic disease is a rare cause of diabetes.
- Acute pancreatitis is associated with transient hyperglycemia which rarely persists.
- Chronic pancreatitis secondary to any cause can lead to permanent diabetes which is typically difficult to control; imaging studies reveal dilated ducts and pancreatic calculi.
- Tropical calcific pancreatitis is a disease of unknown etiology found in low and middle income countries associated with large pancreatic calculi and diabetes (fibrocalculous pancreatic diabetes).
- Hereditary hemochromatosis is an inherited disorder that produces diabetes secondary to iron deposition in the pancreatic islets and subsequent islet cell damage.
- Pancreatic carcinoma may complicate type 2 diabetes, diabetes secondary to chronic pancreatitis and, most commonly, with fibrocalculous pancreatic diabetes. It is important to suspect malignancy in any patient who complains of back pain, jaundice or weight loss in spite of good glycemic control.
- Pancreatic surgery can lead to diabetes that is insulin-requiring and often difficult to control.
- Cystic fibrosis is a relatively common genetic disorder affecting the lung, pancreas and other organs. Up to 75% of adults with cystic fibrosis have some degree of glucose intolerance.

### Introduction

Pancreatic disease is a rare cause of diabetes, accounting for less than 0.5% of all cases of diabetes. A number of disease processes affecting the pancreas can lead to diabetes; some of these are listed in Table 18.1.

Most of these conditions damage the exocrine as well as endocrine components of the pancreas. The exocrine parenchyma and islet tissue lie in intimate contact with each other and are functionally related. This may explain why parenchymal disease can readily impair  $\beta$ -cell function [1].

### Acute pancreatitis

Acute pancreatitis varies considerably in its impact on the gland and its metabolism. Pathologic findings vary from mild edema to hemorrhagic necrosis, and the clinical presentation spans a wide spectrum from mild to fulminating or fatal illness.

The most common causes of acute pancreatitis are alcoholism and gallstone disease. Table 18.2 sets out the causes of acute

pancreatitis. Classically, the disease presents with sudden onset of epigastric pain, associated with nausea and vomiting, aggravated by food and partially relieved by sitting up and leaning forward. Physical examination reveals low grade fever, tachycardia and hypotension. Jaundice may also be found infrequently. Cullen sign (periumbilical discoloration) and Grey Turner sign (flank discoloration) indicate severe necrotizing pancreatitis.

Commonly found metabolic abnormalities include hyperglycemia, hypocalcemia, hyperlipidemia, hypoalbuminemia and coagulation disorders [2]. Serum levels of amylase and lipase are elevated, but these are neither sensitive nor specific. Computed tomography (CT) or magnetic resonance imaging (MRI) shows edema of the pancreas. Loss of the normal enhancement on dynamic CT scanning indicates pancreatic necrosis.

Most patients with acute pancreatitis develop transient hyperglycemia, which mostly results from a rise in glucagon levels rather than from  $\beta$ -cell injury [3]. Hyperglycemia is usually mild and resolves within days to weeks without needing insulin treatment. Permanent diabetes is rare and occurs mostly in cases with fulminant disease and multiorgan failure, in whom the incidence approaches 25% [4]. Blood glucose levels exceeding 11.1 mmol/L (200 mg/dL) during the first 24 hours indicate a poor prognosis [5].

Non-specific elevations of serum amylase and lipase may also be found in diabetic ketoacidosis [6]. Acute pancreatitis, however,

<b>Inflammatory</b>
Acute
Chronic, including fibrocalculous pancreatic diabetes
<b>Infiltration</b>
Hereditary hemochromatosis
Secondary hemochromatosis
Very rare causes: sarcoidosis, amyloidosis, cystinosis
<b>Neoplasia</b>
Adenocarcinoma of the pancreas
Glucagonoma
<b>Surgical resection or trauma</b>
Cystic fibrosis

may affect up to 11% of patients with ketoacidosis, usually with mild or even no abdominal pain [5].

## Chronic pancreatitis

This condition is characterized by progressive and irreversible destruction of the exocrine pancreatic tissue, leading to exocrine pancreatic insufficiency and varying degrees of glucose intolerance which often require insulin. The causes of chronic pancreatitis vary according to the geographic location (Table 18.3).

Alcohol abuse accounts for most of the cases (>85%) in Western populations. Alcohol alters the composition of pancreatic secretions, leading to the formation of proteinaceous plugs that block the ducts and act as foci for calculi formation. Tropical pancreatitis is a distinct form of the disease that is not associated with excessive alcohol intake and is prevalent in the developing world [7].

Hereditary chronic pancreatitis is a rare entity, inherited in an autosomal dominant fashion. Mutations in a number of genes have been implicated including *PRSS1* (encoding cationic trypsinogen), *SPINK1* (serine protease inhibitor, Kazal type 1) and *CFTR* (cystic fibrosis transmembrane conductance regulator) [8–11].

Obstructive chronic pancreatitis is a rare condition that follows occlusion of pancreatic ducts by tumors, scarring, pseudocysts or congenital anomalies. Stones are not seen. Surgery or endoscopic dilatation may occasionally be curative.

Idiopathic pancreatitis, which accounts for 10–20% of all cases, affects two distinct age groups, one with onset at 15–25 years and the other at 55–65 years [12]. Cigarette smoking is a risk factor and mutations in specific genes have also been postulated [11,13,14].

## Epidemiology

Chronic pancreatitis is prevalent worldwide. In Western countries, the incidence is about 4 cases per year per 100 000 popula-

**Table 18.2** Causes of acute pancreatitis.

<b>Common (75% of cases)</b>	<b>Uncommon</b>
Alcohol abuse	<b>Drugs</b>
Gallstone disease	Sulfonamides
Idiopathic	Tetracyclines

	Pancreatic cancer
	Connective tissue diseases
	Pancreas divisum

ERCP, endoscopic retrograde cholangiopancreatography.

**Table 18.3** Causes of chronic pancreatitis.

<b>Common (90% of cases)</b>	<b>Rare</b>
Alcohol abuse	Hereditary relapsing pancreatitis
Idiopathic	Obstructive chronic pancreatitis
Tropical calcific pancreatitis	

tion [15,16]. Tropical chronic pancreatitis is confined to tropical and subtropical regions of the world.

## Pathologic features

The term chronic calcific pancreatitis accurately describes the pathologic changes in over 95% of cases of chronic pancreatitis in Western countries. The ductal and acinar lumina are filled with proteinaceous plugs which later calcify, forming small stones composed chiefly of calcium carbonate or calcite. Huge stones can occur but are more characteristic of tropical pancreatitis. The stones are found diffusely throughout the affected organ. Microscopically, there is atrophy of the ductal epithelium and stenosis of the ducts, associated with patchy fibrosis. There may also be foci of necrosis, with infiltration by lymphocytes, plasma cells and histiocytes [17]. Ultimately, the pancreas shrivels and develops an opaque capsule that may adhere to surrounding organs.

**Figure 18.1** Nesidioblastosis, from a case of fibrocalculous pancreatic diabetes, showing islet tissue arising from ductal remnants. Stain aminoethylcarbazole; magnification  $\times 40$ .

**Table 18.4** Islet cell changes in chronic pancreatitis [25].

Cell type	Changes observed
$\beta$ -cells	Decreased numbers (40% below controls)
$\alpha$ -cells	Increased numbers
$\beta$ -cell : $\alpha$ -cell ratio	0.6–2.5 (controls, 3.0–3.5)
PP cells	Increased numbers
$\delta$ (D) cells	Unchanged

As fibrosis progresses, the acini atrophy and eventually disappear, leaving clusters of islets surrounded by sclerosed parenchyma. Neof ormation of islet cells from ductal tissue can occur (nesidioblastosis) (Figure 18.1). Immunohistochemistry studies reveal generalized decrease in the number of islets, accompanied by overall reduction in  $\beta$ -cell density and insulin immunoreactivity which correspond to disease duration and C-peptide levels (Figure 18.2; Table 18.4) [18,19].

### Clinical features and diagnosis

Abdominal pain is the predominant symptom and the usual reason for seeking medical care. The pain is usually steady, boring and agonizing and located in the epigastrium or left hypochondrium with radiation to the dorsal spine or the left shoulder. Bending forward or assuming the knee–chest position relieves the pain. The cause of the pain is unknown, but may relate to increased intrapancreatic or intraductal pressure, or to ischemia of the pancreas. It tends to remit and relapse and follows an unpredictable course. The development of end-stage pancreatic disease is associated with disappearance of the pain in many cases.

**Figure 18.2** Histologic features of chronic pancreatitis, from cases of fibrocalculous pancreatic diabetes. (a) Exocrine tissue is entirely replaced by dense fibrosis that spares the islets. Hematoxylin and eosin stain; magnification  $\times 40$ . (b) A hyperplastic islet. Section immunostained for insulin; magnification  $\times 40$ .

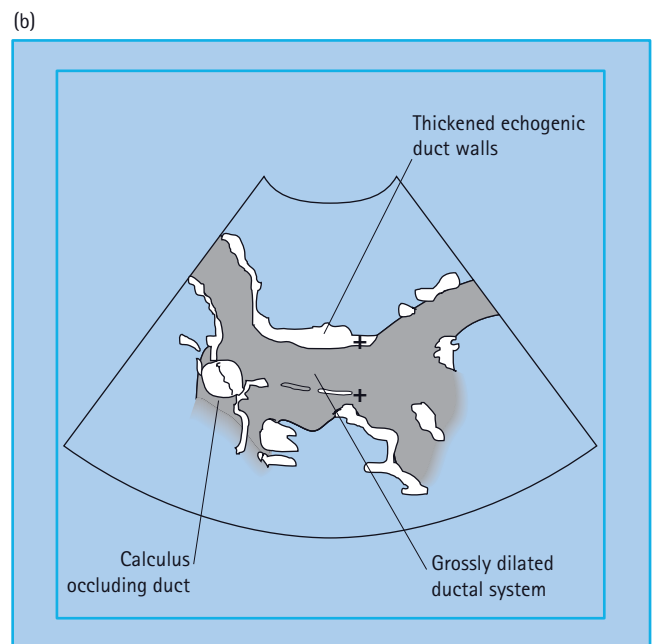

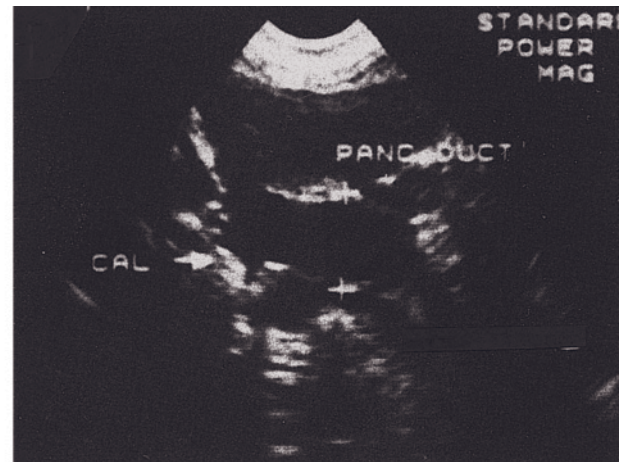

Exocrine pancreatic insufficiency may manifest with steatorrhea and features of fat-soluble vitamin deficiency. Steatorrhea may not be apparent on a low-fat diet. The combination of oily and greasy stools with diabetes should raise the suspicion of chronic pancreatitis.

### Investigations

Demonstration of pancreatic calculi on a plain X-ray of the abdomen is diagnostic (Figure 18.3). In cases where obvious calculi cannot be found, ultrasonography, CT scanning or endoscopic retrograde cholangiopancreatography (ERCP) will help to confirm the diagnosis. ERCP is considered the gold standard and usually reveals irregular dilatation of the pancreatic ducts with filling defects caused by stones (Figure 18.4). CT scanning shows patchy increases in parenchymal density and, ultimately, atrophy of the gland.

**Figure 18.3** Pancreatic calculi, showing characteristic patterns in (a) alcoholic chronic pancreatitis, and (b) fibrocalculous pancreatic diabetes.

**Figure 18.4** Investigations in chronic pancreatitis. (a) Endoscopic retrograde cholangiopancreatogram, showing dilatation and irregularity of the pancreatic ductal system in a patient with alcoholic chronic pancreatitis. Courtesy of Professor Jonathan Rhodes, Liverpool. (b) Ultrasound scan of the pancreas from a patient with fibrocalculous pancreatic diabetes, demonstrating highly echogenic parenchyma and duct walls (fibrosis), grossly dilated ducts and calculi. Courtesy of Dr. S. Suresh, Chennai, India.

Exocrine pancreatic function can be assessed by measuring the urinary excretion of compounds that are liberated in the gut by pancreatic enzyme action on orally ingested precursors such as NBT-PABA (para-aminobenzoic acid) or fluorescein dilaurate (pancreolauryl). Screening tests of pancreatic enzymes (fecal chymotrypsin, fecal elastase) are also used as they are simpler to perform but are less specific. Measurement of pancreatic output (via a tube placed in the duodenum) following ingestion of the Lundh test meal may also be helpful. Serum amylase is usually normal, except during acute attacks.

### Diabetes in chronic pancreatitis

Abnormal glucose tolerance and diabetes complicate around 40–50% of cases of chronic pancreatitis. Unlike acute pancreatitis, the cause here is damage to the  $\beta$ -cells, owing to loss of trophic signals from the exocrine tissue [1,20]. The diabetes is of insidious onset and usually occurs several years after the onset of pain. The prevalence has been assessed at 60% after 20 years [21]. Half or more of patients require insulin for optimal glycemic control [22,23], but ketoacidosis is rare, even if insulin is withdrawn. Possible explanations include better preservation of  $\beta$ -cell function (compared with type 1 diabetes; T1DM) [24], reduced glucagon secretion and lower body stores of triglyceride, the major substrate for ketogenesis [24,25]. On account of the lower glucagon reserve, these patients are also prone to severe and prolonged hypoglycemia, and often diabetes is difficult to control with wide fluctuations of blood glucose levels.

### Chronic diabetic complications

It was originally thought that patients with pancreatic diabetes were not at increased risk of microvascular complications. It has now been shown that retinopathy [26], nephropathy [27] and neuropathy [28] occur in these patients at frequencies similar to those with type 2 diabetes (T2DM). The risks of macrovascular complications, however, are relatively low. This may partly be explained by the low blood lipid levels that often accompany the malnutrition commonly seen in these patients [29].

### Management of diabetes in chronic pancreatitis

Removal of obvious causes such as alcohol and hypertriglyceridemia will help to prevent progression of the damage to the gland.

Pain can be very difficult to manage. Measures include total abstinence from alcohol, dietary modification (small frequent meals with low fat content), analgesics and the somatostatin analogue, octreotide, which suppresses pancreatic exocrine secretion. In a subgroup of patients, massive doses of non-enteric-coated preparations of pancreatic enzymes have been shown to reduce pain. Surgical interventions include sphincterotomy, internal drainage of pancreatic cysts, endoscopic removal of calculi (via ERCP), insertion of duct stents and denervation procedures. Total resection of the pancreas followed by whole pancreas or islet cell transplantation may be an option for intractable cases.

Malabsorption can be effectively treated with a low fat diet with pancreatic enzyme supplements (along with histamine H<sub>2</sub> blocker or proton pump inhibitor to block gastric acid secretion) taken at meal times.

Diabetes can be managed along conventional lines, with a few caveats. High carbohydrate and protein intakes are encouraged along with fat restriction in order to prevent steatorrhea. Over 80% of patients require insulin; however, the required doses are typically low, around 30–40 units/day [22,23]. Diabetic control is often difficult to achieve, with frequent and severe hypoglycemia; reduced glucagon secretion may be responsible.

---

### Tropical calcific pancreatitis

This is a distinct variety of chronic pancreatitis seen predominantly in low and middle income countries in the tropical and subtropical regions of the world [30,31]. This entity was first reported in 1959 by Zuidema [31] in patients from Indonesia. Later on, the disease was reported from several countries in Africa and Asia. The highest prevalence appears to be in Southern India, particularly in the states of Kerala and Tamil Nadu [32].

The disease usually starts in childhood with recurrent abdominal pain and during adolescence progresses to large pancreatic calculi and ductal dilatation (Figures 18.3 and 18.5). By adulthood, frank diabetes is found in more than 90% of patients [33]. Nevertheless, it remains a rare cause of diabetes, constituting less than 1% of all cases of diabetes even in regions where it is most prevalent [34]. A recent study in urban southern India reported a prevalence of 0.36% among subjects with self-reported diabetes and 0.019% among the general population [35].

The term tropical calcific pancreatitis is used to denote the prediabetic stage of the disease whereas the term fibrocalculous pancreatic diabetes (FCPD) is used to describe the clinical picture once diabetes has supervened (Figure 18.6).

The etiology of this condition remains unknown. Poor nutrition has been implicated as a possible factor; however, this may be the consequence rather than a cause of the pancreatopathy. The condition can also affect well-nourished individuals [36]. In the past, attention was also focused on the role of dietary toxins

**Figure 18.5** Calcific stones of various sizes removed from the pancreas of a patient with fibrocalculous pancreatic diabetes.

such as cyanogens (found in cassava), but this link has not been substantiated. Cases have been found to cluster in families, which may suggest a genetic etiology for the disease [37–40]. A number of studies have reported an association between the *SPINK1* gene and tropical calcific pancreatitis [41–47]. A role has also been suggested for oxidant stress and free radical-mediated injury but this has not been proven conclusively [48].

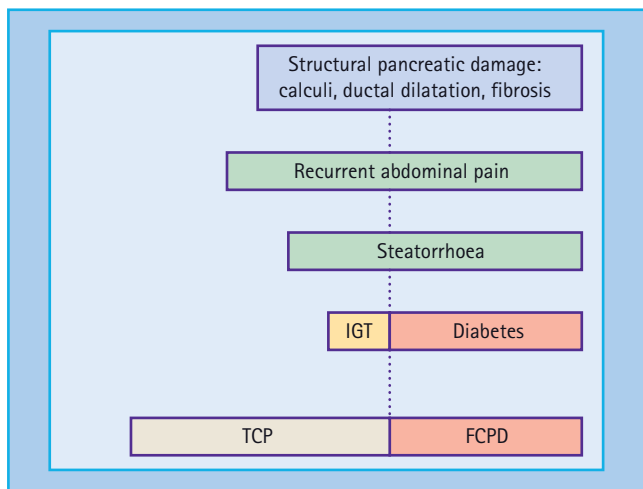

Salient differences between alcoholic chronic pancreatitis and tropical calcific pancreatitis are summarized in the Table 18.5. The classic clinical triad of tropical calcific pancreatitis consists of abdominal pain, steatorrhea and eventually diabetes. The disease often progresses steadily from euglycemia through impaired glucose tolerance to frank diabetes. Most patients require insulin but are generally not prone to ketosis; some can be managed with oral antidiabetic agents (Figure 18.7). Studies have shown that the risk of developing pancreatic carcinoma in tropical calcific pancreatitis is 100-fold greater than in those without the disease and is much higher than in other forms of

chronic pancreatitis [49]. Pancreatic malignancy should be suspected in individuals with tropical calcific pancreatitis if they complain of intractable pain or significant weight loss even after attaining good glycemic control.

Management of tropical calcific pancreatitis and FCPD is similar to that outlined for chronic pancreatitis.

### Hereditary hemochromatosis

This condition, also called idiopathic or primary hemochromatosis, is the most common autosomal recessive genetic disorder in Caucasians, with a prevalence of 4–5 per 1000 [50,51]. The classic triad of diabetes, cirrhosis and bronzed hyperpigmenta-

**Table 18.5** Differences between tropical calcific pancreatitis and alcoholic chronic pancreatitis.

	Tropical calcific pancreatitis	Alcoholic chronic pancreatitis
<b>Demographic features</b>		
Male:female	70:30	90:10
Peak age at onset (years)	20–30	30–50
Socioeconomic status	Poor > affluent	All groups
Alcohol abuse	Absent	Present
<b>Pancreatic morphology</b>		
Prevalence of calculi	>90%	50–60%
Features of calculi	Large; in large ducts	Small, speckled; in small ducts
Ductal dilatation	Usually marked	Usually moderate
Fibrosis	Heavy	Variable
Risk of pancreatic cancer	Markedly increased	Increased
<b>Diabetes</b>		
Prevalence	>90%	50%
Time course	Faster evolution	Slower evolution

**Figure 18.7** The spectrum of diabetes in fibrocalculous pancreatic diabetes. Data from Mohan *et al.* [29].

tion of the skin was first described by Trousseau in 1865 and called “hemochromatosis” by von Recklinghausen in 1889 [52].

### Etiology and pathology

#### Genetic basis

Most cases of primary hemochromatosis arise from mutations in the hemochromatosis gene (*HFE*), located on the short arm of chromosome 6, close to the major histocompatibility complex (MHC), which explains the linkage with HLA A3 [53]. The *HFE* protein encoded by this gene is expressed on the cell surface of various tissues, including the enterocytes of the duodenal brush border, where iron is chiefly absorbed. The *HFE* gene modulates iron absorption by binding to the transferrin receptor. In two-thirds of cases, a C282Y mutation (substitution of cysteine by tyrosine at position 282) in the *HFE* gene is responsible [50]. Another mutation, H63D, seems to act synergistically with C282Y [54]. These mutations inhibit the binding of *HFE* to transferrin, leading to excessive and inappropriate increase in intestinal iron absorption and greatly increased body iron stores. Non-*HFE* mutations are also rarely found to be responsible in some cases.

#### Pathophysiology

The primary defect is excessive iron absorption across the mucosa of the proximal small intestine, which continues even in the setting of greatly increased total body iron stores (often 15–20 g; cf. normal adult iron stores of 1–2 g). Excess iron is deposited preferentially in the liver, pancreas (exocrine tissue as well as islets), pituitary, heart and parathyroids (Figure 18.8). Tissue injury is postulated to occur as a result of rupture of iron-laden lysosomes, generation of free radicals (by the Fenton reaction) and by the stimulation of collagen synthesis by activated stellate cells.

### Clinical features

The classic clinical features are hepatic cirrhosis, diabetes and skin hyperpigmentation (“bronzed diabetes”) (Figure 18.9). Hepatic fibrosis and cirrhosis usually only develop after age 40 years, unless other factors such as alcoholism are present. Portal hypertension, hepatic failure and hepatocellular carcinoma (in 15% of cases) are late sequelae [55]. Bronzing of the skin, which occurs in 70% of cases but may be less evident in darker-skinned races, is caused by both iron deposition in the subcutaneous tissue and increased melanin in the basal dermis. Hypopituitarism, hypogonadism, hypoparathyroidism and chondrocalcinosis with pseudogout are less common features.

Presenting symptoms include weakness, weight loss, diabetic symptoms, arthralgia, erectile dysfunction and skin pigmentation. Signs include hepatosplenomegaly, heart failure, skin pigmentation, testicular atrophy, arthropathy, hypogonadism and occasionally hypothyroidism. Many patients with hemochromatosis, however, are asymptomatic and may be detected during investigation for unrelated reasons.

### Diabetes in primary hemochromatosis

The prevalence of diabetes depends on the severity of iron overload and presence of cirrhosis [56]. Up to 50% of patients have glucose intolerance and 25% have overt diabetes [57], although the disease is an extremely rare cause of diabetes in the general population. Both insulin resistance and  $\beta$ -cell failure contribute to the development of diabetes, and most patients eventually require insulin. These patients are prone to both microvascular and macrovascular complications [58], the risk of nephropathy being particularly high in those carrying the H63D mutation [59].

**Figure 18.8** Hereditary hemochromatosis. Perls stain shows heavy iron deposition (blue) in exocrine and islet tissue in the pancreas (arrows). Original magnification  $\times 375$ . Courtesy of Dr. A. Clark, Wirral Hospital, UK.

**Figure 18.9** Clinical features of hereditary hemochromatosis. The classic triad comprises diabetes, cirrhosis and hyperpigmentation of the skin (“bronzed diabetes”).

### Investigations and diagnosis

The diagnosis should be suspected in any patient with diabetes, hepatomegaly or liver disease, skin pigmentation, arthritis and hypogonadism. A high index of suspicion is required to make an early diagnosis, because significant iron overload can exist with few or none of these clinical manifestations.

The total-body iron stores can be assessed using measurement of serum ferritin and percent saturation of transferrin. Serum ferritin is a useful screening test for relatives of affected individuals, but because ferritin is an acute phase reactant whose levels can be elevated in inflammatory states, abnormally high results should be confirmed by other tests (Table 18.6) [60]. Serum iron and percent saturation of transferrin are elevated early in the course of the disease, but lack specificity. A combined measurement of the percent transferrin saturation and serum ferritin levels provide a simple and reliable screening test for hemochromatosis. A positive test mandates genetic testing.

The role of liver biopsy in diagnosis and management of hemochromatosis has significantly diminished following the development of genetic testing for the C282Y mutation. The major role of liver biopsy at the present time is in excluding the presence of cirrhosis, which is a major risk factor in the development of hepatocellular carcinoma. Hepatic iron overload can also be detected using imaging techniques such as CT or MRI scanning.

All first-degree adult relatives of a patient with hemochromatosis should be tested for C282Y and H63D mutations, in an attempt to detect disease in the early precirrhotic phase at which stage treatment can prevent further progression.

### Treatment

Treatment of hereditary hemochromatosis is by repeated venesection, which must be started as early as possible. Removal of excess iron by venesection prevents diabetes and cirrhosis and prolongs survival (Figure 18.10). Chelating agents such as desfer-

**Table 18.6** Diagnostic tests in hereditary hemochromatosis [60].

	Hemochromatosis	Normal
Serum iron ( $\mu\text{g/dL}$ )	180–300	50–150
Transferrin saturation	80–100	20–50
Total iron-binding capacity ( $\mu\text{g/dL}$ )	200–300	250–370
Serum ferritin ( $\mu\text{g/dL}$ )		
Men	500–6000	20–300
Women	500–6000	15–250
Hepatic iron concentration ( $\mu\text{g/g}$ dry weight)	10 000–30 000	300–1800

**Figure 18.10** Venesection treatment in hereditary hemochromatosis. When treatment is started before the onset of cirrhosis or diabetes, life expectancy is normalized. Adapted from Dymock *et al.* [58].

rioxamine are more expensive, less safe and less effective than venesection. Diabetes may be improved by venesection, but usually requires insulin treatment. Management is often complicated by hypoglycemia caused by concomitant  $\alpha$ -cell damage and glucagon deficiency. Hepatic transplantation for hereditary hemochromatosis were previously associated with a poor prognosis, but survival rates have improved of late. Diabetes tends to worsen after transplantation because of the use of immunosuppressant drugs [61].

### Secondary hemochromatosis

Conditions such as thalassemia major, which require frequent blood transfusion, may lead to massive iron overload. Pancreatic damage and diabetes frequently result. The duration of disease and number of transfusions correlate well with the degree of glucose intolerance. It has been postulated that iron overload may induce autoimmune attack against the  $\beta$ -cells, thereby contributing to development of diabetes [62].

---

### Pancreatic neoplasia

Adenocarcinoma of the pancreas is the fifth most common cause of cancer death and is increasing in its incidence [63]. It has a poor prognosis, with a 5-year survival rate of less than 3%.

Although diabetes has long been associated with pancreatic adenocarcinoma, the nature and strength of the association remain controversial. A meta-analysis of 20 epidemiologic studies showed a twofold increased risk of pancreatic cancer among people with diabetes of more than 5 years' duration [64], suggesting that diabetes is a risk factor for the neoplasm. Other studies, however, have concluded that the cancer preceded and caused the diabetes [65], a view supported by observations that diabetes may improve after resection of the tumor. Some studies have even suggested that diabetes protects against pancreatic cancer [66]. Tropical chronic pancreatitis is associated with a 100-fold increase in the risk of developing pancreatic carcinoma [50].

The diagnosis of pancreatic carcinoma must be suspected in any patient with T2DM who complains of unexplained weight loss (despite insulin therapy and apparently good control of diabetes), back pain or jaundice.

---

### Pancreatic surgery and diabetes

Diabetes is a frequent complication of pancreatic resection performed for various indications. The incidence and severity of diabetes depends on the extent of resection of the distal segment, where the islets are most abundant. In one study, diabetes developed in 56% of cases following distal resection [67].

Diabetes is more likely to follow subtotal pancreatectomy than procedures such as lateral pancreaticojejunostomy and pancreaticoduodenectomy (Whipple procedure). Diabetes is obviously inevitable following total pancreatectomy.

### Management of diabetes caused by pancreatic surgery

The diabetes is usually difficult to control, with wide excursions in blood glucose levels. Patients are exquisitely insulin-sensitive and prone to hypoglycemia as a result of the loss of glucagon function. Frequent small meals and multiple small doses of insulin can minimize these problems to an extent. Use of a subcutaneous insulin infusion pump may be beneficial in some cases. Patients with diabetes following pancreatectomy are ideal candidates for whole pancreas or islet cell transplantation.

Associated exocrine pancreatic insufficiency should also be addressed. Meals should be low in fat and high in carbohydrate and protein. Pancreatic enzyme therapy will help in controlling steatorrhea and stabilizing blood glucose [68].

---

### Cystic fibrosis

Cystic fibrosis is a multisystem disease characterized by recurrent airway infection leading to bronchiectasis, pancreatic insufficiency, abnormal sweat gland function and urogenital dysfunction. It is an autosomal recessive disorder caused by mutations in the *CFTR* gene located on chromosome 7q22. This gene encodes a protein, cystic fibrosis transmembrane conductance regulator (CFTR), which regulates the chloride secretion across epithelial surfaces. Various mutations have been described of which deletion of the phenylalanine residue at position 508 ( $\Delta 508$ ) is the most common [69,76]. The defect produces unusually viscous secretions which lead to pancreatic ductular obstruction, dilatation and pancreatic insufficiency. The incidence is 1 in 2500 live births in Caucasian populations, but the disease is much less common in Africans and Asians [70].

The most common clinical features are steatorrhea, failure to thrive and growth retardation, recurrent lung infections, hepatobiliary complications and symptoms of fat-soluble vitamin deficiency such as night blindness. The diagnosis is confirmed by the presence of an elevated sweat chloride concentration in excess of 60 mmol/L.

### Diabetes in cystic fibrosis

The incidence of diabetes in children with cystic fibrosis is 2–3% (about 20 times higher than in the general population). The incidence rises steadily through adolescence, with up to 25% of patients in their twenties developing diabetes and a further 50% having glucose intolerance [71].

As the treatment of the lung disease in cystic fibrosis has improved, more and more patients are surviving into adulthood. This has led to an increase in the prevalence of diabetes in cystic fibrosis.

The major factor in the pathogenesis of diabetes is damage to the pancreatic  $\beta$ -cells secondary to exocrine pancreatic degeneration. Other postulated mechanisms include enhanced absorption of glucose [72] and autoimmune attack against the  $\beta$ -cell, which may explain why T1DM is more common in relatives of patients with cystic fibrosis [73]. The physiologic insulin resistance of

normal puberty may also contribute. Interestingly, diabetes develops more commonly in patients homozygous for  $\Delta 508$  than in heterozygotes [74].

Diabetes is usually insidious in onset and characterized by a delayed, flattened and prolonged insulin secretory response to glucose [75]. Ketoacidosis is rare, although insulin treatment is usually required. As patients now survive longer [69], chronic microvascular complications are also frequently seen.

### Management

Although some patients initially respond to sulfonylureas, most ultimately need insulin [76]. In addition to controlling diabetes, insulin also improves body weight and pulmonary and pancreatic function [71,77,78]. Starting from adolescence, all patients with cystic fibrosis should be regularly screened for diabetes using the oral glucose tolerance test or serial measurements of HbA<sub>1c</sub> [78].

Dietary modification in patients with cystic fibrosis who also have diabetes presents much the same difficulties as in patients with chronic pancreatitis. A diet rich in carbohydrates and protein but restricted in fat is recommended. Oral pancreatic enzyme therapy helps to improve nutrient digestion and absorption. Enteric-coated preparations of lipase can control steatorrhea. Fibrosing colonopathy is a concern in patients receiving higher strengths of lipase [79].

### Conclusions

Although rare, diabetes secondary to pancreatic disease is potentially important. The underlying pancreatic disease may need treatment in its own right, while disorders with a genetic basis must be identified so that other family members can be screened. Diagnosis of pancreatic diabetes requires a high index of suspicion. Suggestive symptoms include features of pancreatic disease (steatorrhea, unexplained weight loss or back pain) and severe and brittle diabetes in the absence of a family history of diabetes.

# 5 Managing the Patient with Diabetes

# 19

## Clinical Presentations of Diabetes

**Ee Lin Lim & Roy Taylor**

Diabetes Research Group, Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK

### Keypoints

- Patients with type 1 diabetes usually present with classic symptoms and occasionally diabetic ketoacidosis.
- Patients with type 2 diabetes mellitus (T2DM) may be asymptomatic or present with classic symptoms.
- With advancing age, the renal threshold for glucose increases and thirst perception diminishes.
- T2DM may present with complications of diabetes which may be either microvascular or macrovascular.
- Initial diagnosis of T2DM during acute myocardial infarction or stroke is common.
- Presentation may be asymptomatic and discovered on routine examination or laboratory test.

### Introduction

Diabetes has long since taken over from syphilis as the great imitator, and nowhere is this more apparent than in the wide variation of possible modes of initial presentation. The classic triad of thirst, polydipsia and polyuria accounts for only a modest proportion of new diagnoses of diabetes. The relatively acute onset of such symptoms associated with loss of weight is the hallmark of type 1 diabetes mellitus (T1DM). Ketoacidosis and hyperosmolar hyperglycemic syndrome may precipitate a dramatic presentation to emergency services. Non-specific symptoms including tiredness, general malaise and repeated or persistent skin infections may lead to a biochemical diagnosis of diabetes. Screening of at-risk groups or individuals allows early diagnosis. Regrettably, the nature of the condition is such as to allow it to remain asymptomatic for years, allowing the clinical presentation to be a long-term complication of diabetes. This could be in the form of macrovascular disease (myocardial infarction, stroke, black toe) or in the form of microvascular disease (loss of visual acuity, neuropathy). Pregnancy may cause gestational diabetes (GDM), which although may remit after delivery, does indicate a high risk for future type 2 diabetes mellitus (T2DM).

### Clinical considerations at presentation

At the heart of any consultation involving the presentation of diabetes there is a patient. Depending upon prior knowledge,

“diabetes” may be associated in their mind with blindness and amputation, disability and premature death. Alternatively, it may be associated with vague concepts of malaise along with lumbago or fibrositis. The patient’s beliefs and thoughts on diabetes need to be established if the diagnostic consultation is to be a therapeutic consultation. In an era of medicine by numbers, often traduced as “evidence-based medicine,” it is easy to overlook the impact of the consultation itself upon the person who will live with diabetes. “Where were you when JFK was shot?” “What was it like when you were told you have diabetes?” The moment is likely to be memorable and influential.

The therapeutic consultation will involve listening, a process that need not be unduly time consuming. “Do you know of anyone with diabetes?” “What do you know of diabetes just now?” The information received will allow the patient’s likely type of diabetes and immediate prognosis to be put into perspective. Together with other aspects of sound clinical history-taking, it will also transform that person’s view of the consultation. Patients list “listening” as the most valued attribute of a doctor. Although others may listen too, this cannot be delegated to the health care team.

At what stage of diabetes is the person in front of you? The implications for the individual who was identified on routine screening are quite different from those for the person presenting with a black toe. The former is likely to be at an early stage of a long process with good chance of modifying disease progression, whereas the latter is likely to have other tissue complications already established. Clearly, genetic susceptibility to develop complications plays a part as well as natural history time course. The former patient may never develop more than microaneurysms in the eye and be resistant to diabetic nephropathy. Even if they are to be susceptible to complications, these are amenable to intervention over a period of many years. The latter patient, however, requires clear explanation of what can be done and how

future trouble can be avoided. Hippocrates summed it up nicely: “Cure sometimes, relieve often, comfort always.”

The possibility of cure should not be overlooked. Diabetes has long been regarded as incurable. However, this is not always true. At the beginning of the 21st century and with further advances in our understanding, the number of circumstances where diabetes can be cured will increase. Look out for the slatey grey person with large liver and hemoglobin level of 19 gm/dL. Hemochromatosis is rare as a cause of diabetes but it is treatable and therefore important (see Chapter 18). The person taking a combination of thiazide diuretic and beta-blocker will be pleased to have hyperglycemia at least ameliorated by use of alternative agents (see Chapter 16). Cushing syndrome may include curable diabetes (see Chapter 17). Few people on systemic steroid therapy can be taken off treatment just because of development of diabetes, but knowledge is cheering that the diabetes will go away or become much more easily controllable when the steroid course finishes. Cure of T2DM by substantial and sustained weight loss coupled with increased daily physical activity is possible for those who have the determination and willpower to change long-standing behavior patterns. Bariatric surgery produces dramatic and long-term cure of T2DM in the early years of the condition [1].

---

## Types of diabetes

The classification of diabetes will remain the cause of much debate until the exact etiology of each subtype has been established. Currently, the paradigm is to group together those people who appear to have primary  $\beta$ -cell destruction as T1DM, and those who are not slim and who can be controlled at least in the early years with diet and oral agents as T2DM. The monogenic causes of diabetes are capable of precise genetic description and are clearly separate (see Chapter 15). Similarly, pancreatic disease such as chronic pancreatitis, pancreatic carcinoma and hemochromatosis is capable of precise diagnosis (see Chapter 18). T2DM, however, is a term used to describe all those conditions that do not fit into the other, more easily described categories. It is clear that more subtypes will be identified in due course.

The important practical question at the initial presentation of a person with diabetes is whether insulin therapy is necessary. In some circumstances there is no doubt, such as diabetic ketoacidosis or severe weight loss with ketonuria and glycosuria in a child (Figure 19.1). More usually in adult practice the question must be asked. Table 19.1 lays out the common and distinguishing features from the clinical history, examination and urinalysis to help the clinician come to the answer. The subsequent sections consider the separate features in context.

---

## Thirst, polydipsia and polyuria

These symptoms result from an osmotic diuresis as a consequence of hyperglycemia. The symptoms are common to all types

of diabetes although the time course is likely to be shorter and the symptoms more severe in T1DM. Not infrequently, sugar-containing carbonated drinks are selected to slake thirst with resulting worsening of symptoms. A careful history documenting the time course of symptoms and any change in intake of specific drinks is important. Remembering how many times per day urine is passed is not easy, but nocturia is more clear-cut and the number of times urine is passed at night should be quantified. “Do you need to drink water when you get up at night?” is a reasonably objective measure of thirst.

For glucose to escape into the urine, plasma glucose concentration must exceed the renal threshold for tubular reabsorption of glucose and the absolute amount of glucose delivered to the renal tubules must exceed the maximum absorptive capacity. The renal threshold averages 11 mmol/L but displays a wide individual variation of around 6–14 mmol/L [2]. Additionally, the maximum absorptive capacity varies with age such that older people exhibit glycosuria at higher plasma glucose levels [3].

The rise in maximum renal tubular absorptive capacity with increasing age is clinically significant as older people will only develop osmotic symptoms at higher plasma glucose levels. Conversely, a negative urine test is even less likely to exclude a diagnosis of diabetes than in younger people. In addition to the need for higher plasma glucose levels in older people to produce osmotic symptoms, the threshold for triggering the sensation of thirst rises with advancing years [4]. This is important because, once the maximum renal absorptive capacity has been exceeded, dehydration will become considerably more advanced before thirst is sensed. These age-related changes are highly relevant to development of severe hyperosmolar states.

The presence of chronic hyperglycemia itself changes the renal sensitivity to vasopressin such that thirst is not appreciated despite rising plasma osmolarity [5]. Hence, the combination of undiagnosed diabetes and advanced age is particularly potent in delaying appropriate action to increase oral fluid intake as dehydration progresses. The clinical features identified from the history at presentation will vary in relation to the above factors. In older people, thirst may be experienced despite an osmotic diuresis and polydipsia will be absent. The most reliably quantitated feature of an osmotic presentation is therefore frequency of nocturia, and specifically an increase from habitual levels.

In children, enuresis may be the first symptom of polyuria. Sudden onset of enuresis should always prompt testing of urine for glucose. It must be noted that a urine test is entirely appropriate as an initial screen in this situation, as the absence of glucose from the urine absolutely excludes hyperglycemia as a potential cause of polyuria.

---

## Weight loss

Establishing whether significant weight loss has occurred is the most important aspect of history-taking in those with newly presenting diabetes. Unless secondary to concurrent disease, the

**Figure 19.1** A 3-year-old boy before and after 3 months of insulin therapy (1922). The severe wasting of muscle and adipose tissue due to the insulin deficiency of type 1 diabetes is painfully evident in the left-hand panel. There is no more dramatic reminder of weight loss as a prominent presenting feature of type 1 diabetes especially if presentation is delayed. The speed of restoration of body mass on replacing insulin (right-hand panel) is impressive. Reproduced with permission from Eli Lilly & Co.

**Table 19.1** Clinical features at presentation of type 1, type 2 and monogenic diabetes. This is a diagnostic guide with exceptions because of specific circumstances. It is not exhaustive and does not include rarer forms of diabetes, including syndromic diabetes.

	Type 1	Type 2	Monogenic	Pancreatic
Weight loss	Yes (not essential e.g. in slow onset T1DM)	Usually, no	No	Possible. If marked consider pancreatic carcinoma
Ketonuria	Yes (not essential in slow onset T1DM)	No unless recent fasting	No unless recent fasting	Yes, but not necessary for diagnosis
Time course of symptoms	Weeks or days	Months	Months	Weeks or months
Severity of symptoms (e.g. nocturia >3)	Can be marked	Variable but not usually extreme unless fueled by sugary drinks to assuage thirst	Not usually severe	Depends on clinical situation
Family history	Possibly of insulin dependence at a young age	Present in 30% with onset in adult life	Present in almost all with onset in childhood or adult life	Only by chance except in association with hemochromatosis
Age	Peak age in preschool and teenage years but can present at any age	Typically after the age of 20 years	Childhood, adolescence or adult	Usually middle aged and older

symptom strongly suggests insulin deficiency and hence newly presenting T1DM. Its absence does not exclude T1DM as the speed of onset of insulin deficiency and the presence of intercurrent illness, which may have exacerbated osmotic symptoms, may mean that weight loss has not yet commenced.

Weight loss at presentation of T2DM may occur as a result of dietary restriction often undertaken because of suspicion of impending health problems. Such deliberate changes in eating habit are readily established from the history. Typically, weight does not change, or even continues to rise, prior to the symptomatic onset of T2DM.

The weight loss reflects mainly the relative loss of the anabolic actions of insulin. Muscle wasting may be prominent, especially in young men. Associated loss of muscle strength may be reported. As an anabolic hormone, insulin acts principally to inhibit protein degradation [6]. Its relative absence allows the balance between continuous protein synthesis and breakdown to be disturbed. There is an additional effect of insulin deficiency in the failure of normal promotion of lipogenesis and inhibition of lipolysis. Excess non-esterified fatty acids accumulate in plasma, forming substrate for ketogenesis. If the clinical presentation of diabetes is acute, a component of the weight loss will reflect the loss of both intracellular and extracellular water.

---

## Blurred vision

Major changes in plasma glucose will be followed over a period of days and weeks by blurring of vision. The symptom is typically present after a relatively acute change, usually in the context of presentation of T1DM or in the specific circumstance of a hyperosmolar presentation of T2DM. It is most important to explain to the patient that the visual blurring will become worse following the relatively rapid correction of gross hyperglycemia. This explanation is vital to avoid the supposition that diabetic blindness is already progressing with consequent unnecessary worry. It is also important to prevent the unnecessary purchase of spectacles that will be redundant after the hyperglycemia is treated.

It is reasonably assumed that shifts in osmotic pressure between plasma and inside the eyeball accounts for the visual change. Certainly, this provides a practical and immediately understandable explanation. Detailed tests, however, have not to date tied down any identifiable refractive change [7].

---

## Infections

Exposure of leukocytes to glucose concentrations above 11 mmol/L produces paralysis of phagocytic and other functions [8]. This effect, together with other possible effects upon immune function, explains the impaired ability to fight off bacterial and fungal infections. Susceptibility to viral infections appears to be little changed although clear data are lacking.

Recurrent or refractory yeast infections may draw attention to previously undiagnosed diabetes. Most frequently this involves vaginal candidiasis in women or balanitis in men. Initial control of blood glucose levels will permit clearance of the infection with continued antifungal application. Staphylococcal pustules, boils and carbuncles may be present at the diagnosis of diabetes, especially T1DM. This clinical observation was supported by a prospective study of 482 patients with skin or mucous membrane sepsis presenting to an accident and emergency department who were found to have over a threefold increased incidence of capillary blood glucose  $>7.8$  mmol/L compared with a background population [9].

Very rare but serious infective presentations of diabetes must be considered. Necrotizing fasciitis is considerably more common in people with diagnosed and undiagnosed diabetes [10]. Fournier gangrene (gangrene of the perineum and genitalia) is associated with diabetes in almost 50% of cases [11]. The rare and often fatal facial and/or maxillary sinus fungal infection mucormycosis is most often associated with diabetes [12].

---

## Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) occurs as a result of marked insulin deficiency associated with an increase in circulating levels of counter-regulatory hormones. It is characterized by hyperglycemia, acidosis and ketonuria. It mainly occurs in patients with T1DM, but it is not uncommon in some patients with T2DM. There is a wide geographic variation in the reported incidence of DKA. For example, EURODIAB, a cross-sectional survey of 3250 people with T1DM in 29 centers in Europe, reported that 8.6% of patients had been admitted with a diagnosis of DKA in the previous 12 months [13]. In 25% of cases, DKA is the presenting feature of T1DM [14]. The overall mortality rate from DKA ranges 2–5%, but is higher in the elderly.

DKA typically presents with the symptoms of hyperglycemia (i.e. thirst, polyuria and polydipsia). Patients may also complain of malaise or lethargy and muscle cramps. Abdominal pain and vomiting may be sufficiently severe as to mimic an acute surgical problem. It is critically important to recognize this, as the administration of an anesthetic is almost invariably fatal. All doctors dealing with emergencies should be aware of the potential pitfall of missing this telltale sign of DKA.

Clinical signs include dehydration, deep, sighing respirations (air hunger or Kussmaul respiration) and a sweet-smelling fetor (like nail varnish remover) caused by the ketones on the breath. As the ability to detect the smell of ketones is genetically determined, and approximately one-third of people are unable to do this, it is important that individual doctors are aware if they are not equipped with this additional diagnostic tool. Consciousness may be clouded. If the condition has progressed to the stage of coma, the associated signs of dehydration must lead to urgent checking of blood glucose, urinary ketones and arterial blood pH in order to expedite definitive treatment.

The marked deficiency or absence of insulin in this condition means that insulin-mediated glucose uptake into tissues such as muscle, fat and liver cannot occur. In the meantime, the dysregulated secretion of counter-regulatory hormones (glucagon, growth hormone and catecholamines) enhances the breakdown of triglyceride into free fatty acids and increases the rate of gluconeogenesis, which is the main cause for the high blood glucose level in diabetic ketoacidosis. Beta-oxidation of these free fatty acids leads to formation of ketone bodies ( $\beta$ -hydroxybutyrate, acetoacetate and acetone). Acetone is volatile and is released from the lungs, giving the characteristic sweet smell to the breath. Metabolic acidosis ensues when the ketone bodies are released into circulation and deplete the acid buffers.

The hyperglycemia-induced osmotic diuresis further depletes sodium, potassium, phosphates and water. Patients are often profoundly dehydrated and have a significantly depleted total body potassium at presentation. Sometimes, a normal or even elevated serum potassium level is seen as a result of the extracellular shift of potassium with severe acidosis. Great care must be taken to monitor serum potassium levels repeatedly once insulin treatment is started as the concentration can drop precipitously.

---

## Hyperosmolar hyperglycemic syndrome

Hyperosmolar hyperglycemic syndrome (HSS) occurs exclusively in patients with T2DM. Often there is a history of several days of ill health. The principal clinical feature is profound dehydration. Confusion is usual, and focal neurologic symptoms such as weakness on one side or hemi-sensory abnormalities may develop and be easily confused with stroke. HSS was previously termed hyperosmolar non-ketotic coma. This terminology has been changed as coma is a relatively rare feature (<10%) and mild ketosis may be present at diagnosis.

HSS shares many features in common with DKA, the major exceptions being the absence of significant ketoacidosis. This is likely because of the residual low level insulin secretion, which suppresses lipolysis sufficiently to avert ketogenesis but not sufficient to prevent hyperglycemia. Additionally, hyperosmolarity itself may decrease lipolysis, limiting the amount of free fatty acids available for ketogenesis. HSS accounts for 10–30% of hyperglycemic emergencies. As the prevalence of T2DM rises inexorably, it is becoming an increasingly common hospital admission. Up to two-thirds of those affected have not previously been diagnosed as having diabetes.

---

## Macrovascular presentations

### Acute myocardial infarction

As the risk of ischemic heart disease is linearly related to fasting and post-prandial blood glucose concentrations, it is not surprising that both impaired glucose tolerance (IGT) and diabetes are over-represented in populations presenting with acute myocar-

dial infarction (AMI) [15]. Consequently, T2DM frequently presents for the first time at hospitalization for AMI.

This presentation is complicated by stress hyperglycemia resulting from the catecholamine and cortisol elevations. Although this may cause problems for the purist wishing to evaluate an effect of diabetes per se, from the perspective of the patient with a life-threatening condition exacerbated by dysglycemia, exact definitions of diabetes are not relevant. Stress hyperglycemia and established diabetes have similarly increased mortality from AMI. In a New York municipal hospital cohort of patients with AMI, 3-year mortality was 52% in those with stress hyperglycemia (defined as admission blood glucose >7.0 mmol/L) compared with 42% in those with diabetes [16]. The 3-year death rate in those with normal glucose levels was 24% in the same study. A meta-analysis has confirmed this effect, with a 3.9-fold increase risk of death associated with stress hyperglycemia compared with a 1.7-fold increased risk of death associated with established diabetes [17]. In this context, one of the most important findings of the DIGAMI study is often overlooked. The effect of reasonable glycemic management (blood glucose <10 mmol/L) for those with no prior insulin therapy and stratified as having low coronary risk factors produced a 52% improvement in mortality [18]. This group would have included those with stress hyperglycemia. In contrast, the DIGAMI study showed no significant benefit of acute blood glucose control for individuals previously treated with insulin.

Estimates of the incidence of stress hyperglycemia at presentation of AMI range 10–16% [19,20]. This compares with estimates of prevalence of diabetes at presentation of AMI of 25–32% [19,21,22]. Variation in these figures is likely to reflect the background prevalence of IGT and T2DM in the population, as well as increased awareness and effective screening processes to identify previously undiagnosed T2DM.

Good clinical practice demands measurement of plasma glucose on diagnosis of an acute coronary syndrome. If plasma glucose is raised (7 mmol/L may be quoted, but in the individual case interpretation depends upon time since last meal), then both fasting plasma glucose and HbA<sub>1c</sub> should be measured. Raised plasma glucose should indicate a need for particular attention to adequate glucose control during the acute event. Given that the HbA<sub>1c</sub> result is unlikely to be available immediately, hyperglycemia indicates a need for rapid control in the acute situation when the first few hours are critical. A fasting plasma glucose of >5.6 mmol/L during the acute admission and/or admission plasma glucose of >7.8 mmol/L yielded a sensitivity of almost 90% and a positive predictive value of 44% for detecting diabetes [23].

Where there is diagnostic uncertainty, targeted screening in the post-acute setting with a standard 75 g oral glucose tolerance test (OGTT) is acceptable. But when is the optimal time to perform this test? In a group of AMI patients with no previous diagnosis of diabetes, both pre-discharge and 6 weeks post-discharge OGTTs were performed and correlation with pre-discharge OGTT was good [24]. There was 49% concordance between clas-

sifications to which each patient was assigned in both OGTTs. The best predictor of abnormal glucose handling (IGT or diabetes) being diagnosed at 3 months was observed to be the 60-minute blood glucose level during the pre-discharge OGTT.

### Acute stroke

The prevalence of previously diagnosed diabetes in patients with acute stroke is 8–28% but an additional 6–42% have unrecognized pre-existing dysglycemia [25]. Plasma glucose at presentation is a major prognostic factor. One series of 86 patients with acute stroke demonstrated that full functional recovery at 4 weeks was restricted to those with presenting blood glucose levels <8 mmol/L [26]. None of the individuals with a raised presenting plasma glucose regained full function by 4 weeks. The extent to which this reflects the metabolic stress response in proportion to the severity of the cerebrovascular insult as opposed to hyperglycemia itself impairing subsequent recovery from ischemic damage cannot be ascertained from these observational data.

The observations on poorer outcome in those who had stress hyperglycemia following AMI have been reproduced in respect of acute stroke disease. In a systematic review of observational studies examining the prognostic significance of hyperglycemia in acute stroke, the unadjusted relative risk of in-hospital or 30-day mortality was 3.07 (95% CI 2.50–3.79) in non-diabetic patients with admission plasma glucose level >6–8 mmol/L and 1.30 (95% CI 0.49–3.43) in those with known diabetes [27]. The relative risk of poor functional outcome in hyperglycemic non-diabetic patients was 1.41 (95% CI 1.16–1.73). It appears that sudden increase in plasma glucose levels impair tissue function more in those individuals who have not been habituated to hyperglycemia.

Persistent hyperglycemia (defined as blood glucose >7.0 mmol/L) in the 72 hours after acute stroke was found to be associated with an increase in infarct size, measured using magnetic resonance imaging, and worse stroke outcome [28]. Nonetheless, there are currently no satisfactory outcome studies of control of plasma glucose upon the outcome of stroke [29]. The largest study to date, which included 993 patients, failed to achieve control of plasma glucose at 24 hours [30]. Importantly, no assessment has yet been conducted of plasma glucose control during the first few hours after presentation with acute stroke, and it is likely that it is in this window of time that this particular presentation of hyperglycemia may most beneficially be managed.

## Microvascular presentations

### Eye presentations

Symptomatic loss of vision may occasionally be the presenting feature of T2DM, where hyperglycemia has been present for an uncertain number of years, silently causing tissue damage and retinopathy. Loss of vision as a diagnostic event is most often a consequence of macula edema but may also be secondary to vitre-

ous hemorrhage. Central or branch retinal vein occlusion is more common in diabetes and may also cause symptomatic presentation of the condition.

Around the time of diagnosis of T2DM, marked retinopathy with cotton wool spots or intraretinal microvascular abnormalities (IRMA) was found to be present in 8% of men and 4% of women in the UK Prospective Diabetes Study (UKPDS) [31]. The critical importance of arranging full retinal examination, preferably by digital retinal imaging, is illustrated in Figure 19.2. Approximately 1% of individuals presenting with symptomatic T2DM have sight-threatening retinopathy at that time. Very early recognition is essential as the initial treatment of the diabetes will decrease blood glucose levels, cause retinal blood flow to return acutely to normal levels and may result in marked worsening of the retinopathy.

In the UKPDS, the severity of retinopathy was found to be related to higher fasting plasma glucose levels. In addition, in men, increased alcohol consumption was related to increased

**Figure 19.2** Upper panel: immediate laser therapy was required for the macular edema associated with the severe exudative maculopathy present at the time of diagnosis. Lower panel: new vessels are present both arising from the optic disk and from the peripheral retina. Bleeding from the latter caused the prominent pre-retinal hemorrhages which obscure the fovea and in this case caused presentation because of loss of visual acuity.

severity of retinopathy, while leaner women had more severe eye lesions. Visual acuity was normal in most patients, but in men there was a trend for those with more severe retinal lesions to have worse visual acuity.

The potential severity of diabetic retinopathy at the time of diagnosis of T2DM is illustrated by the observation that 15% of those with moderate background retinopathy progress to require photocoagulation therapy within 3 years [32]. The specific reason for photocoagulation therapy was maculopathy alone in 72% and proliferative retinopathy in 11% in this group of individuals with T2DM.

---

## Neuropathic syndromes

Although any of the neuropathic syndromes of diabetes may precipitate the initial presentation, symmetrical distal sensory neuropathy, mononeuropathies and amyotrophy are the most likely candidates. The possibility of diabetes underlying most presentations of neurologic symptoms must be considered.

Diffuse symmetrical sensory neuropathy is the most common neuropathy. A precise estimate of the true prevalence of this neuropathy has been difficult to ascertain, and reports vary from 7 to 60% in people with diabetes, depending on the criteria and methods used to define the neuropathy [33,34]. The prevalence increases with both age and duration of diabetes. At 12-year follow-up in the UKPDS, 64% of men and 44% of women who were free of neuropathy at baseline developed at least one neuropathic abnormality [35].

Any nerve may be affected by an acute diabetic mononeuropathy, but palsy of cranial nerves III, IV, VI and VII present most often. It is a rare mode of presentation of T2DM, but not T1DM.

Diabetic amyotrophy may present as weight loss, and unless pain in the thighs is prominent the clinical picture may resemble that of malignant disease. Weakness of quadriceps, with visible wasting and absence of the knee tendon reflex, should allow recognition and lead to the measurement of plasma glucose. Such presentation is likely to be associated with T2DM but again is rare.

A foot lesion can be a presenting sign of diabetes, and it is estimated that the lifetime risk of developing a foot ulcer in people with diabetes may be as high as 25% [36]. Presentation with a black toe is associated with T2DM particularly. Peripheral neuropathy leads to sensory motor and autonomic dysfunction, with loss of the protective pain sensation, dry skin and callus formation. Loss of pain sensation in the feet is usually unnoticed and subsequent trauma does not come to attention until obvious injury is apparent. In approximately half of these patients with foot ulcers, concomitant peripheral arterial disease (PAD) is present [37]. In the EURODIAB study, foot ulcers with presence of PAD were associated with considerably lower healing rates, higher major amputation and mortality rates [38].

---

## Pregnancy

The time course of presentation of GDM may be predicted from knowledge of its pathogenesis. The key variable is the physiologic insulin resistance that develops during pregnancy. Although several necessarily small studies have quantitated this, it is most clearly illustrated by an observation of the change in exogenous insulin requirements during pregnancy in T1DM. During steady glycemic control and food intake, insulin requirements do not change until around 18 weeks' gestation, whereafter there is a linear increase until around 28 weeks' gestation [39]. The extent of change varies in individual pregnancies from none to over threefold increase, with an average increase in daily insulin dose of 40% [40]. The range is assumed to be a function of the placenta (fetal-derived tissue) as considerable variation is exhibited between successive pregnancies in the same woman.

In the light of this information, it can be understood why the elevated blood glucose levels of GDM are not seen in the first half of pregnancy. Screening for GDM will be most sensitive later in pregnancy but this sensitivity must be balanced with the opportunities to intervene. Current guidelines therefore recommend testing at 24–28 weeks' gestation. Predisposed women cannot mount an adequate  $\beta$ -cell response if the degree of insulin resistance becomes too great. Following one pregnancy complicated by GDM, although increased, the risk of recurrence in a subsequent pregnancy is far from certain, reflecting the variation in insulin resistance in successive pregnancies. Higher rates have been reported in South Asian and Hispanic populations, as would be expected from the higher background prevalence of T2DM (52–69%) [41]. The importance of detection and treatment of GDM is reflected by the data shown in Figure 19.3. The rate of intrauterine growth is as rapid in GDM as it is in T1DM and T2DM [42]. Early diagnosis of GDM carries major advantages for mother and child. The risk of developing subsequent diabetes in those with GDM ranges from 2.6 to 70% over periods from 6 weeks to 28 years [43]. Current NICE guidelines (March 2008) for “Diabetes in Pregnancy” recommend that fasting plasma glucose should be performed at 6 weeks as well as repeated annually for those patients with GDM. This will miss a proportion of women with normal fasting plasma glucose and IGT, but it should be noted that the occurrence of GDM should be the trigger to advise vigorous lifestyle change and weight loss in particular.

Mild degrees of elevation of plasma glucose may be sufficient to be deleterious to the fetus, and these are far less than those that could produce osmotic symptoms [44]. Screening for GDM is therefore essential. Symptomatic presentation of GDM is unusual in the context of a health care system that provides universal screening for GDM. Where osmotic symptoms and superficial fungal infections are part of the clinical presentation, however, it is important to ask whether this is new onset T1DM or T2DM. The former tends to be associated with higher plasma glucose levels and ketonuria. Both are associated with clearly elevated

**Figure 19.3** Similar rates of increase in fetal abdominal circumference in gestational diabetes (GDM) and pre-gestational diabetes as measured by ultrasound. Reproduced from Lim *et al.* [42], with permission from RSM Journals.

HbA<sub>1c</sub> levels as the hyperglycemia has been present for several weeks or months. If the presentation is in the first half of pregnancy, it is likely that it will not remit after delivery. If the presentation is in the first half of pregnancy and is associated with raised HbA<sub>1c</sub>, then a diagnosis of non-GDM may confidently be made and discussed with the patient [42].

## Screening

It has been estimated from the 2002 NHANES survey that one-third of the 13.3 million US adults with diabetes remained undiagnosed [45]. A similar estimate has been made for the UK [46]. Universal screening has not been implemented in the UK, however, as criteria for cost-effective and clinically effective screening are not met [47]. It is recommended that screening of high-risk groups (obese, strong family history of diabetes, South Asian or other high-risk ethnicity) should be undertaken.

Fasting glucose, 2-hour post-challenge glucose and HbA<sub>1c</sub> all equally well predict the future microvascular complications of diabetes and can be considered diagnostic as well as screening tests [48]. The use of the concept of “impaired fasting glucose” with a cutoff of 5.5 mmol/L offers a simple way of excluding or demonstrating dysglycemia [49]. Urinalysis for glycosuria has a

high specificity (96–100%) but a low sensitivity (16–43%). Testing random blood glucose is specific but insensitive [50].

The population of individuals with early T2DM who are identified by any screening procedure differs considerably from those who present symptomatically. They are less likely to have established microvascular or macrovascular complications of diabetes. Attitudes to health may differ. The diagnosis will be less welcome as it does not point the way to relief of discomfort and may not be accepted as important for future health. Compliance with therapeutic advice concerning weight, diet and physical activity may not be as good as following a symptomatic presentation. For these reasons, a more careful approach to discussing the need for future action is required with appropriately sensitive follow-up by the diabetes team.

## Other presentations

Ants clustering around urine is a classic description of diabetes, although it is not clear how often this comprises the presenting complaint today. Periodontal disease, especially aggressive periodontitis, is more common in those with diabetes and may occasionally be the presenting complaint [51]. Cataracts typically develop 10 years earlier in people with diabetes [52]. Altered taste or excess production of saliva have been reported as presenting features of diabetes [53].

## Conclusions

The mode of presentation is enormously varied. Especially as the incidence of diabetes is rising in all age groups, both in the UK and worldwide [54], the onus is upon health care professionals to diagnose the condition effectively. Failure to recognize presenting features of diabetes can be costly for the patient.

<sup>2</sup>Clinical Research, Metabolism, Merck Research Laboratories, Rahway, NJ, USA

### Keypoints

- People with diabetes should be seen as individuals with a condition that has medical, personal and social consequences, instead of being passive recipients of health care.
- The optimal management of diabetes occurs when the multidisciplinary diabetes care team actively involves the person with diabetes as an equal partner in their care.
- Life-threatening diabetes emergencies, such as diabetic ketoacidosis, should be effectively managed, and attention paid to prevention.
- Acute symptoms of hyperglycemia need to be addressed by careful lifestyle and pharmacologic management.
- Much of diabetes management is focused on reducing the risk of long-term complications through screening and supporting achievement of improved glycemic control and cardiovascular risk factor management.
- The time of diagnosis is a key milestone in the management of diabetes, when education, support and treatment are needed.
- Regular lifelong contact between the person with diabetes and their health care team is essential in order to support them to cope with the demands of a complex condition which changes throughout life.
- Diabetic complications should be managed effectively, if and when they present, to reduce morbidity.

### Introduction

Diabetes is a lifelong condition that is, for the majority, currently incurable. It is associated with premature mortality and morbidity from an increased prevalence of cardiovascular disease and microvascular complications affecting the kidney, nerve and eye [1,2]. High-quality randomized trials have shown that improving glycemic control is associated with a reduction in microvascular complications [3–5] while a multifaceted approach to cardiovascular risk factors will reduce cardiovascular morbidity and mortality [6].

The person living with diabetes will spend the vast majority of their time managing their diabetes and only an estimated 1% of their time in contact with health care professionals. Therefore, the person with diabetes needs to be supported to take upon themselves much of the responsibility for the management of their diabetes. Given the central role of the person with diabetes and the relatively little contact with health care professionals, it is important that the purposes of the consultation or other contacts with the diabetes health care team are well defined and their

aims are made clear so that the patient derives the maximum benefit from the time spent with their diabetes health care team, whether this is in a hospital or primary care setting. As well as the clinic visit, diabetes care may also be through phone or email contact or through educational sessions outside a traditional clinic setting.

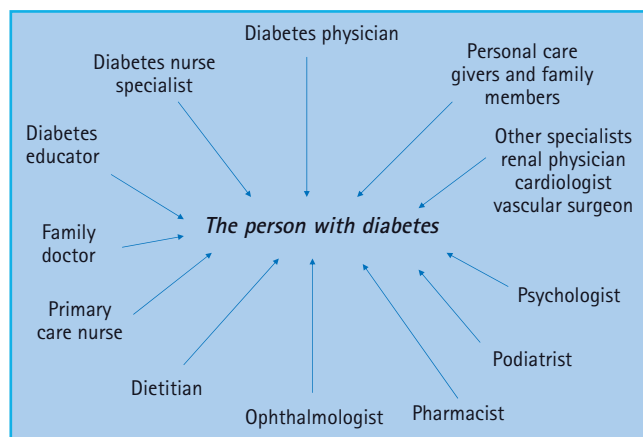

This chapter provides an overview of the aims and philosophy of diabetes care. Separate aspects of care are covered in greater detail in subsequent chapters. The aims of diabetes care and management are fourfold. Life-threatening diabetes emergencies, such as diabetic ketoacidosis or severe hypoglycemia, should be managed effectively including preventative measures. The acute manifestations of hyperglycemia, such as polyuria and polydipsia, need to be addressed. In practice, these occupy only a minority of the work undertaken by diabetes health care professionals. Much of the focus of care is therefore directed towards minimizing the long-term complications through screening and working together with the person with diabetes to support improved glycemic control and cardiovascular risk factor management. This provides a challenge for the diabetes team because people often have no symptoms at the time of care and yet are asked to make lifestyle changes and take medications that may place a considerable burden on that individual. It is also important that clinicians bear in mind the fourth aim of care which is to avoid iatrogenic side effects, such as hypoglycemia. Involvement of the person with diabetes in this care planning is paramount to success.

## St. Vincent's Declaration

During the 1980s, there was a transformation in the widely held perceptions of the roles of people with diabetes and philosophy of care. Instead of being viewed as passive recipients of health care, there was an increasing recognition that people with diabetes were individuals with a condition that has medical, personal and social consequences. During this time, there was an increasing awareness and acceptance of the concept that each person with diabetes should accept part of the responsibility for their treatment and act as equal partners with health care professionals. In response to this paradigm shift, representatives of government health departments and diabetes organizations from all European countries met with diabetes experts under the auspices of the Regional Offices of the World Health Organization (WHO) and the International Diabetes Federation (IDF) in the hillside town of St. Vincent, Italy, October 10–12, 1989. They unanimously agreed upon a series of recommendations for diabetes care and urged that action should be taken in all countries throughout Europe to implement them [7]. Since this time, this philosophy of partnership between people with diabetes and health care professionals has been adopted within individual nation's strategies to improve the quality of diabetes care.

## The diabetes care team

The diabetes care team involves a multidisciplinary group of health care professionals who are available to support the person with diabetes (Figure 20.1). A key component of diabetes care is to ensure that the individual with diabetes is at the center of the provision of care. This means that the person with diabetes should work together with the health care professionals as an equal member of the diabetes care team. This relationship should provide the information, advice, and education to support the

**Figure 20.1** The multidisciplinary group of health care professionals who are available to support the person with diabetes.

## Box 20.1 St. Vincent's Declaration [7]

- Elaborate, initiate and evaluate comprehensive programs for detection and control of diabetes and of its complications with self-care and community support as major components
- Raise awareness in the population and among health care professionals of the present opportunities and the future needs for prevention of the complications of diabetes and of diabetes itself
- Organize training and teaching in diabetes management and care for people of all ages with diabetes, for their families, friends and working associates and for the health care team
- Ensure that care for children with diabetes is provided by individuals and teams specialized both in the management of diabetes and of children, and that families with a child with diabetes obtain the necessary social, economic and emotional support
- Reinforce existing centres of excellence in diabetes care, education and research
- Create new centers where the need and potential exist
- Promote independence, equity and self-sufficiency for all people with diabetes, children, adolescents, those in the working years of life and the elderly
- Remove hindrances to the fullest possible integration of people with diabetes into society
- Implement effective measures for the prevention of costly complications:
  - Reduce new blindness caused by diabetes by one-third or more
  - Reduce numbers of people entering end-stage renal failure by at least one-third
  - Reduce by half the rate of limb amputations
  - Cut morbidity and mortality from coronary heart disease by vigorous programs of risk factor reduction
  - Achieve pregnancy outcomes in women with diabetes that approximate that of women without diabetes
- Establish monitoring and control systems using state-of-the-art information technology for quality assurance of diabetes health care provision and for laboratory and technical procedures in diabetes diagnosis, treatment and self-management
- Promote European and international collaboration in programs of diabetes research and development through national, regional and World Health Organization (WHO) agencies and in active partnership with the person with diabetes and diabetes organizations
- Take urgent action in the spirit of the WHO program, "Health for All," to establish joint machinery between WHO and International Diabetes Federation European Region to initiate, accelerate and facilitate the implementation of these recommendations

empowerment of the individual with diabetes to enable them to take control of their condition and ensures that care offered is made appropriate for the individual and their circumstances.

The large number of health professionals involved in the diabetes care team means that the roles and responsibilities of all must be clearly presented and agreed. It is often helpful for the person with diabetes if the key members of the diabetes care team are identified, as they will have more contact with some health care staff than others.

Most routine diabetes care takes place in a primary care setting but some people with diabetes with additional or complex needs will require management and support in a specialist setting for some or all of their care [8]. The diabetes physician usually takes the overall responsibility for the diabetes medical care but other specialists may be involved, for example an ophthalmologist may be needed to examine the eyes carefully and treat diabetic retinopathy if present. Diabetes care is multidisciplinary, involving doctors, nurses and many allied health care professionals whose responsibility is to support the person living with diabetes in the management of their condition. A close collaboration between primary and secondary health care professionals and among specialists is needed to ensure that all involved are aware of the issues that are relevant to the individual with diabetes and that care is integrated and coordinated across the wide range of disciplines involved. Placing the person with diabetes at the center of care is likely to facilitate collaboration.

Given the chronic nature of diabetes, continuity of care is essential. Ideally, this should be provided by the same doctors and nurses at each visit, but where this is not possible, the health care team should have access to previous records so that they are fully aware of the medical history and background of the person with diabetes. In some low and middle income countries, where medical records are focused on the acute care of infectious diseases, this is particularly challenging [9].

With the involvement of the person with diabetes in the diabetes team come a number of responsibilities for that individual. The task of implementing the day-to-day management plan lies with the person with diabetes and sometimes it can be difficult for health care professionals to accept this. It must be understood that managing diabetes is challenging, but the diabetes care team should be there to support the person through their experiences with their condition. Adolescence can be particularly challenging as this period of the person's life coincides with a time of change when experimentation and adaptation by the adolescent are to be expected (see Chapter 52).

### **Improving the outcome of the consultation**

The time that a person with diabetes spends with a health care professional is limited and should be used as effectively as possible. It is important that both the person with diabetes and the health care professional prepare for the clinic visit. In the UK, the Department of Health has provided literature entitled *Questions*

#### **Box 20.2 Top tips for people with diabetes to achieve a successful consultation [10]**

##### *Before your appointment*

- Write down your two or three most important questions
- List or bring all your medicines and pills – including vitamins and supplements
- Write down details of your symptoms, including when they started and what makes them better or worse
- Ask your hospital or surgery for an interpreter or communication support if needed
- Ask a friend or family member to come with you, if you like

##### *During your appointment*

- Don't be afraid to ask if you don't understand. For example, "Can you say that again? I still don't understand"
- If you don't understand any words, ask for them to be written down and explained
- Write things down, or ask a family member or friend to take notes

##### *Before you leave your appointment check that:*

- You've covered everything on your list
- You understand, for example "Can I just check I understood what you said?"
- You know what should happen next – and when. Write it down
- Ask who to contact if you have any more problems or questions
- Ask about support groups and where to go for reliable information
- Ask for copies of letters written about you – you are entitled to see these

##### *After your appointment, don't forget to:*

- Write down what you discussed and what happens next. Keep your notes
- Book any tests that you can and put the dates in your diary
- Ask what will happen if you are not sent your appointment details
- "Can I have the results of any tests?" (If you don't get the results when you expect – ask for them.) Ask what the results mean

*to Ask*, which provides guidance about the questions a person with diabetes should ask during a consultation to maximize the benefit from the visit to their health care team [10].

The consultation or education program should lead the person with diabetes to gain a clear understanding of their condition. This can only be achieved effectively when professionals and people with diabetes are enabled to work together. The interaction should not be seen as an opportunity for the health care profession to "give care" to the patient, but an opportunity for equal involvement in decision-making and care.

People with diabetes should be encouraged to ask questions to check knowledge and further explanation and literature may be needed. It is good practice to provide the person with diabetes with copies of any letters written about them [11,12]. Questions about their treatment should be encouraged and they should be

aware of what will happen next, including any requirement for further investigation. Regular review of management plans through joint dialogue, listening, discussion and decision-making between the person with diabetes and health care professional, sometimes known as care planning, is the key to enhancing relationships and partnership working [13]. Contact details should be made available so the individual with diabetes knows where to seek help if further questions arise.

---

## Following diagnosis

The period following the diagnosis of diabetes is crucial for the long-term management of diabetes. A huge amount of information and skills need to be assimilated by the person with diabetes at a time when they may be in denial or angry with the diagnosis [14]. Considerable skill is therefore needed to support them at this time. The diabetes team should perform a medical examination (usually the physician) and develop a program of care with the person with diabetes. It is important that this is individualized so that it suits the particular person with diabetes and should include treatment-oriented goals.

## Issues relating to diagnosis

The diagnosis of diabetes is based on the finding of one or more glucose values above internationally agreed values (see Chapter 2) [15]. Usually, a diagnosis has been made prior to referral to the diabetes clinic but this is not always the case. In the absence of symptoms, individuals should have two values above the diagnostic criteria. Where there is diagnostic doubt, the 75-g oral glucose tolerance test is the investigation of choice but there is ongoing discussion about the use of glycated hemoglobin as a diagnostic test [16].

While the diagnosis of diabetes has frequently been made prior to referral, advice may be required to determine the type of diabetes as the distinction is not always as clear as may be expected. When a young preschool child develops weight loss, polyuria, polydipsia and ketoacidosis over a short period of time, the diagnosis is obviously type 1 diabetes mellitus (T1DM). In contrast, if an asymptomatic elderly overweight individual is found to be hyperglycemic, the diagnosis is type 2 diabetes (T2DM) (see Chapter 19). These presentations lie at two ends of a spectrum, and the diagnosis of the type of diabetes may be less clear when the onset occurs in the thirties in an overweight adult who is found to have islet cell antibodies. Diabetes health care professionals should also be alert to the possibility of monogenic causes of diabetes (see Chapter 15).

Although a precise diagnosis may not be needed from the outset, an early decision should be made about the necessity for insulin therapy (see Chapter 19). While there are clinical features that suggest the type of diabetes, time is often a useful diagnostic tool to determine whether the person with diabetes requires insulin.

## Diabetes education

A key component of the empowerment of the person with diabetes is the provision of diabetes education (see Chapter 21) [17]. This information should be provided in a patient-centered manner as it is retained more effectively when delivered in this way. Education may be provided individually or in a group setting.

It is essential that the person with diabetes understands their diabetes and develops the skills and competencies required to take control of their condition as well as possible if they are going to be an effective partner in the diabetes care team.

People with newly diagnosed diabetes should have the chance to speak with a diabetes specialist nurse (or practice nurse) who can explain what diabetes is [18]. This will provide an opportunity to discuss the treatment and goals as well as providing a practical demonstration of any equipment required to manage the diabetes such as blood glucose meters or insulin devices. The importance of ketones testing for those with T1DM should be explained. When self-monitoring of blood glucose has been advocated, it is essential that the person with diabetes knows how to interpret the results and what action is required in response to the treatment.

A qualified dietitian should provide advice about how to manage the relationships between food, activity and treatment (see Chapter 22). Where necessary, they should explain about the links between diabetes and diet and the benefits of a healthy diet, exercise and good diabetes control. As an essential member of an effective clinical care team, a diabetes specialist nurse or practice nurse often has a role in providing dietary advice together with relevant literature [18].

The social effects of diabetes should be discussed, as they may relate to employment, insurance or driving (see Chapter 24). Some countries require individuals with diabetes to inform the appropriate licensing authorities. Advice about diabetes and foot care should also be given (see Chapter 44).

Although education is essential following diagnosis, it is important to appreciate that this is a lifelong process that should take into account recent advances in medical science and changes in circumstances of the person with diabetes [17].

The best measure of successful education may not be simply that someone knows more, but rather that they behave differently. The simple provision of knowledge by itself is often insufficient to influence behavioral change. This can be a particular challenge for the person with T2DM who may have been asymptomatic prior to diagnosis. High demands are placed on the person with diabetes regardless of the type of diabetes, especially when the benefits are not immediate, may only accrue with time and even then may not be appreciated. The individual with diabetes needs to gain an understanding that improved glycemic control can help in preventing the complications of diabetes, such as a myocardial infarction or proliferative retinopathy, even though they may have never experienced these conditions.

The diagnosis of diabetes may provoke a grief reaction and support is needed from the diabetes team to help person with diabetes through this. Engagement is needed to help the person

with diabetes come to terms with their diabetes and take control rather than being left with the feeling that their diabetes or their health care team is taking control of them. For some it may take a very long time to accept their diabetes and the demands this places on their life. Therefore, emotional and psychological support and techniques need to be available in the long term.

People with newly diagnosed diabetes often want to speak with others who have diabetes who have had similar experiences while developing diabetes. Many countries have diabetes-related charities that can provide this support and it is therefore important that the information given includes local centers or patient support groups.

---

## The clinic visit

The diabetes team needs to work together with the person with diabetes to review the program of care including the management goals and targets at each visit [19]. It is important that the person with diabetes shares in any decisions about treatment or care as this improves the chance of jointly agreed goals being adopted following the consultation. A family member, friend or carer should be encouraged to attend the clinic to help them stay abreast of developments in diabetes care and help the person with diabetes make informed judgments about diabetes care.

An important goal of diabetes management is to prevent the microvascular and macrovascular complications of diabetes without inducing iatrogenic side effects. This involves active management of hyperglycemia together with a multifaceted approach targeting other cardiovascular risk factors.

## Glycemic management

Enquiries and discussions should be made about hyperglycemic symptoms, problems with medications, including issues relating to injections, hypoglycemia and self-monitoring of blood glucose.

### Hyperglycemic symptoms

Symptoms relating to hyperglycemia usually occur when the blood glucose rises above the renal threshold leading to an osmotic diuresis. Polyuria, particularly at night, polydipsia and tiredness may ensue. General malaise may also occur and is not always ascribed to the hyperglycemia.

### Medications

The diabetes care team is responsible for ensuring that the person with diabetes has access to the medication and equipment necessary for diabetes control. In many countries this is available free or at a reduced rate; many people with diabetes may be unaware of this and timely advice may alleviate some of the anxieties about the cost of diabetes.

### Oral hypoglycemic drugs

Each of the oral hypoglycemic drugs has its strengths and profile of side effects (see Chapter 29) and these should be discussed.

Strategies should be devised to maximize the tolerability of diabetes medications. For example, the timing of metformin in relationship to meals, or the use of long-acting preparations, may reduce the risk of gastrointestinal upset. Where treatments are not being tolerated, these may need to be changed in order to facilitate improved concordance with the regimen. Another example is the need to discuss the risks of hypoglycemia with sulfonylureas.

### Insulin

Insulin therapy is complex: it must be given by self-injection or pump and there is considerable variation in the doses, regimens and devices available. It is important that during the clinic visit the individual has an opportunity to discuss injection technique and any difficulties with injection sites, which should be examined at least annually. Information about the appropriate storage of insulin and safe disposal of sharps (needles) is needed.

The most common side effects of insulin are hypoglycemia and weight gain (see Chapter 27). In addition to these, there are a number of other issues that should be addressed including injection site problems, such as lipohypertrophy, and device problems.

### Assessment of glucose control

Supporting the person with diabetes to achieve excellent glycemic control is an essential component of diabetes care. The methods of assessing glucose control essentially involve short-term measures such as self-monitoring of blood glucose and long-term measures such as glycated hemoglobin (see Chapter 25). Not all those with diabetes will undertake self-monitoring of blood glucose, but when they do it is incumbent on the health care professional to discuss the findings with the person with diabetes and how these will affect future management. The glycated hemoglobin provides a further measure of the adequacy of glycemic control and sometimes there may be a discrepancy between this measure and self-monitored blood glucose. It is important to explore the reasons that underlie the differences, which may range from biologic issues such as genetically determined rates of glycation, through to inappropriately timed glucose readings to fabricated results. A pristine sheet (with no blood stains from fingersticks) and with the use of a single pen color may be a clue to the latter. The use of computers and the ability to download results may help to observe patterns of hyperglycemia, although it is important to make sure that the meter has not been shared.

It is clearly important that people with diabetes are encouraged to tell the truth. Sometimes clinicians can appear judgmental which may result in people with diabetes falsifying their results because they are scared. They can feel as if some clinicians are headteachers and they do not want to be reprimanded. It is understandable why someone would not put themselves through that if they did not have to. It is better to break down these barriers and to build a relationship whereby the person with diabetes feels that it does not benefit them to lie, and that the health care professional is there to support, not to judge.

**Table 20.1** Glycemic and cardiovascular risk factor targets [20–22,38].

	Glycated hemoglobin	Blood pressure (mmHg)	Lipid profile
ADA	<53 mmol/mol (<7.0%)	<140/90	LDL < 100 mg/dL HDL > 40 mg/dL for men >5.0 mg/dL for women Triglycerides < 150 mg/dL
EASD	<53 mmol/mol (<7.0%)	<130/80	LDL < 1.8 mmol/L (<70 mg/dL) HDL > 1.0 mmol/L (>40 mg/dL) for men >1.2 mmol/L (>46 mg/dL) for women Triglycerides < 1.7 mmol/L (<150 mg/dL)
IDF	<48 mmol/mol (<6.5%)	<130/80	LDL < 2.5 mmol/L (<95 mg/dL) Triglycerides < 2.3 mmol/L (<200 mg/dL) HDL > 1.0 mmol/L (>39 mg/dL)
NICE	<48 mmol/mol (<6.5%)	<130/80	Total cholesterol 4.0 mmol/L LDL cholesterol 2.0 mmol/L

ADA, American Diabetes Association; EASD, European Association for the Study of Diabetes; HDL, high density lipoprotein cholesterol; IDF, International Diabetes Federation; LDL, low density lipoprotein cholesterol; NICE, National Institute for Health and Clinical Excellence.

The Diabetes Control and Complications Trial and the UK Prospective Diabetes Study (UKPDS) have clearly established that lower levels of glycemia are associated with a reduced risk of long-term microvascular complications in T1DM and T2DM, respectively [3–5]. For this reason, learned societies such as the American Diabetes Association (ADA) and European Association for the Study of Diabetes (EASD), and government bodies such as the National Institute for Health and Clinical Excellence have set tight glycemic targets to minimize the risk of complications for person with diabetes (Table 20.1) [20–22]. Despite these targets, many people with diabetes are unable to achieve this level of control. It is important for the health care professional to explore the reasons with the person with diabetes why the control is not ideal. Advice about adjustment of treatment or further education may be needed.

A common limiting factor in the ability to achieve good control is hypoglycemia which is one of the most uncomfortable, inconvenient and feared side effects of diabetes medication (see Chapter 33). The frequency and severity of hypoglycemic episodes should be discussed. An exploration of the underlying causes and advice about prevention are required for the future.

When a person with diabetes is treated with insulin, it is important to ensure that they carry a readily accessible source of glucose such as glucose tablets. Concentrated glucose solution and glucagon should also be made available for use in more severe hypoglycemia. As these treatments may only be used infrequently, it is worth checking whether they are in date. Furthermore, as they need to be administered by another individual, it is important to

ensure that the friends and relatives of the person with diabetes know how to administer them before they are needed.

In some instances, the only way of avoiding disabling hypoglycemia is to accept a lesser degree of glycemic control. This recalibration of glycemic goals should be decided with the person with diabetes and an individual target appropriate for the circumstances should be agreed. As well as the risk of hypoglycemia, other factors should be considered when discussing the target including the overall clinical situation and risk of complications affecting the individual.

The natural history of the development of complications is long and in some situations may be longer than the life expectancy of the person with diabetes. It would be a poor trade to insist on switching a frail complication-free 90-year-old person to insulin if they subsequently fell and broke their hip and died as a result of insulin-induced hypoglycemia. Less melodramatic but still important is the consideration about dietary and lifestyle change in people with low risk of disabling complications: is it really necessary to deny an elderly person with diabetes a piece of birthday cake if this is one of the few pleasures in their life? A more sensible approach would be to advise a limit to portion size, rather than insist on severe dietary limitations.

Although there is a clinical emphasis on glycemic targets, the results of the Action to Control Cardiovascular risk in Diabetes (ACCORD) trial [23], the Action in Diabetes and Vascular disease: Preteraz and diamicron MR controlled evaluation (ADVANCE) trial [24] and Veterans Affairs Diabetes Trial (VADT) have led to a note of caution [25]. These trials have shown that tight glycemic control in people with a longer duration of diabetes did not prolong life. In the case of the ACCORD trial, increased cardiovascular mortality was seen in those receiving intensive glycemic control [23]. The underlying reasons for these findings are discussed in Part 8, but again their findings highlight the need for individualized targets.

### Assessment of cardiovascular risk

The most common cause of death in people with diabetes is cardiovascular disease (CVD) and much effort has been expended to develop strategies that will reduce its morbidity and mortality [26].

Cardiovascular risk should be assessed at least once a year for people with diabetes. This should include a history of cardiovascular risk factors, such as family history, smoking, an examination to include weight, waist circumference and blood pressure as well as investigations such as a lipid profile. The results of this assessment can be used to calculate cardiovascular risk using the various risk engines available. Some, such as the UKPDS risk engines for coronary heart disease and stroke, were designed specifically for use in people with diabetes [27,28].

Because the risk of myocardial infarction is as high in people with diabetes as in non-diabetic people with pre-existing CVD, the diabetes itself is widely considered to be a major risk factor for CVD [29]. This has influenced prescribing guidelines which now recommend that specific pharmacologic interventions are

required to reduce the incidence of CVD in people with diabetes regardless of risk assessment. Large randomized controlled trials have shown the effectiveness of these interventions and are discussed in greater detail in Chapter 40 [30].

Although physicians may appreciate the close connection between diabetes and CVD, many people with diabetes have never been told about this increased risk, and the importance of blood pressure and lipid control in diabetes. Thus, many individuals are not taking appropriate drugs for cardiovascular prevention or if they are then the doses may be inadequate to bring the individuals to the recommended targets (Table 20.1). When working with someone with diabetes, it is important that strategies to reduce CVD and the need for preventative drugs are discussed. In addition, the increased vascular damage promoted by smoking in the setting of diabetes may not be appreciated.

The main classes of drugs used are lipid-lowering drugs, predominantly statins, antihypertensives, particularly drugs acting on the renin-angiotensin system and aspirin. Antihypertensives are also important in the prevention of microvascular complications.

While each individual intervention for various risk factors is important in the prevention of macrovascular disease, the Steno II study has demonstrated that a coordinated approach to the management of cardiovascular risk can be successful [6]. In this study, the clinic setting and protocol-driven approach to overall cardiovascular risk led to improved mortality compared with routine care.

### Microvascular complications

Around 80% of individuals will have developed microvascular complications by the time they have had diabetes for 20 years [31]. Many complications will remain asymptomatic until they have catastrophic consequences. The management of microvascular complications involves measures to prevent, detect and treat. General measures such as optimal glycemic and blood pressure control lead to a reduction in the incidence and progression of microvascular complications but specific preventative measures are also needed and are discussed below [3–5,32].

#### Eyes

Diabetic retinopathy is the most common cause of blindness in people of working age (see Chapter 36). It is almost invariably asymptomatic until there is a catastrophic sight-threatening hemorrhage. For this reason it is important to screen regularly for retinopathy to allow treatment before hemorrhage and visual loss occur. Traditionally, this has been performed by examination of the visual acuity and fundoscopy within the diabetes clinic at least on an annual basis. Alternatively, in many countries, dilated ophthalmologic examinations are regularly performed by a specialist.

The gold standard for screening now is digital retinal photography, which may be undertaken in several different settings. When this is performed outside the traditional diabetes clinic, communication between the screener and diabetes team is essential if other aspects of diabetes care are to take account of the

development of retinopathy. Where retinopathy is detected within the clinic, it is the responsibility of the clinic to ensure that the patient is referred for specialist ophthalmologic attention in a timely fashion.

#### Neuropathy

Distal symmetrical polyneuropathy is the most common form of neuropathy seen in diabetes and is addressed in the following section on the diabetic foot. Autonomic neuropathy may affect the person with diabetes in a number of ways (e.g. gustatory sweating, postural hypotension or bloating) (see Chapter 38). Health care professionals should be alert to this possibility if symptoms suggestive of these conditions are raised.

#### Diabetic foot

Diabetes is the most common cause of non-traumatic lower limb amputation in the developed world (see Chapter 44). Around 10–15% of all people with diabetes develop a foot ulcer as a result of the combination of peripheral neuropathy and vascular insufficiency to the foot.

Prevention of ulceration is an important goal and requires education of the person with diabetes so that they are aware of this possibility. It is important to inform people that they should not delay obtaining professional help if problems ensue.

An assessment of the risk of foot ulceration is needed at least annually, and more frequently when neuropathy or vascular disease is present. The assessment should include a history of previous ulceration and trauma as well as an examination of the skin, vascular supply and sensation. Opportunistic foot screening should also be performed if an individual with diabetes is admitted to hospital.

In patients with numbness, close attention to discovering unsuspected foot lesions, including examination of the sole of the foot using a small mirror, must be performed by the patient on a regular basis. This can lead to a rapid intervention and prevent an early infection from progressing, potentially averting such devastating consequences as osteomyelitis and gangrene.

Prompt referral to the podiatrist and foot clinic should be arranged by the diabetes clinic if needed.

#### Kidneys

Diabetic nephropathy is characterized by a progressive increase in urinary albumin excretion which is accompanied by increasing blood pressure and decline in glomerular filtration rate, ultimately culminating in end-stage renal disease (ESRD). It is also associated with a marked increase in the rate of CVD.

Microalbuminuria, the earliest stage of nephropathy, affects around 50% of people with diabetes after 30 years while frank proteinuria affects one-quarter of people with T1DM after 25 years. Diabetic nephropathy is a common reason for the initiation of renal replacement therapy. Although it appears that with modern treatments of diabetes, the percentage of people with diabetes developing ESRD appears to be falling, the absolute numbers requiring renal replacement therapy is

increasing in line with the increased prevalence of diabetes worldwide.

Diabetic nephropathy is asymptomatic and so screening is required annually. This is usually achieved by measurement of urinary albumin excretion. The most common method is a single urinary albumin:creatinine ratio (ACR) measurement which should be repeated 2–3 times if abnormal. An estimation of glomerular filtration rate should be obtained annually.

The primary prevention of nephropathy relies on excellent glycemic control as well as tight blood pressure control. Once nephropathy is present, blood pressure management is the mainstay as there is little evidence that glycemic control at this stage slows the rate of progression. The antihypertensive drugs of choice are angiotensin-converting enzyme (ACE) inhibitors of the renin-angiotensin system (ACE inhibitors or angiotensin-2 receptor antagonists) as they have specific effects on renal blood flow [33,34].

There has been some debate about the value of undertaking urinary ACR measurements in people with T2DM, the argument being that tight blood pressure control (often including an ACE inhibitor or angiotensin-2 receptor antagonist) together with good glycemic control should form part of the general management of cardiovascular risk reduction.

It is important that the person with diabetes understands the need for screening and then treatment if nephropathy develops. Timely referral to the nephrology team is needed to ensure that the management of renal disease is managed promptly in patients with abnormal renal function.

## Diabetes emergencies

### Diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome

Diabetic ketoacidosis and hyperosmolar hyperglycemic syndrome are potentially life-threatening emergencies (see Chapter 34). It is important that the person with diabetes is educated about the risk of these and discusses strategies to prevent them. If a person with diabetes has been admitted with diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome, the opportunity should be taken to explore the reasons why this episode occurred and to identify what might be changed to prevent this from happening in future. The most common causes of hyperglycemic emergencies in those with pre-existing diabetes are infections and insulin omission and errors. It is particularly important that people with diabetes understand the “sick day” rules: insulin should never be discontinued and indeed doses may need to be increased, even when appetite is diminished.

### Hypoglycemia

Hypoglycemia is a much more common diabetic emergency, affecting around 10% of people with T1DM and 2.4% of insulin-treated people with T2DM (see Chapter 33). Hypoglycemia can have a major adverse effect on quality of life and is the most important limiting factor in the achievement of good glycemic control.

### Box 20.3 Causes of hypoglycemia

#### Excessive insulin administration:

- Person with diabetes, doctor or pharmacist error
- Deliberate overdose during a suicide or parasuicide attempt

#### Excessive sulfonylurea administration

#### Unpredictable insulin absorption:

- Insulin is absorbed more rapidly from the abdomen
- Lipohypertrophy

#### Altered clearance of insulin:

- Decreased insulin clearance in renal failure

#### Decreased insulin requirement:

- Missed, small or delayed meals
- Alcohol: inhibits hepatic glucose output
- Vomiting: may occur with gastroparesis, a long-term complication of diabetes
- Exercise
  - Promotes glucose uptake into muscle
  - Increases rate of insulin absorption

#### Recurrent hypoglycemia and unawareness

It is important that the person with diabetes is educated about the symptoms of hypoglycemia and the actions to be taken to prevent and treat this. Friends and family members should be invited to learn about hypoglycemia and its management in order to intervene where necessary, for example providing glucagon treatment if the person with diabetes is unconscious. If hypoglycemia becomes disabling or recurrent it is important to explore underlying causes.

### Lifestyle issues

Diabetes has a number of social, as well as medical, consequences and one aspect of diabetes care is to discuss how diabetes is affecting issues such as driving, education and employment (see Chapter 24). The health care professional may need to act as an advocate for the person where discrimination is occurring. Some aspects of lifestyle also affect diabetes care, such as diet, exercise, smoking and alcohol. These issues should be discussed carefully and sensitively in order to help the person with diabetes understand how their lifestyle affects their diabetes and general health. Support should be given to help and encourage a person with diabetes to make changes to their lifestyle.

### Psychologic issues

The diagnosis of diabetes can provoke a number of psychologic reactions, such as anger and sadness in the individual which may be akin to a bereavement reaction (see Chapter 49). More serious mental health problems such as depression are common in people with diabetes and these can impede the person's ability to achieve good glycemic control (see Chapter 55) [35].

It is important for those working in diabetes care to explore with the person with diabetes whether they are experiencing psychological problems as there may be reticence in raising this in the consultation. While all members of the diabetes team should be able to recognize and address basic psychological issues, the psychologist is an important team member to address more complex needs, such as eating disorders. Despite the importance of psychological issues, this need is frequently unmet because of a lack of trained health care professionals.

### **Sexual health**

#### **Sexual dysfunction**

Sexual dysfunction is more common in both men and women with diabetes than the general population. This can affect the person's quality of life considerably. Many people are reluctant to discuss this aspect of their lives because of embarrassment and so it is the responsibility of the health care professional to enquire about this. There are now effective treatments for erectile dysfunction and failure to ask about this can deny the person with diabetes the opportunity to receive treatment.

#### **Pregnancy planning**

Starting a family is an important milestone for many and the presence of diabetes can make this decision more difficult for the woman or man with diabetes (see Chapter 53). People are often worried about the effects that diabetes will have on their pregnancy and vice versa. The implications for the long-term risk of diabetes in the offspring are also of concern.

Planning for a pregnancy by a woman with diabetes can dramatically improve the outcome, reducing the risk of miscarriage, congenital malformations and macrosomia, with its attendant risks of shoulder dystocia, and neonatal hypoglycemia [36]. Some oral medications should not be used in pregnancy and the treatment regimen may need to be altered as part of the planning process.

Despite this, women frequently enter pregnancy without adequate preparation or pre-conception care. It is therefore incumbent on the health care professional to discuss pregnancy with all women of childbearing age, including adolescents, to ascertain their plans regarding pregnancy. The answers are often not black and white; women may state that they are not actively planning to become pregnant despite being sexually active and not using effective contraception. Contraceptive advice is needed and where a pregnancy is being planned, women should be referred to a dedicated pre-conception clinic as these have been shown to improve the outcomes of diabetic pregnancies.

With an increasing number of women with T2DM of childbearing age, it is important that pre-conception is not solely focused towards those with T1DM. This is particularly relevant as some women with T2DM are not seen in specialist centers.

Prompt referral to a joint diabetes antenatal clinic is necessary once a woman becomes pregnant.

---

## **Inpatient diabetes care**

It is estimated that around 10–15% of people in hospital have diabetes (see Chapter 32). In many instances, the diabetes is coincidental to the admission and the person with diabetes remains capable of managing their own diabetes, often with greater skill than the health care professionals around them. Good diabetes control remains an important goal as this improves the rate of recovery and may lead to an earlier discharge.

Admission to hospital is a worrying time but much of the fear can be alleviated if a full explanation of the treatment in hospital is given along with an opportunity to discuss any particular concerns. Being given the opportunity to discuss the management of diabetes is reassuring. Where possible, the person with diabetes should be allowed to continue to self-manage their diabetes. The individual should be encouraged to bring in their own insulin supplies where admissions are planned. There should be access to their regular diabetes health care team where possible as the admission may provide an occasion to check techniques and results. Ready access to carbohydrate and appropriate coordination of mealtimes, snacks and medication should obviate the need for more dramatic treatment of hypoglycemia.

There will be times when the person with diabetes is unable to manage their diabetes themselves. In these instances, the responsibility will fall entirely on the health care team, for example during surgery when the person with diabetes is unconscious and requires intravenous insulin and dextrose.

Following discharge, clear communication with the primary care team and diabetes clinic is essential so that any changes in management or medication are made known to those involved in the individual's care.

---

## **Involving people with diabetes in the planning of health care and service development**

Involving people with diabetes and their carers in the planning and decision-making of local health services allows these to be built around the needs of those who use the service, rather than the needs of the system [37]. An open dialogue is needed and service users should feel that their views are listened to. This will improve the accountability and legitimacy for any decisions made and is likely to improve clinical and care outcomes. People with diabetes should be encouraged to express their views and concerns about their services as better feedback about service provision which should help to improve and shape future provision of care.

---

## **Conclusions**

The aim of diabetes care is to improve the lives of those with diabetes. This can only be achieved through a partnership between

the person with diabetes and a multifunctional health care team that should be in place to support the person with diabetes.

---

## Educating the Patient with Diabetes

Carolé Mensing<sup>1</sup> & Barbara Eichorst<sup>2</sup>

<sup>1</sup>Joslin Diabetes Center, Boston, MA, USA

<sup>2</sup>Healthy Interactions, Chicago, IL, USA

### Keypoints

- Diabetes education is an important cornerstone of diabetes care, and supports the philosophy of the chronic disease model.
- Diabetes education improves clinical outcomes, and requires periodic follow-up.
- Time spent with a diabetes educator is the best predictor for improvement in diabetes outcomes.
- Patients and physicians agree that diabetes education is a necessary part of care.
- Being prepared with a variety of educational delivery methods is beneficial and necessary to meet the variety of patient learning styles.
- Understanding educational theories builds a strong base for selecting appropriate approaches to meet the needs of individual patients.
- A written plan developed in collaboration with a patient and their educator and care provider offers more chance of achievement.

### Introduction

Diabetes education continues to be cited as a cornerstone of effective diabetes care and supports the philosophy of chronic care models (Table 21.1) [1,2]. It is well established that the practice of diabetes self-management education (DSME) is critical to the care and management of people with diabetes, and that measurable behavior change is the unique outcome of working with a diabetes educator [3,4].

Now more than ever, diabetes educators are being held more accountable for their role in diabetes management. Over time it has become apparent that education standards and a system or framework describing self-care behavior could have an important role in supporting people with diabetes to consider behavior changes that might enhance their quality of life and support better management of their condition. The 2000 Standards for Diabetes Self-Management Education [5] and recent 2007 update [6], American Association of Diabetes Educators (AADE) Standards Development for Outcome Measure [3] and the outcomes model, the AADE7™ Self-Care Behaviors framework [7,8], now provide a common reference for establishing behavior change goals and establishing measurable outcomes. The seven self-care behaviors are: healthy eating; being active; monitoring; taking medicine; problem-solving; reducing risks; and healthy coping.

### Background

#### Standards and educational practice guidelines

DSME is central to delivering desirable metabolic and clinical care in diabetes. DSME is a comprehensive patient education structure that involves a multidisciplinary team to help achieve the necessary metabolic outcomes and improve the lives of those living with diabetes [9,10]. Metabolic improvements such as glucose, lipids and blood pressure in type 2 diabetes (T2DM) care are best achieved with a healthy lifestyle and appropriate use of pharmacologic interventions.

In 2003, the AADE published Standards for Outcomes Measurement of Diabetes Self-Management Education [3], complementing the National Standards for DSME in 2000 [5]. This publication was subsequently updated and revised in 2007 [6]. These standards offer the educator a program framework, which is based on five evidence-based principles:

- 1 In the short term, diabetes education is effective for improving clinical outcomes and quality of life;
- 2 DSME has evolved to a more theoretically based empowerment model;
- 3 There is no one best approach;
- 4 Ongoing support is critical to sustain progress; and
- 5 Behavioral goal setting is an effective strategy to support self-management behaviors.

This publication clearly identified that behavior change was the unique measurable outcome of diabetes education [3]. In 2004, these self-care behaviors were adopted by AADE leadership, trademarked as the AADE Seven™ [7,8], and have been incorporated into a framework for educators, community leaders and

**Table 21.1** Definitions.

<b>Diabetes educator:</b> a professional who provides education
<b>Diabetes self-management education (DSME):</b> the ongoing process of facilitating the knowledge, skill and ability necessary for diabetes self-care [7]
<b>Education:</b> a combination of interactive experiences
<b>Instructional curriculum:</b> a deliberate arrangement of conditions, written content, to promote actions towards an intentional goal [20]
<b>Learning:</b> An active goal-directed process, transforming skills, knowledge and application of values into new observable behavior
<b>MNT:</b> medical nutrition therapy
<b>Teaching:</b> a system of actions to bring about learning

medical professionals to advocate for diabetes self-care management. In addition, this framework provides the potential to be generalized to other chronic diseases and wellness care, and thrives on assessment and documentation.

Educators are guided by professional and discipline-specific scope of practice; these position papers, evidence-based research and standards for diabetes education practise the belief that behavior change can be effectively achieved by using these frameworks.

Three of the main components of DSME are an assessment, intervention and outcomes evaluation of the patient [9,11]. Ongoing collaboration and partnership between the patient and health care professionals is essential for effective DSME. The process involves interactive, collaborative and ongoing education that engages a person with diabetes in therapeutic decision-making [9]. DSME is available throughout the lifespan of the individual with diabetes and enables ongoing reassessment of self-management goals [9]. Diabetes is a progressive disease in which the clinical manifestations vary throughout the patient's lifespan [12]. Changes in stress, acute illness, aging and metabolic abnormalities can impact the clinical manifestations [12]. DSME approaches are typically adjusted as the patient's lifestyle changes and their condition progresses [9,11].

Also appreciated are the similarities and yet the variety of methodologies and delivery options to assist all people with diabetes and those affected by diabetes to achieve healthier outcomes, including adults, children, parents and older people. The purpose of this section is to introduce the concepts of how to acquire useful self-care information, and change concepts into behaviors that can be useful, measured and maintained over time. Although people with diabetes vary in age, type and duration of diabetes, the principles of education remain the same and are reflected in the following content.

---

## Considering change

The provision of DSME is challenging in any setting, whether outpatient, private practice, community service areas or hospital

settings, and is constantly changing. A paradigm shift has occurred in diabetes education. The learner is no longer the “patient,” rather a “person with diabetes.” DSME includes a circle of further learners, and others who are affected by diabetes, such as family members, work colleagues and neighbors. The health care team (nurse, dietitian, pharmacist, physician, other providers) are not just a deliverer of information, with a complacent learner; rather they are “educators” with learners involved in an active “interactive” (go-between) process. In this paradigm, the learners are both the educator and the people involved with diabetes. Each acquires a desire to learn based on need and consider all the alternatives available to them including information, treatment choices and equipment. Both attendee and educator are adjusting to new technologies, and the ever-changing techniques, approaches, settings and fiscal directives.

In addition, researchers on diabetes education programs have adequately demonstrated increased participant knowledge and corresponding improvements in glycemic control [13–16]. The optimal approaches in DSME delivery that are associated with better outcomes focus on behavioral strategies, encourage active engagement of patients, build self-efficacy, use cognitive reframing as a teaching method, are learner-centered and evidence-based where possible [10,17].

Diabetes education is a revered first step in preparing people with diabetes to make the necessary modifications to their lifestyle. Typically, health care professionals teach patients information that they believe is necessary. Evidence indicates, however, that most of the information shared by a health care professional with patients is forgotten soon after. Up to 80% of patients forget what their doctor tells them as soon as they leave the clinic and nearly 50% of what they remember is recalled incorrectly [18]. The Diabetes Attitudes, Wishes, and Needs (DAWN) study indicates that while 50% of persons with T2DM receive DSME, only 16.2% report adhering to the recommended self-management activities [19]. The DAWN study identified key goals that need to be achieved to improve outcomes: reducing barriers to therapy; promoting self-management; improving psychologic care and enhancing communication with health care providers, people with diabetes and their primary care providers that is consistent with educational standards (DSME) previously presented.

This said, the traditional lecture format, with its instructional knowledge-based content outlines, has also changed to involve and evolve using more interactive processes. The new standards for DSME [6] offer the format of “structure, process and outcome” directives for an established program to meet. These formats serve as an influence for third party reimbursement as well as offering the educator a structured evidence-based format for program development, implementation and evaluation. The standards also encourage new opportunities for alternative program involvement of educational options. The nine curricula (Table 21.2) offer the educator a written instructional topic-driven plan for education, and intentionally closely resemble the AADE7 self-management outcome behaviors (Table 21.3). The AADE7 then offers a template for behavior change identification,

**Table 21.2** Nine content areas (DSME) [6].

- 1 Describing the diabetes disease process and treatment options
- 2 Incorporating nutritional management into lifestyle
- 3 Incorporating physical activity into lifestyle
- 4 Using medication(s) safely and for maximum therapeutic effectiveness
- 5 Monitoring blood glucose and other variables and interpreting and using results for self-management decision-making
- 6 Preventing, detecting and treating acute complications
- 7 Preventing, detecting and treating chronic complications
- 8 Developing personal strategies to address psychosocial issues and concerns
- 9 Developing personal strategies to promote health and behavior change

process for change and evaluation of outcome. New and less experienced providers of education may find adopting these existing formats useful, while experienced educators may reconstruct, adapt and create more unique options. All educators are encouraged to participate in the discovery of alternative and creative activities to engage the learner and provide excitement and variety to their educational delivery methods. Mensing and Norris [20] offer instructional tips and educational skills for both.

The purpose of this chapter is to offer the educator and their colleagues the ability to review current education practice and to acquire more in-depth knowledge of interventions focusing on self-care behaviors. These behaviors can then more strongly offer information and potential behavior change opportunities based on a set of practices, presented in a curriculum framework.

The new standards and AADE7 frameworks offer educators an approach that is holistic, empowering and opportunities for patients to strengthen their independence and quality of life. The approach also supports a more public health, patient-centered approach for the person with diabetes and the educator.

### Patient-centered educational approaches

Patient-centered education, or learner-centered education, is now promoted by educators moving from provider-directed to “patient-centered” care and education in line with public health and chronic disease models of illness management. Diabetes educators were early proponents of this model and quickly incorporated strategies to meet the patients’ agenda at each encounter [21].

This more patient-centered approach frees the educator to provide personalized (less didactic) information, encouraging lessons to be learned and then applied into patients’ own lives thereby providing reinforcement and follow-up. As summarized by Funnell [7], patients are more successful if they hear consistent messages and the same single messages from all care providers, educators and team members.

Diabetes education is a first step in preparing patients to make necessary modifications to their lifestyle. As many patients forget

**Table 21.3** The AADE7 self-management outcome behaviors. Data from AADE website ([www.diabeteseducator.org/AADE7](http://www.diabeteseducator.org/AADE7)).

- 1 Healthy eating** Making healthy food choices, understanding portion sizes and learning the best times to eat are central to managing diabetes. Diabetes education classes can assist people with diabetes in gaining knowledge, teaching food choice skills, and addressing related barriers
- 2 Being active** Regular activity is important for overall fitness, weight management and blood glucose control. Collaboration between patients, providers and educators best addresses barriers, and helps develop an appropriate activity plan that balances food and medication with the activity level
- 3 Monitoring** Daily self-monitoring of blood glucose provides people with diabetes the information they need to assess how food, physical activity and medications affect their blood glucose levels. Monitoring includes: blood pressure, urine ketones and weight. Education is offered about equipment choices, testing times, target values, and interpretation and use of results
- 4 Taking medication** Diabetes is a progressive condition. The health care team will be able to determine which medications people with diabetes should be taking and help them understand how the medications work. Effective drug therapy in combination with healthy lifestyle choices, can lower blood glucose levels, reduce the risk for diabetes complications and produce other clinical benefits
- 5 Problem-solving** Assistance to make rapid informed decisions about food, activity and medications, and develop coping strategies
- 6 Reducing risks** Effective risk reduction behaviors such as smoking cessation, and regular eye, foot and dental examinations reduce diabetes complications and maximize health and quality of life, available preventive services. These include smoking cessation, foot inspections, blood pressure monitoring, self-monitoring of blood glucose, aspirin use and maintenance of personal care records
- 7 Healthy coping** Health status and quality of life are affected by psychologic and social factors. Coping: a person’s ability to self-manage their diabetes is related to their skills. Identifying the individual’s motivation to change behavior, set achievable behavioral goals and provide support.

much of what is said in clinic, educators and clinicians must recognize the need to involve patients in determining what they feel they need and address this first as a way to engage patients, and improve their retention of information.

The information sharing among health care professionals and retention of information by people with diabetes is not enough to help them to change their behavior. The quality and quantity of effective communication between health care professionals and people with diabetes is the most critical indicator of successful DSME. Increased contact time between health care professionals and patients has been associated with better regimen adherence and glucose reduction [15].

So what is the best way to teach people with diabetes? How do we know that they are learning? What is the evidence supporting the education methods we choose to utilize? A simple elementary school approach from Anna Devere Smith, which “thinks of edu-

cation as a garden where questions grow,” seems to describe the learner-centered approach applicable for adults with diabetes most aptly [73]. People with diabetes need an appropriate environment where they can share their challenges with their lives with diabetes, ask health care professionals for help with strategies and consequently concord with the prescribed regimen.

The principles of facilitation and patient-centered intervention have been recognized to be superior to a didactic and more passive teaching approach [9,10]. One of the DSME standards states that “there is no one best education program or approach; however, programs incorporating behavioral and psychosocial strategies demonstrate improved outcomes. Ongoing support is critical to sustain progress made by participants during the DSME program” [9]. There is strong evidence that goals generated by patients produce better outcomes than goals that are generated by health care professionals [9].

There are many educational approaches that are utilized by diabetes educators to help patients acquire knowledge, skills and commitment to self-care behaviors necessary for effective diabetes care [9]. Typically, individual adult T2DM education interventions allow the educator to tailor the approach to the patient’s specific needs and consequently provide effective therapy. However, evidence indicates that group diabetes interventions can be more cost-effective, patient-centered and provide interactive learning with a high level of patient satisfaction compatible with individual interventions. The educational approaches and methods utilized in group education differ among diabetes educators. Therefore, further research is needed to determine which educational approach and method utilized by diabetes educators contributes to effective teaching that produces the best clinical outcomes in adults with T2DM. The existing best practices in group education indicate that the best outcomes are produced with an empowerment approach, which focuses on when and what patients want to learn. Problem-based, culturally tailored approaches that include psychosocial, behavioral and clinical issues relevant to the patients’ needs and readiness to learn have resulted in improved outcomes [22].

DSME aligns with a chronic disease model that indicates that educational approaches should be non-complex, individualized to a patient’s needs and lifestyle, reinforced over time, respectful to an individual’s habits, and should incorporate social support [9,23,24]. Chronic disease care approaches use similar strategies to DSME as they focus on collaborative problem definition, goal-setting, continuum of self-management training and support services [9]. The general consensus on chronic disease interventions indicates that the most beneficial components of education are individualization, relevance, feedback, reinforcement and facilitation [23–25].

How do we provide learner-centered education in a group setting? How do we evaluate everyone’s unique learning needs and provide individual attention they deserve? The complexity of the individual needs assessment and training in a group setting presents a challenge for effective self-management education. The challenge is to individualize the approaches similar to a typical

one-on-one session but in a group session. Successfully individualizing the group session allows the patients to learn, retain their knowledge and be committed to the follow-up action plan. Traditional didactic education that focuses on teaching information through lectures without patients’ engagement has been shown to be ineffective in helping patients change their lifestyle behaviors necessary to improve clinical outcomes [26–28]. Diabetes knowledge does not guarantee changes in behaviors that eventually lead to better outcomes. The learner-centered approach employs non-didactic and less passive strategies in an attempt to promote active engagement in the learning process. A patient-centered education reflects the best practices and theories that have been shown to promote patients’ knowledge retention, commitment and improved self-care outcomes. These include facilitation, empowerment, motivational interviewing, behavioral goal-setting, behavioral and psychosocial strategies, and ongoing support [26–34]. The process allows for the patients to discuss their understanding of diabetes, internalize their commitment and determine their priorities. This process also allows for ongoing implementation of short and long-term goals, which can then be monitored for progress. Patients come up with their own solutions to their own diabetes challenges instead of being told what they should do by the educator. The expectation is that by identifying what is practical and achievable, patients ultimately own their own commitments and will be more likely to accomplish the requisite lifestyle changes [28,35,36].

Effective diabetes education aligns with the principles of adult learning as adults learn most effectively when information is simple, practical and relevant (i.e. directed by their interests), the learning builds on participants’ experiences and there is a focus on application (i.e. when learning is applied to action) [37]. This process of learning involves cognition, emotions and environmental factors that impact knowledge level, skill acquisition and views [38].

---

### **Educational theory behind the practice: models and methods**

The core foundation of the diabetes education philosophy is that patients are ultimately responsible for their own self-management. The assumption is that patients want to maximize the quality of their life and self-management education [39]. Health care professionals help patients identify ways to make changes necessary for a healthy way of life. Each person with diabetes differs and therefore requires unique lifestyle skill strategies that are applicable to his or her circumstances.

Traditional lecture-based didactic education approaches place the learner in the role of the recipient and the instructor in the role of the “knowledge-giver.” It does not allow the learner to think critically and perceive their own personal and social reality, which are critical steps for adapting to chronic disease [30,31]. DSME allows patients to be part of the decision-making about their self-care and management [32]. Patients develop confidence

in making informed decisions about their medical condition and can choose to act on it.

An additional approach that aligns with effective diabetes education methodology is motivational interviewing. This is closely linked with the empowerment theory as it focuses on creating opportunities for patients to come up with their own assessments and set their own goals [33]. Motivational interviewing is another example of a learner-centered intervention that is considered an effective approach to promote patients' knowledge retention, self-care commitment and improved self-care outcomes [24,33,34].

The proposed theoretical basis evident in a patient-centered diabetes education concept includes the Health Belief Model, the Trans-theoretical Model/Stages of Change, Common Sense Model, the Social Learning Theory and the Dual Processing Theory [40–43]. These commonly utilized theories in diabetes education allow for successful communication with patients through fostering effective listening, relationship building and creating an environment of respect and trust. These theories strengthen an educator's theoretical basis for an effective diabetes education technique. The theories also reflect on the approaches utilized to promote a meaningful dialogue with those involved in diabetes education. The theories help to integrate concepts better for a wider variety of individuals, regardless of age, gender or ethnicity.

### **Theory: the Health Belief Model**

The Health Belief Model is a psychologic framework that outlines predictable health related behaviors [40]. People's life experiences and exposures to past events shape their perception of susceptibility, severity, barriers, benefits and cost of adhering to prescribed interventions. The process of diabetes education should allow for an effective discussion and exploration of beliefs which is needed to promote appropriate self-care. Without an adequate Health Belief Model patient assessment, patients may lack the necessary motivation to overcome their belief barriers.

### **Theory: the Stages of Change Model**

Learning and making changes in one's lifestyle is a process of adjusting what can be done, when and how. The multiple interactions with patients allow diabetes educators to guide them to transition with their commitments to make the change. The Prochaska's Stages of Change Model [44] outlines the predictable process of change as patients not only learn what they are ready to learn, but also understand the reasons behind the need for change and strategies. The Stages of Change Model illustrates the five stages in a continuum of behavior change: pre-contemplation, contemplation, preparation, action, maintenance and relapse [44]. Each stage has an important role in supporting an evolutionary process whereby learners recognize the need for change, act, evaluate and react.

Diabetes educators can help patients to increase their realization of importance of change, confidence, and readiness by asking meaningful questions. Importance of change can be addressed

by asking why? Is it worthwhile? Why should I? How will I benefit? What will change? At what cost? Do I really want to? Will it make a difference? By asking how and what diabetes educators can help patients to evaluate their confidence to change. Consider asking, can I? How will I do it? How will I cope with ...? Will I succeed if ...? What change ...? When assessing readiness, start asking when? Should I do it now? How about other priorities? [45].

### **Theory: the Common Sense Model**

The theoretical framework of the Common Sense Model is based on the balance of danger and fear control [40]. This theory implies that people will not self-regulate unless there is a significant and relevant understanding of the condition, cause, disease timeline, consequences, curability and controllability. The internal cognitive representation of the illness is balanced by emotions that require effective coping skills and appraisal.

The first component of the five assumptions in the theory is that patient identifies the condition. The second is the patient's perception on what actually caused the condition. The third consideration is of a timeline and how long the patient thinks that the condition is going to last. The fourth component of the Common Sense Model is the patient's understanding of the consequences of the disease and how it will affect their future. The fifth component relates to a patient's perception of treatment effectiveness [40]. The perceived vulnerability to diabetes complications is more significant among patients who have witnessed severe complications among people they know, such as family members or loved ones [46]. Witnessing and getting to know other patients in a group setting with varied levels of diabetes complications can allow people to internalize the necessary steps to control their condition more effectively.

### **Theory: the Social Learning Theory**

The foundation of the group education session is a discussion among patients that allows them to learn from one other. The Social Learning Theory outlines the social context necessary for role modeling. It also asserts that the inspiration and support generated by group interaction helps patients change their behaviors [41]. Both social interactions and psychologic factors influence learning. According to Bandura [47]: "Learning skills is not enough, individuals should also develop confidence in the skills that they are learning. Success is not necessarily based on the possession of the necessary skills for performance; it also requires the confidence to use these skills effectively."

### **Theory: the Social Cognitive Theory**

In the attempt to turn the Social Learning Theory into an observational behavior that the educator can witness, four categories can be derived from the Social Cognitive Theory [47]. In terms of the educator's role, these four categories can illuminate the behaviors seen within the group education session. The first characteristic is the role of the facilitator who creates an environment for a successful experience. The second is role modeling through

various experiences whereby the educator observes others' performance. The third is verbal persuasion, where the facilitator skillfully summarizes the information, acknowledges the situation and participants' beliefs, indicating that the problem can be managed. The facilitator actively encourages people to be verbally explicit when elaborating on their management and future choices. The final aspect involves physical and affective state of identification of physical and emotional sources of symptoms. The facilitator acknowledges and/or responds to emotional utterances by the participants [47].

### Theory: the Dual Processing Theory

The Dual Processing Theory relates to a patient's individual understanding of the medical condition by allowing the learner to discover his or her own solutions. The theory dictates the need to involve patients actively in the learning process [42]. The Dual Processing Theory has two actions, such as activation of a mental representation of an issue and its interpretation based on mental retrieval of events and feelings related to it [43]. The effective group education needs to allow a learner to discover his or her own solutions which increases the patient's understanding of their medical condition.

Effective diabetes group education approaches use facilitation instead of traditional didactic teaching to produce effective learning [26–28]. The health care professional is responsible for managing the group dynamics and the scope of the group's conversation. Participants are responsible for addressing issues of relevance to their diabetes management and developing strategies to care for themselves better.

Productive diabetes education strategies utilize the best in adult education methodology that allows for patient engagement. Learning theories demonstrate that adults learn best what is personally applicable and important to them [31]. Without a meaningful learning experience, they may ignore or dismiss the presented information. Also, adults learn best in social circumstances rather than classroom settings [32]. Adults prefer to learn from discussion, incorporation of life experiences and other interactive approaches over lecture, print, computer-based or audiovisual presentations [33,48]. Effective learning activities for adults should involve participants in the learning process, motivate, promote self-determination, meet the learning needs, allow the sharing of personal knowledge and experiences, promote competence, reinforce positive behaviors and help adults to identify consequences of behaviors [32,49].

---

## Curriculum

There are many DSME curricula available for the diabetes educator to choose that can be integrated as a complementary tool to the existing DSME curriculum or can be used as a stand-alone approach. However, most of the curricula have not been validated with sound research and studies. Many of the available curricula utilize evidence-based approaches in diabetes self-

management education but as an independent approach have not been validated.

An example of a reliable and valid curriculum has been carried out in a study by Kulzer *et al.* [26], which compared three diabetes educational methods and their effect on clinical indicators. The three educational approaches were:

- 1 A didactic method involving four sessions of 90 minutes in a group setting with a focus on knowledge acquisition, skill and information;
- 2 A group education with a non-didactic focus on self-management and empowerment that addressed the emotional side, the cognitive side and motivational interviewing to promote learning within 90 minutes over 12 sessions; and
- 3 The same empowerment focus as the second method but conducted as individual interventions for half of the 12 sessions and as a group for the other half.

The study included 181 patients with T2DM, non-insulin treated, body mass index (BMI) above 26.7 kg/m<sup>2</sup>, no acute psychiatric illness and the ability to read and speak German. The results indicated no change in HbA<sub>1c</sub> for the didactic group. There was a significant improvement in HbA<sub>1c</sub> in the second group, which was the empowerment-based group. The third group intervention resulted in an initial improvement in HbA<sub>1c</sub> that was not sustained for the duration of the study, indicating that individual intervention to deliver empowerment had no superior effect to group intervention. The results of this study build on the patient-centered educational assumptions that effectively facilitated group diabetes education produces superior clinical and behavioral outcomes than individual interventions. Also, patient-centered approaches and empowerment focused education produced better outcomes than a didactic curriculum. The applicable curriculum attempts to utilize the principles of the effective group-based empowerment education.

An example of a curriculum that is based on a collection of the evidence-based approaches but not validated as an independent strategy is the Diabetes Conversation Map™ program. In an effort to increase the availability of DSME to adults with T2DM, Healthy Interactions Inc. collaborated with the American Diabetes Association (ADA) to develop the US Diabetes Conversation Map® tools and on a global market with the International Diabetes Federation (IDF) to develop the Diabetes Conversations program [50]. The goal of the program is to engage patients more effectively through their interactions with health care professionals and to learn about diabetes and lifestyle modifications that can lead to improved diabetes self-management [51].

The Diabetes Conversation Map tools' content is based on current clinical practice guidelines that represent the best intervention approaches and national standards for DSME. The tools are designed to create meaningful discussions about diabetes between participants that are patient-focused and that help formulate behavior change goals. Patient-centered group interventions such as those used in the Conversation Map learning approach are intended to improve behavioral, clinical and meta-

bolic markers [ 35,36,52–55]. A few other examples of curricula are: *Life with Diabetes: A Series of Teaching Outlines* by the Michigan DRTC (ADA); *Diabetes Education Curriculum: Guiding Patients to Successful Self-Management* (AADE); *Basics Diabetes Education Curricula*, International Diabetes Center products; and *On the Road* (USDA, Joslin Diabetes Center).

In 2003, the *Technology Appraisal 60* from the National Institute for Health and Clinical Excellence (NICE) in the UK defined diabetes patient structured education as: “a planned and graded programme that is comprehensive in scope, flexible in content, responsive to an individual’s clinical and psychological needs, and adaptable to his or her educational and cultural background.” In its review of the evidence, NICE identified some principles of good practice including that: “education should be provided by an appropriately trained multidisciplinary team to groups of people with diabetes, unless group work is considered unsuitable for an individual.”

Further work published in 2005, *Structured Patient Education in Diabetes – Report from the Patient Education Working Group*, identified the criteria to be used when assessing whether diabetes structured education programs met the NICE guidance. In 2006, a self-assessment tool was developed for existing and future programs, which helped to make the criteria more explicit, and which gave programs a framework for developing an action plan so that the criteria could be met [56–58].

The key criteria for to meet NICE guidelines for structured education are that the programs must:

- Have a structured written curriculum;
- Have trained educators;
- Be quality assured; and
- Be audited.

The current status of Diabetes Structured Education in the UK includes several well-established national and local programs for both T1DM (DAFNE) and T2DM (DESMOND and X-PERT). In addition, there are a number of locally developed programs such as JIGSAW and BERTIE. Not all of these programs profess to meet the NICE guidance in its entirety, as elements of the criteria are still in various stages of development for different programs (e.g. audit, quality assurance). What is currently being expected of programs is that they are “seeking to fulfil the NICE criteria” or “working towards meeting the criteria for NICE guidance” and have development plans in place.

The main limiting factor in Diabetes Structured Education is that it does not include ongoing care and education. Once patients complete the program in its entirety they do not have a component of ongoing support to allow tailoring of the education to their changing lifestyle and diabetes care needs. The provided education becomes education for life and therefore conclusive, without opportunity for an information refresher or support mechanism needed to adjust to changes in perceived needs and preferences of people with diabetes. The lifelong process of diabetes self-management requires adjustments in knowledge, skills and motivation to assess the risks, to under-

stand what there is to gain from changing the behavior or lifestyle and to act on that understanding by engaging in appropriate behaviors. Education should be a lifelong process, starting at the point of diagnosis and remaining as an essential component of diabetes care.

Despite availability and good access to Diabetes Structured Education in 55% of primary care trusts, less than 10% of people reported attending an education course on how to manage their diabetes. A total of 16–41% of people with diabetes who had not attended a course, however, reported that they would like to attend such a course [74].

The DSME in the USA has a component of ongoing lifelong education where it is federally covered for the Medicare beneficiaries with diabetes. DSME is delivered for 10 hours initially during the first education program and 2 hours annually for subsequent education programs [59]. However, only 54.3% of people with diabetes who responded to a national survey in 2005 reported attending some type of DSME class [60]. The 2007 Diabetes Patient Market Study indicated that 26% of patients had seen a diabetes educator in the past 12 months [61]. The AADE analysis of the Center for Medicare and Medicaid Services reimbursement for DSME found that only about 1% of its applicable beneficiaries received DSME in 2004 and 2005 [62]. These results might suggest that patients with diabetes choose not to attend the DSME programs, do not know about their availability or have inadequate access. The existing trends in diabetes education rates indicates a strong probability that the Healthy People 2010 goal of increasing the DSME rate to 60% is unlikely to be achieved [63].

A systematic review of the clinical effectiveness of diabetes education models for type 2 diabetes indicates varied significance and inconsistent results in achieving desirable markers of success. The positive trends are attributable to longer term interventions with a shorter duration between the end of the intervention and the follow-up evaluation point with a multidisciplinary team approach. The inconsistencies in the markers of success and applicable approaches to measure them in the long-term constitute a barrier in their interpretation and practical applications. Also, it is unclear what is needed to prepare and support educators adequately to ensure that they can deliver programs successfully. The need for future research still exists on the comprehensive, ongoing and complex interventions education methods; this should include high quality, longer term studies with a careful consideration around the nature of any control group as well as factors and/or qualifications necessary among educators to ensure success and cost-effectiveness of education programs [64].

---

## Patient education: engaging techniques

Education is initiated at the first encounter by asking what information the person wishes to obtain from this visit. To engage patients in the process and assess needs, a few simple techniques can be applied:

1 Ask “leading” questions, as people respond better to their own interests:

- For example, utilize the technique of open-ended enquiry stems: “Tell me about ...,” “What do you find the most challenging about ...” or “How do you ...?”
- Reflective listening stems are another source of assessment tools. The phrases “It sounds like ...” or “Let me see if I understand you ...” Allow for conversation, clarification, developing some of their own solutions and a chance for the patient to determine if you have the correct information and understand their situation. Encouraging them to tell their personal story helps open the door for a more personal collaborative relationship [65,66].

2 Encourage interaction leading to content discovery, determining the need for more information, improving accuracy and skill development. This technique is as useful for other group attendees, including family and friends who are also attending the visit with the patient.

3 Take more time to get the real story, not just yes or no answers to questions. As described by Anderson and Patrias [67]: “When patients fully describe their concerns and express their feelings, it is time to help them consider possible solutions.”

- The use of a form with leading questions, completed while in the waiting room, pre visit, can set the stage for a more patient-centered directed visit [67].
- In addition, directing enquiry statements to focus towards the AADE7 healthy behaviors assists in crafting goals and targeting behaviors and action plans for the future.

---

### **Planning ahead: experiment, reframe, facilitate, evaluate**

Difficulties sometimes arise when there are time constraints or a variety of learning styles (audio, visual, tactile). New diagnoses or an unexpected change in treatment plan may also be challenging for the individual. The learning environment and acquisition of knowledge and skills can be compromised. It is to the educator’s advantage to plan ahead both for coping and problem-solving and to alter the curriculum to fit the situation. In times of stress, however, some educators may fall back on more traditional lectures, and the use of PowerPoint and pre-prepared handouts. Having a variety of core techniques, topics and alternative key delivery strategies can help to refocus back to the person, keeping the session patient-centered [20,21,65].

These core techniques help the educator regroup, and aid in planning for a variety of ways to deliver the same message.

#### **Experiment**

As you begin to understand the patient and their preferences and desires, think about experimenting with alternative ways to deliver the informational message, build skills, knowledge base and application in the real world. For example, to deliver a key message about the AADE7 domain of “healthy eating,” consider

using a local restaurant’s menu to plan a festive holiday dinner instead of the didactic teaching of the number of “carbs” in a meal plan.

#### **Reframe the information**

Change your wording; for example, instead of “dieting” – use “meal planning.” Another example in the domain of “being active” could be the reframing of “increasing activity.” Think of using a phrase such as “decreasing inactivity” and “new activity planning.”

#### **Plan ahead**

Identify at least two or three alternatives for the delivery of a concept; for example, appeal to each of the audio “Hear a message”, visual “See the message in words or picture” and tactile/kinesesthetic “Perform an activity” learning styles. In addition, the use of a variety of effective teaching learning strategies assists in moving concepts across the spectrum of age, culture and literacy.

#### **Facilitate, don’t teach**

You already know the answer and so the key to facilitation is to determine what the patient knows and what information they have on hand to begin problem-solving (discovery learning). Your expertise is, of course, implied. Drawing out information and encouraging problem-solving from the patient directly helps them integrate and synthesize information that will support future thinking and confidence.

#### **Trust**

A relationship of trust between educator and patient is the basis for successful achievement, and the patient has a right to privacy.

#### **Evaluate**

It is important to plan to keep track of content items discussed and the behavior change goals that are set. Often, educators spend the majority of their time covering the same content, repeating concepts over and over again. This may be because of educator comfort level, and preplanned content, rather than establishing what the person with diabetes might prefer. This may occur in both DSME and during medical nutrition therapy sessions. When this happens, behavior outcome goals related to healthy coping and behavior change goal-setting are often the least addressed, whereas healthy eating, monitoring and being active are the most common behavior change goals identified. Thus, mutually identified healthy coping and problem-solving goals may improve targeted appropriate educational strategies to support patients in meeting their goals and finding resources from the outside world [68].

Whitlock reviewed self-management processes and described a model for educational counseling to assist with broadening the educational experience by focusing on patient needs versus educator goals for the session. This approach consists of 5 A’s (Table 21.4): assessment, advise, agreement, assistance and arrangement. Another approach is the Mensing reference (Table 21.5) which

**Table 21.4** Whitlock model.

- 1 **Assess** risks and readiness to change
- 2 **Advise** with clear personalized change advice
- 3 **Agree** by setting collaborative goals
- 4 **Assist** using behavior change techniques and social support
- 5 **Arrange** for follow-up

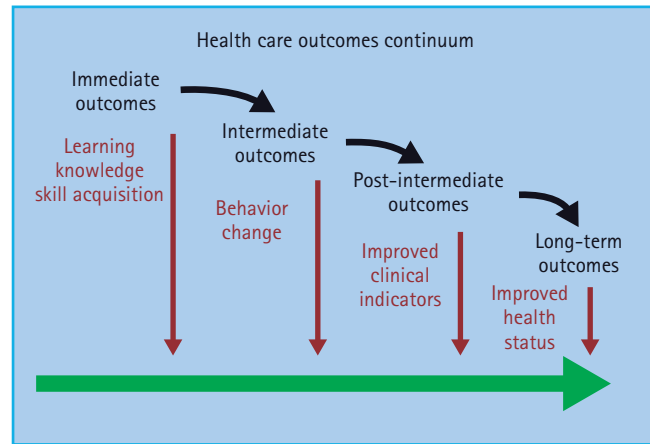

**Table 21.5** Drafting a Written Plan. Adapted with permission from Mensing [65].

Assessment	View as critical to problem-solving – listen Tune into culture, uses new techniques
Developing a plan	Plan ahead, be practical, plan some problem-solving Keep a good pace, and include a behavioral action plan Better to cover fewer topics and select implementation plan Avoid overload
Implementation of diabetes education	Consider learning styles, readiness of learner and teacher Practice sensitivity and cultural awareness Help translate the science into everyday self-care practices Be flexible Education is ongoing, not just a one time event
Evaluate and document outcomes	Captures information, progress and fosters reinforcement Useful to patient progress, teaching strategies and process Assists with tracking educational content consistency Acknowledges potential behavior change goals, and comparisons with clinical care goals

offers a set of quick reminders, key elements and assessment, through follow-up and documentation [20,69].

### Collaboration: drafting a written plan

A critical outcome of diabetes education is the patient’s behavior change plan. Self-care behaviors as the key outcome of DSME have been established. A written plan is set up with indicators such as an overall goal and an identified outcome. The goal is defined as a general non-specific health outcome (e.g. to lose weight, or to feel better). The AADE7 domains are useful categories. The patient and educator collaboratively take this goal and set up very concrete, specific actions as a plan, which describes the steps to be taken to achieve this goal. The steps are written in very concrete terms, are measurable, realistic and mark progress over time. The action steps clearly describe exactly what the patient intends to do. Educators are encouraged to help the patient determine how convinced they are that this activity will happen, how confident they are. This is sometimes objectively identified on a scale of 0–10 (not confident to extremely confident) [8,65]. This technique offers clarity and discussion, while supporting the establishment of realistic action plans. Review of

**Figure 21.1** Diabetes self-management education (DSME) outcomes continuum. Reproduced from Peeples *et al.* [70], with permission from Sage Publications.

the plan at intervals assists the patient and the educator in evaluating progress towards the goal, if the goal is appropriate or if expectations and action steps need to be altered. The AADE outcomes system assists with identifying immediate outcomes (knowledge, skill) and sets the expectation for longer term outcomes, such as improved HbA<sub>1c</sub>, lipids and general health status (Figure 21.1).

In addition, it has also evaluated progress, and has provided tools for data documentation, tabulation, configuration, aggregation, analysis and review. A number of data software systems are available to ease data recording. Zgibor *et al.* [68] identified that the domains of “healthy eating” and “physical activity” are the most frequently identified behaviors. Educators are encouraged to consider offering more time to identifying these problem-solving goals. Of note, patients seldom identified more than one goal, and clearly not more than one of substance, yet, as was referenced, the domains of healthy coping and problem-solving may be more useful in the long-term behavior changes that help patients toward successful accomplishments, rather than just the familiar food, activity, monitoring references [68].

In summary, educators should utilize of a wide variety of models and techniques that enhance the acquisition of information, and offer an interesting and creative educational, learning and empowering environment for all the learners, educators and patients alike.

### Maintaining and promoting achievement

Measurable behavior change is the unique outcome of working with a diabetes educator. Healthy People 2010 has identified the need to increase the percentage of patients with diabetes receiving education, so that the current 40% would be increased to be at least 60% [68].

Adopting an outcomes framework, directing energy and time to developing educational plans following the guidance of the

main existing frameworks, DSME and incorporating the AADE7 approach into everyday practice is just the beginning. The structure helps to assess current preferences and behaviors of the individual with diabetes, discuss potential benefits, barriers, problem-solving and set a mutually agreed upon plan of behavioral interventions.

Key to the process lies in the follow-up. Methods for setting up measurable indicators, monitoring schedules and documentation are needed for evaluation. Summary information is then available for the patient, health care team, and potentially for insurance and regulatory purposes.

---

## Conclusions

In summary, as more and more systems and standardized educational frameworks such as the AADE7 are implemented, behaviors and clinical outcomes will be better linked and evidence-based benchmarks will become available. Behavior change and diabetes education have been shown to be effective for short-term outcomes [71,72]. Further investigation needs to be conducted to assess long-term outcomes. Clinician and educator time will be well spent by individualizing care plans, paying attention to the process of educational information delivery methods and offering patient-centered care.

## Lifestyle Issues: Diet

### Monika Toeller

German Diabetes Center, Heinrich Heine University Düsseldorf and Leibniz Center for Diabetes Research, Düsseldorf, Germany

#### Keypoints

- Lifestyle interventions to improve glucose, blood pressure and lipid levels, and to promote weight loss or at least to avoid weight gain remain the underlying strategy throughout the management of diabetes even when additional medications are needed.
- Metabolic variables, such as HbA<sub>1c</sub>, post-prandial blood glucose concentrations, serum triglyceride and low density lipoprotein cholesterol levels, can be used to suggest the most appropriate intakes of carbohydrate-containing foods.
- Vegetables, legumes, fruits and wholegrain cereal-based foods should be part of the diet because they are rich in dietary fiber, low in glycemic index or load and provide a range of micronutrients.
- In those treated with insulin or oral hypoglycemic agents, the timing and dosage of medication should match the quantity and nature of carbohydrate to avoid hyperglycemia or hypoglycemia. Blood glucose self-monitoring may help to make appropriate choices.
- Saturated, trans-unsaturated fatty acids and dietary cholesterol should be restricted to reduce the risk for vascular disease, whereas oils rich in monounsaturated fatty acids as well as oily fish rich in n-3 polyunsaturated fatty acids are useful fat sources.
- In patients with type 1 or 2 diabetes without evidence of nephropathy, usual protein intake (up to 20% of the total energy intake) need not be modified. In those with established nephropathy, protein restriction to 0.8 g/kg normal body weight per day may be beneficial.
- Alcohol intake should be moderate.
- Foods naturally rich in dietary antioxidants, trace elements and other vitamins are encouraged. Routine supplementation and the use of so-called special diabetic foods are not recommended.
- Individual dietary advice by physicians and dietitians and structured nutritional training are an essential part in the continuing treatment and education process of people with type 1 and 2 diabetes.

### Introduction

Nutritional management in diabetes aims to assist in optimizing metabolic control and reducing risk factors for chronic complications. This includes the achievement of blood glucose and glycosylated hemoglobin (HbA<sub>1c</sub>) levels as close to normal as is safely possible and serum lipid concentrations as well as blood pressure values that may be expected to decrease the risk for macrovascular disease. Individual therapeutic needs and the quality of life of the person with diabetes have to be considered when nutritional objectives are defined [1,2].

Diabetes health care teams should use the best available scientific evidence while giving dietary advice to the individual patient with diabetes. During recent years, the development of evidence-based guidelines in the management of type 1 (T1DM) and type 2 diabetes (T2DM) has adopted a more formal approach to the evaluation of evidence underlying the guidance [3].

Currently available evidence-based nutritional recommendations for individuals with diabetes have involved a formal search

of the literature using agreed sets of descriptors and relevant databases. The strength of evidence for the different nutritional recommendations is graded according to the type and quality of published studies as well as by statements from expert committees, which also take into account clinical experiences of respected authorities. Ideally, evidence-based guidelines are formulated from trials with fatal or non-fatal clinical endpoints; however, as this information is often not available, surrogate endpoints, such as glycemia, body composition, lipoprotein profile, blood pressure, insulin sensitivity and renal function, are frequently used to determine the potential of dietary modification to influence glycemic control and risk of acute and chronic complications of diabetes [1]. Tables 22.1–22.3 provide important dietary recommendations for people with T1DM and T2DM and the degree of evidence assigned to these recommendations by the Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes (DNSG EASD) and the American Diabetes Association (ADA).

### Energy balance and body weight

Controlling body weight to reduce risks related to diabetes is of great importance. When weight loss and increased levels of activ-

ity are achieved and maintained, in T2DM in particular, these interventions represent an established and effective therapeutic strategy for achieving target glycemic control [1,2,4]. Therefore, there is a consensus that such lifestyle interventions should be initiated as part of the treatment of new-onset T2DM [5–8]. Even modest weight loss, especially in abdominal fat, improves insulin sensitivity and glucose tolerance and reduces serum lipid concentrations and blood pressure. Weight loss may lead to greater benefit for cardiac risk factors in people with a high waist circumference [1,4]. Visceral body fat, as measured by waist circumference, is used in conjunction with body mass index (BMI) to assess the risk of diabetes and cardiovascular disease (CVD).

Overweight patients with T1DM may also become insulin resistant and weight reduction in these people may lead to a decrease of the insulin dose and improved glycemic control [1].

Prevention of weight regain is an important target in those who have lost some excess weight. Long-term restricted energy intake is necessary to sustain the metabolic improvements that can be achieved by weight reduction.

Losing weight is particularly difficult for those genetically predisposed to obesity. Nevertheless, the potential of structured weight loss programs should be exploited in overweight patients to achieve the possible beneficial effects [1,4,9]. Standard weight loss strategies plan 500–1000 fewer calories than estimated for weight maintenance. This may result in an initial loss of 0.5–1.0 kg body weight per week; however, many people regain the weight they have lost, and continued support by the health care team is needed to achieve long-term improvements of body weight and waist measurement. Advice concerning the reduction of high-fat and energy-dense foods, in particular those high in saturated fat and free sugars, will usually help to achieve weight loss. In addition, fiber intake should be encouraged. Regular physical activity should also be an important component of lifestyle approaches to the treatment of overweight. So far, the consensus by experts is that the use of very low energy diets, as an approach to promote initial weight loss, should be restricted to people with a BMI >35 kg/m<sup>2</sup> [1,2]. The evidence for recommendations regarding energy balance and body weight published by the ADA and by the DNSG EASD is summarized in Tables 22.1 and 22.3.

**Table 22.1** Nutritional recommendations with the evidence grade A for persons with type 1 and type 2 diabetes. Evidence obtained from meta-analyses of randomized controlled trials or at least one randomized controlled trial [1,2].

	DNSG EASD	ADA
Energy balance and body weight	Energy reduction in overweight (BMI >25 kg/m <sup>2</sup> ) to move towards recommended BMI range Prevention of weight regain	Weight loss in overweight and obese individuals (improves insulin resistance) For weight loss low CHO or low fat calorie restricted diets may be effective in the short-term (up to 1 year)
CHO	Metabolic characteristics suggest the most appropriate intake: vegetables, legumes, fruits, wholegrain foods, naturally occurring foods rich in fiber Fiber intake should be ideally ≈20 g/1000 kcal/day Low glycemic index foods provided other attributes of these foods are appropriate Moderate amounts of free sugars (up to 50 g/day)	Monitoring carbohydrate by CHO counting, CHO exchanges or experience-based estimation of CHO remain a key strategy in achieving glycemic control Sucrose-containing foods can be substituted for other carbohydrate; if added should be covered with insulin or other glucose-lowering medication, excess intake should be avoided
Dietary fat	Saturated and trans-unsaturated fatty acids <10% total energy (<8% if LDL cholesterol is elevated) Dietary cholesterol <300 mg/day (further reduction if LDL is elevated)	Saturated fat <7% total energy
Protein	0.8 g/kg normal body weight in patients with type 1 diabetes and established nephropathy	Protein should not be used to treat or prevent nighttime hypoglycemia; it can increase insulin response without increasing plasma glucose in type 2 patients
Micronutrients	Salt intake should be <6 g/day; further reduction for patients with elevated blood pressure	No clear evidence of benefit from vitamin or mineral supplementation Routine supplementation (e.g. vitamins E, C and carotene) is not advised; because of concern related to long-term safety
Type 1 diabetes		Patients using rapid-acting insulin should adjust the meal and snack insulin based on the carbohydrate content of meals and snacks
CVD risk		Sodium intake (<2300 mg/day) Diet high in fruits, vegetables and low-fat dairy products in normotensive and hypertensive individuals
Hypoglycemia		15–20 g glucose is the preferred treatment (also other glucose-containing carbohydrate possible)

ADA, American Diabetes Association; BMI, body mass index; CHO, carbohydrate; DNSG EASD, Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes; HDL, high density lipoprotein; LDL, low density lipoprotein.

**Table 22.2** Nutritional recommendations with the evidence grade B for persons with type 1 and type 2 diabetes. Evidence obtained from at least one well designed and controlled study without randomization, well-designed quasi-experimental or non-experimental descriptive studies [1,2].

	DNSG EASD	ADA
CHO	There is no justification for the recommendation of very low carbohydrate diets in persons with diabetes Cereal-based foods should, whenever possible, be wholegrain and high in fiber	CHO from fruits, vegetables, whole grains, legumes and low fat milk is encouraged Consumption of a variety of fiber-containing foods is recommended The use of glycemic index and load may provide a modest additional benefit over that when total CHO is considered
Dietary fat	Oils rich in mono-unsaturated fatty acids are encouraged (10–20% total energy), total fat <35% total energy 2–3 servings of oily fish/week and plant sources of n-3-fatty acids (e.g. rapeseed oil, soybean oil, nuts) are recommended	2 or more servings of fish/week (n-3-poly-unsaturated fatty acids) are recommended
Protein	10–20% total energy in patients with no evidence of nephropathy	
Alcohol	Moderate use up to 10 g/day for women and up to 20 g/day for men is possible In patients treated with insulin or insulin secretagogues alcohol should be taken with carbohydrate to avoid hypoglycemia	Moderate intake (when ingested alone) has no acute effect on glucose and insulin, alcohol co-ingested with CHO may raise blood glucose
Microvascular complications		0.8–1 g protein/kg body weight/day in early stages of chronic kidney disease (microalbuminuria, decline in glomerular filtration) 0.8 g protein/kg body weight/day in later stages (macroalbuminuria) of kidney disease
CVD risk		HbA <sub>1c</sub> to be kept as close to normal as possible without significant hypoglycemia
Acute illness		Adequate amounts of fluids and carbohydrate (glucose and ketone testing)
Long-term care facilities		Caution when prescribing weight loss diets in elderly; avoid undernutrition

### Macronutrient distribution in weight loss diets

The optimal macronutrient distribution of weight loss diets has not yet been established [2,10–12]. Low fat diets have been traditionally and effectively promoted for weight loss [1,13]; however, recently it has been demonstrated that low carbohydrate, higher fat diets may result in even greater weight loss over short periods of time, up to 6 months [2,10,14]. Although changes in serum triglycerides and high density lipoprotein (HDL) cholesterol were more favorable with low carbohydrate, higher fat diets than with high carbohydrate and lower fat diets in these trials, low density lipoprotein (LDL) cholesterol was significantly higher in patients on high fat, low carbohydrate diets [2]. However, long-term metabolic effects of low carbohydrate, high fat diets are unclear and no controlled long-term trials are available to prove their safety with regard to CVD. Such diets eliminate several foods that are important sources of fiber, vitamins and minerals. It has also been shown that it was difficult to substitute monounsaturated fatty acids (MUFA) as the favorable fat source for carbohydrate because foods providing appreciable amounts of MUFA are limited, and even in Mediterranean areas, nowadays, people tend to consume undesirably high amounts of saturated fat in high fat diets. The ADA has summarized the current

recommendations for weight loss in diabetes as follows: “For weight loss either low-carbohydrate or low-fat calorie restricted diets may be effective in the short-term (up to 1 year)” [2]. After initial weight loss it is important to avoid regain of weight [1].

### Weight loss in the prevention of diabetes

With regard to weight loss in the prevention of diabetes in individuals at high risk for developing T2DM, lifestyle changes that included a reduced energy and a reduced dietary fat intake, and an increased fiber consumption together with regular physical activity (e.g. 150 minutes/week) [15,16] have shown improvements in several vascular risk factors including dyslipidemia, hypertension and markers of inflammation in addition to the significant reduction of the development of T2DM. So far, clinical trials on the efficacy of low carbohydrate diets for primary prevention of T2DM are not available.

## Carbohydrate and diabetes

It is important that the advice for carbohydrate intake is individualized, based on the patient’s nutrition assessment, metabolic

**Table 22.3** Nutritional recommendations for persons with type 1 and type 2 diabetes with lower grades (C–E) of evidence. Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities [1,2].

	DNSG EASD	ADA
Energy balance and body weight	Prevention of weight regain Avoidance of further weight gain Advise reduction of energy-dense foods high in saturated fat and free sugars	When low CHO diets are used for weight reduction monitor lipid profiles, renal function, protein intake (in those with nephropathy) and adjust hypoglycemic therapy
CHO, fiber, sucrose and other free sugars	Consider quantity, sources and distribution of CHO to facilitate near-normal long-term glycemic control Timing and dosage of insulin or hypoglycemic agents should match quantity and nature of CHO Daily consumption of 5 servings of fiber-rich vegetables or fruits and 4 servings of legumes per week help to achieve recommended fiber intake Total free sugars should not exceed 10% total energy	When fixed daily insulin doses are used CHO intake (time and amount) should be consistent For planned exercise extra CHO may be needed Blood glucose tests can be used to monitor appropriate adjustments There is no evidence to support prescribing diets such as “no concentrated sweets” or “no sugar added”
Dietary fat	Polyunsaturated fatty acids should not exceed 10% total daily energy Total fat intake should not exceed 35% total energy	Intake of trans-fats should be minimized (evidence grade B in the guidelines of 2009) Cholesterol below 200 mg/day
Protein	Insufficient evidence for recommendations about the preferred type of dietary protein For type 1 diabetes with incipient nephropathy and type 2 diabetes with incipient or established nephropathy no firm recommendations regarding protein restriction	For persons with diabetes and normal renal function insufficient evidence to modify usual protein intake (15–20% of energy) High protein diets are not recommended as a method for weight loss Long-term effects of protein >20% of calories on kidney function are unknown
Alcohol	Intake should be limited in overweight, hypertensive, hypertriglyceridemic individuals as well as during pregnancy and in advanced neuropathy	Daily intake should be limited to a moderate amount (1 drink for women, 2 drinks for men) Alcohol should be consumed with food in individuals treated with insulin or insulin secretagogues to reduce the risk of nocturnal hypoglycemia
Micronutrients	Foods naturally rich in dietary antioxidants, trace elements and other vitamins are encouraged: daily consumption of a range of vegetables and fruit, regular intake of wholegrain breads, cereals and oily fish	Benefit from chromium supplementation is not proven and therefore not recommended

ADA, American Diabetes Association; CHO, carbohydrate; DNSG EASD, Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes.

results and treatment goals [1,2,17–19]. There is a broad range of possible carbohydrate intake in people with diabetes (e.g. 45–60% of total energy intake). This advice is mainly based on recommended restrictions for the intakes of fat and protein. In many European countries, the mean carbohydrate intake of people with diabetes is only around 42% of total energy intake (Table 22.4) [20,21]. In the EURODIAB Complications Study, which included 3250 people with T1DM coming from 31 different European centers, the mean carbohydrate intake did not show major changes at the 7-year follow-up investigation compared with these intakes at baseline. Similar relatively low proportions of carbohydrate consumption and high intakes of total and saturated fatty acids have also been demonstrated in people with T2DM from the Mediterranean area [22,23].

Usually, carbohydrate intake in people with diabetes is lower than recommended by nutrition associations for the general population who receive advice to consume around 50% of total energy intake as carbohydrate. Many people with diabetes tend to reduce their carbohydrate intake because they fear an increase

in blood glucose concentrations after the ingestion of carbohydrate-containing foods. In affluent countries, lower carbohydrate diets are usually accompanied by high fat, predominantly an undesirable high saturated fat intake. With such a diet it is also difficult to achieve sufficient fiber intake to meet recommendations [1,24,25]. Having this in mind, it does not appear to be productive to overemphasize the present renaissance of low carbohydrate strategies in diabetes. Furthermore, several recent reports on this topic do not clearly define what is meant by “low” or “high” carbohydrate and whether a carbohydrate intake of around 40% of total energy, which is consumed by many people with diabetes, already corresponds to a low carbohydrate diet [26,27].

### Glycemic effects of different carbohydrate

Not only the amount of carbohydrate, but also the quality of carbohydrate is important for individuals with diabetes. Vegetables, legumes, fresh fruit, wholegrain foods and low fat milk products should be part of a healthy diet [1,2]. These foods provide also a range of micronutrients and fiber.

**Table 22.4** Nutritional intake and further life-style factors in persons with type 1 diabetes. Data are presented for the total EURODIAB cohort (31 centres, n = 3250) and different European regions [21].

	South (n = 1371)	East (n = 539)	Northwest (n = 1340)	All (n = 3250)	Center range
Total energy (kcal/day) <sup>a</sup>	2148	2352	2407	2288	1851–2786

The amount of carbohydrate is an essential factor for post-prandial glucose results in people with T1DM and T2DM [28–30]. In the process of achieving desirable glycemic control, many individuals with diabetes use either carbohydrate counting, carbohydrate exchanges or experience-based estimation of carbohydrate intake as a helpful means to monitor their consumption of carbohydrate at meals or snacks [2]. Different carbohydrates have different glycemic effects. Besides the amount of carbohydrate, other factors including the nature of starch, the amount of dietary fiber and the type of sugar influence the glycemic response to carbohydrate-containing foods [31–34].

The glycemic index (GI) of a carbohydrate-containing food describes its post-prandial blood glucose response over 2 hours in the area under the blood glucose curve compared with a reference food with the same amount of carbohydrate, usually 50 g glucose (or white bread in some studies). Foods can be differentiated into high (GI: 70–100), average (GI: 55–70) or low (GI: <55) glycemic index foods; however, measured GIs are only available for a range of foods, with the data mainly coming from investigations in Canada and Australia. The glycemic load considers the amount as well as the quality of carbohydrate and is defined as gram of carbohydrate within the food multiplied with the GI of the food divided by 100.

It has been shown that the use of the GI or glycemic load of a food may confer moderate additional benefits – over that observed when only total carbohydrate is considered – not only for post-prandial glycemia, but also for the lipid profile [2,35]. Therefore, foods with known low GI (e.g. legumes, pasta, parboiled rice, wholegrain breads, oats, certain raw fruits) should be substituted when possible for those with a high GI (e.g. mashed potatoes, white rice, white bread, cookies, sugary drinks) [36–39]. For

example, eating fresh fruits is superior to a fruit juice with the same amount of carbohydrate. Low GI foods are only favorable, however, provided other attributes of these foods are also in line with a healthy nutrition [1]. Some foods with a low GI are high in fat and energy. Chocolates are such an example, with low GI but a high content of saturated fat. Some products specifically advertised for people with diabetes have reduced the GI of usual foods by replacing sucrose with sugar alcohols or fructose. A substantial benefit from these expensive so-called “diabetic” preparations has not been proven. Therefore, special foods for people with diabetes are not recommended. Proper food labeling may help the person with diabetes to make healthy choices from available usual foods.

### Potential of dietary fiber

In many countries, people with diabetes consume only few foods that are rich in dietary fiber and therefore total fiber intake is much lower than recommended (Figure 22.1). With the relatively low carbohydrate intake in people with diabetes it is not easy to meet recommended quantities of fiber. Total dietary fiber intake in the EURODIAB Complications Study was on average only 8.0 g/1000 kcal or 19.5 g/day [20,21]. People with diabetes should be encouraged to choose a variety of fiber-containing foods (vegetables, fruits, wholegrain products) to profit from the proven benefits for glycemic control, insulinemia and serum lipid concentrations [32–34,40]. Although total fiber intake was not high, epidemiologic data based on the EURODIAB Complications Study showed an inverse association between dietary fiber intake and HbA<sub>1c</sub> independent of possible confounders [32], an inverse association between fiber and LDL cholesterol and a positive association between fiber and HDL cholesterol. In addition,

**Figure 22.1** Fiber intake (g/day) in persons with type 1 diabetes (total n = 1102) from 21 centers in Europe. Data from EURODIAB Complications Study [20,21].

dietary fiber was inversely and significantly related to cardiovascular disease [34]. Dietary fiber was also associated with lower levels of BMI [26]. The degree of evidence for recommended carbohydrate and dietary fiber intakes is shown in Tables 22.1–22.3.

### Sucrose and other sugars

Moderate intake of sucrose (<10% total energy) or other added sugars may be included in the diet of people with diabetes without worsening glycemic control [1,2,25,41]. Although fructose produces a reduction in post-prandial glycemia when it replaces sucrose, this potential benefit is tempered by the fact that fructose may adversely affect serum triglycerides as well as uric acid levels [1,8]. There is no reason to recommend that people with diabetes should avoid naturally occurring fructose (e.g. in fruits, vegetables or other foods) [1,2]; however, added fructose, added sugar alcohols or other nutritive sweeteners are energy sources that do not have substantial advantage over sucrose and therefore should not be encouraged. Higher quantities of sugar substitutes may promote undesirable gastrointestinal side effects. Furthermore, it is unlikely that energy-containing sugar substitutes such as sugar alcohols in the amounts likely to be consumed will contribute to an appreciable reduction in total energy intake although they are only partially absorbed from the small intestine [2,8].

Approved non-nutritive sweeteners may also be used by people with diabetes although a special long-term benefit in metabolic control has not been proven. Nevertheless, they are safe when acceptable daily intakes (ADI values) are followed [2,8].

### Adjustment of insulin or insulin secretagogues to carbohydrate intake

For people who are treated with insulin or hypoglycemic agents, it is important to match the medication with the amount, type and time of carbohydrate intake to avoid hypoglycemia as well as excessive post-prandial hyperglycemia [1,2]. Individuals receiving intensive insulin treatment should adjust their premeal insulin dose based on the amount of carbohydrate in snacks or meals while considering also the GI of these foods [37,42,43]. This advice is now part of many nutrition education programs for people with diabetes who are treated with intensified insulin regimens [18,44]. Self-monitoring of blood glucose offers a helpful means of determining the most appropriate timing of food intake and to make optimal food choices [1]. Individual preferences and the needs of different treatment strategies remain the most important determinants of appropriate meal frequency, portion sizes and carbohydrate intake. Extra carbohydrate may be needed prior to exercise although adjustment of the insulin dosage in those on intensified insulin treatment is often an alternative and preferred choice. Structured training and continuing advice by the diabetes team is needed to enable the people with diabetes to adjust the insulin dosage while considering all three components: blood glucose results, amount and quality of carbohydrate intake as well as the degree of physical activity.

### Dietary fat

The primary goal concerning dietary fat intake is to restrict the consumption of saturated fatty acids, trans-fats and dietary

cholesterol to reduce the risk for vascular disease [1,2,45,46]. Compared with the non-diabetic population, people with diabetes have an increased risk of developing vascular disease. Fat modification in people with diabetes is an established principle to assist in achieving desirable serum lipid concentrations and to avoid vascular lesions in high-risk groups. Although most of this evidence is obtained from studies of people without diabetes, it seems that the recommendations are also relevant in the diabetic population as their risk for vascular disease is even higher than in the general population [1,47]. Even if statins are often needed to meet the treatment goals for serum lipid concentrations, possible lifestyle modifications should always be exploited, and remain the basic therapeutic approach to achieve a desirable lipid profile. The degree of evidence for the recommendations relating to the recommended amounts of fat intake or fat modification, respectively, is shown in Tables 22.1–22.3.

**Reduction of saturated fatty acids**

It is suggested that saturated fatty acids could be either replaced by carbohydrate foods rich in fiber or by unsaturated fatty acids, particularly by *cis*-monounsaturated fatty acids for people on a weight-maintaining diet. Such diets have been shown to achieve improvements in glycemia, insulin sensitivity and serum lipid values, compared to diets high in saturated fat [47–51].

**Omega-3-fatty acids**

Observational evidence supports the intake of n-3 polyunsaturated (omega-3) fatty acids as they have the potential to reduce serum triglycerides and have beneficial effects on platelet aggregation and thrombogenicity, thus offering cardioprotective effects [52]. A consumption of 2–3 servings of oily fish and plant sources

such as rapeseed oil, soya bean oil and nuts will help to ensure an adequate intake of n-3 fatty acids [1,2,53,54].

**Trans-fats and dietary cholesterol**

Unfortunately, in most countries, the quantity of trans-unsaturated fatty acids is not well documented on many food products. The effects of trans-fats are similarly adverse as those of saturated fatty acids in raising LDL cholesterol. Therefore, their intake should be minimized [1,2]. Trans-fats are found in many manufactured products such as biscuits, cakes, confectionery, soups and some hard margarine. Food labeling informs whether hydrogenated fats and oils were added to a food product and the ranking of ingredients on the food label gives at least some information whether high quantities of trans-fats could have a role.

Data from healthy people and individuals with T1DM support the recommendation to restrict dietary cholesterol. With increasing intake, serum cholesterol levels may increase and contribute to the development of CVD [1,55].

**Current fat intake in individuals with diabetes**

Fat intake data of European people with T1DM from the EURODIAB Complications Study demonstrated that on average the current target to keep the intake of saturated fatty acids below 7% of total energy was not achieved (Table 22.4). In the whole cohort of this study, the mean intake of saturated fatty acids was 14% of total energy (twice as high as recommended by the ADA) (Figure 22.2) [20,21], and even patients from the Mediterranean area who traditionally consumed a favorable fat intake no longer reach the goal to remain below 7% of saturated fat consumption [22,23]. In conclusion, fat modification remains an important

**Figure 22.2** Intake of saturated fatty acids (% of energy) in persons with type 1 diabetes (total n = 1102) from 21 centers in Europe. The solid vertical line marks the currently recommended upper limit of intake for saturated fatty acids by the ADA (7% total energy) The dotted vertical line represents the limit of 10% total energy for saturated fatty acids recommended by Diabetes and Nutrition Study Group of the European Association for the Study of Diabetes (DNSG EASD) in 2004. Data from the EURODIAB Complications Study. [20,21].

target nutritional education topic to reduce the risk for vascular disease in people with both T1DM and T2DM.

---

## Dietary protein

For individuals with diabetes and normal renal function, there is insufficient evidence that usual protein intake should be modified [1,2]. From nutrition intake data of different countries and patient groups, it is documented that there seems to be little concern that people with diabetes may develop protein deficiency (Table 22.4) [20–23]. However, it is unclear whether a long-term high protein intake above 20% of total energy would have untoward effects on renal function [2,56,57]. Although such diets may produce short-term weight loss and improved glycemia, it has not been established that these benefits are maintained long term. Therefore, high protein diets are not recommended as a method for weight loss at this time [2].

## Protein restriction

Several studies have focused on protein restriction as a means to reverse or retard the progression of proteinuria in people with diabetes [58–60]. Progression of diabetes complications may be modified by improving glycemic control, lowering blood pressure and potentially reducing protein intake. Normal protein intake (15–20% of energy) does not appear to be associated with an increased risk of developing diabetic nephropathy [1,2]. In some studies of subjects, particularly with T1DM and macroalbuminuria, urinary albumin excretion rates and decline in glomerular filtration were favorably influenced by a reduction of protein intake to around 0.8 g/kg body weight/day [59]; however, there is insufficient evidence to make recommendations about the preferred type of dietary protein. The evidence for recommended protein intake in diabetes is summarized in Tables 22.1–22.3.

---

## Micronutrients

Regular consumption of a variety of vegetables, fresh fruit, legumes, low fat milk products, vegetable oils, nuts, wholegrain breads and oily fish should be encouraged to ensure that recommended vitamin and mineral requirements are met [1]. Salt or sodium intake, respectively, should be limited particularly when elevated blood pressure is a problem [61,62]. Replacement of added salt intake using salt substitutes with potassium and magnesium in hypertensive people with T2DM has been shown to lead to a significant reduction in systolic but not in diastolic blood pressure. Such substitutes may be tried in selected patients but cannot generally be recommended to lower high blood pressure in people with diabetes.

People with diabetes may have increased oxidative stress and several studies have investigated the potential benefit of recommending the intake of antioxidant vitamins [63]. These trials

have failed to show clear benefit from supplementation [64]. Therefore routine supplementation (e.g. of vitamins E, C and carotene) is not advised because of concern related to long-term safety [1,2]. Also, the role of folate supplementation in reducing cardiovascular events is not clear and still under further investigation. In the light of current evidence, diabetes associations do not offer recommendations regarding supplements or functional foods [1,2]. Most of the promoted fiber-enriched products, margarine which contain plant sterols or stanols, supplements containing various n-3 fatty acids, minerals, trace elements and herbs, some of which have been shown to have potentially relevant functional effects, have not been tested in long-term formal clinical trials. As long as there is insufficient evidence from randomized studies to demonstrate significant benefit without causing undesirable side effects they cannot be recommended [1,2,65]. Vitamin or mineral supplementation in pharmacologic dosages should be viewed as a therapeutic intervention and recommended only in cases of proven deficiencies [1]. Given the importance of vitamin D in bone metabolism and the bony consequences associated with diabetes, it appears that dietary vitamin D intake, sunshine exposure and vitamin D levels should be monitored. Nutrition education to promote healthy eating and to meet recommended intakes is important for people with T1DM and T2DM.

---

## Alcohol

Alcohol may have both undesirable and beneficial effects [66–69] which exhibit a U-shaped relationship. The intake of moderate amounts (5–15 g/day) is associated with a decreased risk of coronary heart disease, while a strong association between excess habitual alcohol intake (>30–60 g/day) and undesirable raised blood pressure is found in both men and women. The amount of alcohol seems to be predictive whereas the type of alcohol-containing beverages consumed does not appear to be of major importance. If people with diabetes choose to drink alcohol, intake should be moderate, with no more than 10 g/day alcohol (1 drink) for females and no more than 20 g/day alcohol (2 drinks) for males [1,2]. These limits are also recommended to the healthy population by nutrition associations.

In studies where alcoholic beverages were consumed with carbohydrate-containing food by people with diabetes, no acute effects were seen on blood glucose. The recommendation, particularly to patients treated with insulin or insulin secretagogues, to consume carbohydrate when alcohol is taken is made because of the potential risk of alcohol-induced hypoglycemia [70,71]. The risk increases with the quantity of alcohol consumed and may last well into the following day. Abstinence from alcohol is advised in women during pregnancy, people with a history of pancreatitis or alcohol abuse as well as in those with hypertriglyceridemia and advanced neuropathy. Alcohol may also be an important energy source which should be considered in people with overweight. High alcohol consumption is associated with

greater waist:hip ratio independently of BMI. The evidence obtained from studies and expert reports concerning alcohol intake are shown in Table 22.2 and 22.3.

## Diet in special circumstances

### Diet in pregnancy

To avoid fetal and maternal complications it is essential to achieve blood glucose concentrations as close to normal as possible without inducing hypoglycemia [72]. Nutritional therapy should assist in achieving recommended fasting blood glucose values of 60–90 mg/dL (3.3–5.0 mmol/L) and post-prandial values below 120 mg/dL (6.7 mmol/L). To reach this goal, women with known T1DM as well as women who develop gestational diabetes during pregnancy need detailed dietary counseling as an essential part of therapy. Energy intake should be adequate to provide appropriate weight gain and nutrient intakes should consider special needs during pregnancy. In women with normal weight additional energy intake may be 70–240 kcal/day in the first and second trimester and 300 kcal in the third trimester of pregnancy. Additional calorie intake should be less in obese pregnant women; however, total daily energy should not be under 1600 kcal/day.

During pregnancy, hyperglycemia as well as ketonemia and starvation ketosis should be avoided. As in all pregnant women, folic acid supplementation is recommended to prevent neural tube defects. Several bodies (e.g. National Institute for Health and Clinical Excellence) have recommended using higher doses of folate supplementation (5.0 mg vs 400 µg) in women with diabetes because of the higher risk of neural tube defects in women with diabetes. Further individual supplementation with calcium, iron and iodine may be considered to avoid deficiencies (Table 22.5).

### Diet in children with diabetes

Dietary recommendations should focus on achieving desirable blood glucose concentrations without severe hypoglycemia. As in all healthy children, energy and nutrient intakes should be adequate to ensure normal growth and development. Healthy nutrition may also contribute to maintaining normal serum lipid values and blood pressure goals. Individualized counseling is necessary to support adequate decision-making for food intake and flexible insulin doses based on blood glucose self-monitoring. Meal plans must be individualized to accommodate food preferences and the eating pattern of the family.

Planning carbohydrate intake and premeal insulin dosage are the main educational targets in the training of children with T1DM and their parents. As energy requirements change with age, growth rates have to be monitored and the evaluation of a meal plan has to be rechecked at least once a year. In a case where the child becomes overweight, calories should be restricted. The child with diabetes has also to learn that early signs of hypogly-

**Table 22.5** Diet in pregnancy.

Food choices for adequate weight gain, normoglycemia and absence of ketones
Weight loss is not recommended
For overweight or obese women with gestational diabetes, modest energy and carbohydrate intake
Starvation ketosis should be avoided
Pregnant women on insulin therapy need individualized carbohydrate-controlled recommendations with consistency of times and amounts of food to avoid hypoglycemia
Insulin and meal plan adjustments should be guided by blood glucose self-monitoring
Consider changes in insulin sensitivity and the necessity to adjust the insulin dosage during the different trimesters of pregnancy
Consider special needs of protein (1.2–2 g/kg body weight), calcium (1300 mg/day), iron (30 mg/day), iodine (230 µg/day) and folate (600 µg/day) beginning in the second trimester of pregnancy

cemia must lead to taking rapidly available carbohydrate (glucose) and that unusual exercise needs blood glucose monitoring before and after physical activity, which should be used to guide potential extra carbohydrate or insulin dosage adjustments [73].

## Nutritional training in individuals with T1DM and T2DM

Nutritional training must be an integral component of disease management in all individuals with diabetes [2,18,72–75]. It requires the use of currently available scientific evidence on the potential of diet to assist in achieving treatment goals. A knowledgeable diabetes care team including the individual with diabetes should work together to maintain the pleasure of eating and drinking, while only limiting food choices when this is indicated by scientific evidence (Table 22.6). A balance must be achieved between the demands of metabolic control, risk factor management and the patient's well-being and safety [76]. Furthermore, it has to be taken into account that the therapeutic needs of an individual person will change with time and special life events, and therefore nutritional assessment and continuing dietary advice must be provided.

### Evaluation of outcome

All steps in the dietary management of the individual with diabetes should be documented in the patient's record forms. The outcome should be evaluated by important markers such as HbA<sub>1c</sub>, fasting and post-prandial blood glucose concentrations, blood pressure, serum lipids, albumin excretion rate, body weight, waist circumference and well-being of the individual with T1DM and T2DM [18,77].

**Table 22.6** Dietary advice and structured nutritional training for individuals with diabetes.**How often is nutritional advice needed?**

- Always at diagnosis of diabetes mellitus
- At each consultation if metabolic control is insufficient or vascular risk factors are not well controlled
- Every year as a routine
- At the initiation of insulin therapy
- When special nutritional problems come up

**What should be checked on a regular basis?**

- Is healthy eating part of the individual's lifestyle?
- Is energy intake appropriate to achieve or maintain a desirable body weight?
- Is alcohol intake moderate or could it be undesirably influencing hyperlipidemia, hypertension or the risk of hypoglycemia?
- Does the person consume unnecessary special diabetic food products?
- Does the selection and distribution of meals reflect the glucose-lowering medication?
- Does raised blood pressure suggest a benefit from salt restriction?

**Which advice is essential to achieve a healthy diet?**

- Restrict the intake of saturated fatty acids and trans-fats  
Choose only small portions of fatty meat, sausages, cheese, spreads and fatty bakery  
Prefer lower fat products  
Chocolates, cakes, cookies, cream, chips and fatty fast food should be eaten in small servings only and not consumed on a daily basis
- Consider the quality of fat  
Prefer vegetable oils (e.g. olive oil, rapeseed oil, soybean oil), nuts, seeds  
Consume oily fish 2–3 times per week
- Consume foods rich in dietary fiber and micronutrients  
5 servings of fresh fruit and vegetables per day as well as the consumption of legumes and wholegrain products are recommended
- Sugar is not forbidden; however, excessive intake is not desirable.  
Non-caloric sweeteners are safe, when daily allowances are followed
- Alcoholic beverages should only be taken in moderation  
1–2 small glasses of wine or beer are tolerable when no specific contraindication must be considered; however, consider the caloric amounts and also the risk of hypoglycemia when consumed without food
- Special dietetic foods for persons with diabetes are unnecessary. Persons with diabetes can enjoy usual foods
- Meals, snacks and food choices should match individual therapeutic needs, preferences and culture

## Lifestyle Issues: Exercise

Jane E. Yardley<sup>1,2</sup>, Angela Alberga<sup>2</sup>, Glen P. Kenny<sup>1,2</sup> & Ronald J. Sigal<sup>1,2,3</sup>

<sup>1</sup>Ottawa Hospital Research Institute, University of Ottawa, Ottawa, Ontario, Canada

<sup>2</sup>Faculty of Health Sciences, University of Ottawa, Ottawa, Ontario, Canada

<sup>3</sup>Faculties of Medicine and Kinesiology, University of Calgary, Calgary, Alberta, Canada

### Keypoints

- Regular exercise increases insulin sensitivity in both individuals with and without diabetes.
- In individuals without diabetes, plasma insulin levels decrease during low to moderate intensity exercise to compensate for increases in insulin sensitivity. Glucose production and glucose disposal increase in parallel in order to maintain blood glucose homeostasis.
- In individuals with type 1 diabetes (T1DM), low to moderate intensity exercise can result in hypoglycemia, as insulin levels cannot be regulated physiologically.
- During and after high intensity exercise, glucose production can exceed glucose disposal, causing hyperglycemia in individuals both with and without diabetes. In T1DM, hyperglycemia can be more marked and prolonged, as insulin cannot increase in response.
- It is recommended that individuals with T1DM adjust their insulin dose and carbohydrate consumption prior to, during and/or after exercise to accommodate the type, intensity and duration of exercise performed.
- While regular exercise has not conclusively been found to improve glycemic control in T1DM, it is associated with decreased long-term morbidity and mortality in this population.
- Structured supervised diet and exercise interventions can reduce the risk of developing type 2 diabetes mellitus (T2DM) by about 60% in individuals with impaired glucose tolerance.
- Regular exercise improves glycemic control significantly in T2DM.
- Individuals with T1DM and T2DM with moderate or high aerobic fitness have long-term mortality that is 50–60% lower than individuals with diabetes and low cardiorespiratory fitness.
- Resistance training is a safe and effective means of improving glycemic control in individuals with T2DM of all ages. To maximize the impact of lifestyle measures on glycemic control, combined aerobic and resistance exercise is more effective than either type of exercise alone.

### Glossary of terms

The definitions in Table 23.1 are adapted from those found in the *Physical Activity Guidelines Advisory Committee Report, 2008* produced by the US Department of Health and Human Services [1].

### Types of exercise training and their effects on healthy individuals

#### Aerobic exercise

##### Effects of regular aerobic exercise training

Regular aerobic training generally leads to improved lung function and cardiac output, allowing for the provision of more oxygen for working muscles. Higher plasma volume and greater

capillary density in the muscles allow increased muscle blood flow during peak exercise. Eventually, a shift in the fuels being used to supply the energy demands of activity is seen as the oxidative metabolic system becomes more efficient. In general, changes become more noticeable when training is of higher volume and intensity.

##### Fuel metabolism during acute aerobic exercise

During the first 5–10 minutes of exercise, muscle glycogen is the main source of energy. As exercise continues, the bloodborne substrates, glucose and non-esterified fatty acids become increasingly important. If exercise of moderate intensity continues for several hours, the contribution of glucose diminishes and non-esterified fatty acids become the major fuel (Figure 23.1) [2]. During moderate intensity aerobic exercise, blood glucose levels remain virtually unchanged. Insulin secretion is reduced while the release of glucagon is promoted, encouraging a two- to four-fold increase in hepatic glucose production (controlled by the glucagon:insulin molar ratio at the portal vein) [3] to meet the needs of the exercising muscle. Glucose production and utilization fall rapidly and in parallel to baseline during the post-

*Textbook of Diabetes*, 4th edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein. © 2010 Blackwell Publishing.

**Table 23.1** Glossary of terms.

**Physical activity** The expenditure of energy above that of resting by contraction of skeletal muscle to produce bodily movement

**Exercise** A type of physical activity that involves planned, structured and repetitive bodily movement performed for the purpose of improving or maintaining physical fitness

**Cardiorespiratory fitness/cardiorespiratory endurance/aerobic fitness** Refers to the circulatory and respiratory systems' ability to supply oxygen during sustained exercise

**Aerobic exercise** Exercise that uses primarily aerobic energy-producing systems and involves the repeated and continuous movement of the same large muscle groups for extended periods of time (at least 10 minutes at a time). If performed with sufficient intensity and frequency this type of exercise increases cardiorespiratory fitness. Aerobic activities include walking, cycling, jogging, swimming, etc.

**Anaerobic exercise** Short, high intensity exercise involving anaerobic energy-producing systems. If performed with sufficient intensity and frequency this type of exercise can increase the body's ability to tolerate acid-base imbalance during high intensity exercise

**Intensity of aerobic exercise** Generally described in relation to an individual's maximal aerobic capacity ( $\dot{V}O_{2max}$ ), as measured using indirect calorimetry during a graded maximal exercise test. An activity level corresponding to 40–60% of  $\dot{V}O_{2max}$  is generally considered to be "moderate" in intensity, while "vigorous" aerobic activities consist of those performed at greater than 60% of  $\dot{V}O_{2max}$

**Muscular fitness** Includes the force a muscle can exert (strength) and the ability of the muscle to perform continuously without fatigue (endurance)

**Resistance exercise** Also known as strength training or weight training. Resistance exercise involves the use of muscular strength to work against a resistive load or move a weight. Examples include lifting free weights, or using weight machines. Regular resistance exercise at sufficient (moderate to high) intensity increases muscular fitness

**Intensity of resistance exercise** The intensity of resistance exercise is often considered "moderate" if the resistance provided is 50–74% of the maximum that can be lifted a single time (1 repetition maximum [1 RM]). High intensity resistance exercise involves resistance  $\geq 75\%$  of 1 RM

**Repetition** The number of times a resistance exercise is repeated during each set

**Set** A grouping of repetitions of a specific resistance exercise

exercise "recovery" phase, as insulin levels rise and glucagon secretion decreases. If moderate intensity aerobic exercise lasts for several hours without caloric intake, hepatic glucose production can no longer keep pace with increased utilization, and the blood glucose level begins to decline, eventually resulting in hypoglycemia [4].

### Effects of regular training on fuel metabolism

Aerobically trained athletes without diabetes have low fasting plasma insulin levels and reduced insulin responses to a glucose challenge in the face of normal glucose tolerance, and increased insulin-mediated glucose uptake under glucose clamp conditions [5]. Physical training is also known to increase muscle and hepatic

**Figure 23.1** The relative contributions of muscle glycogen breakdown and uptake of blood-borne glucose and non-esterified fatty acids (NEFA) to fuel utilization at various stages of prolonged low-intensity exercise in a healthy individual. The exercise intensity corresponds to 30% of maximal. Data from Ahlborg *et al.* [2].

insulin sensitivity in previously untrained individuals [6]. Lipid and lipoprotein profiles become less atherogenic with regular training: serum high density lipoprotein (HDL) cholesterol levels may increase, while total and low density lipoprotein (LDL) cholesterol levels may remain unchanged or decline [7,8]. Some studies have found that serum triglyceride levels decline after training [7,8]. Even when LDL cholesterol concentrations remain unchanged with aerobic exercise training there is an increase in mean LDL particle diameter, reflecting more buoyant and less atherogenic LDL cholesterol particles [9].

### Anaerobic exercise

#### Effects of regular anaerobic exercise training

Regular anaerobic training improves the body's ability to provide the fuels necessary for the production of anaerobic power. Adenosine triphosphate (ATP) and phosphocreatine levels (the main fuels for short powerful bursts) increase within muscle tissue, allowing the individual to sustain higher absolute exercise intensities for longer periods of time.

#### Fuel metabolism during anaerobic activity

With very intense exercise (more than 80% of  $\dot{V}O_{2max}$  – a level sustainable for no more than 15 minutes by most individuals), hepatic glucose production may exceed the rate of glucose utilization, leading to a 5- to 10-fold increase in blood glucose [10–12]. During recovery from very intense exercise, hyperglycemia often occurs in fit individuals without diabetes, as glucose utilization decreases more quickly than glucose production [10–12]. In response to the hyperglycemia, plasma insulin levels increase and glycemia is restored to baseline within about 45 minutes.

## Resistance exercise

### Effects of regular resistance exercise training

Declines in muscle strength of approximately 12–15% per decade have been reported after the age of 50 years [13,14], with muscle mass decreasing as much as 6% per decade [5,16]. With regular heavy resistance training, increases of greater than 30% in muscle strength [15,17] and gains in muscle mass ranging from 3 to 12% [18,19] have been found within the first couple of months of training, with relative increases typically being higher in elderly subjects [16,18]. Initial strength gains during the first 6 weeks are generally as a result of peripheral nervous system adaptations (improved muscle recruitment) and are not accompanied by muscle hypertrophy. Resistance training can be of additional benefit to older adults as improvements in postural stability and dynamic balance may decrease the risk of fall-related injuries [20].

When muscles are forced to perform for a given period of time at or near their maximal strength and endurance capacity (either by lifting weights or working against some other form of resistance), it will result in an increase in muscle strength, endurance and hypertrophy. Performing more repetitions (up to 2 minutes per set of each exercise) with lower resistance tends to increase endurance, while lifting heavier weights for fewer repetitions will favor strength gains [21].

### Fuel metabolism during resistance exercise

High intensity, short duration resistance exercise is fueled by energy generated from the breakdown of stored intramuscular high-energy phosphates, ATP and phosphocreatine. During such exercise, adequate rest periods (2–5 minutes) between sets are necessary to allow regeneration of phosphocreatine stores. Glycolytic anaerobic energy production (with concomitant blood lactate accumulation) becomes more important as intensity decreases, the number of repetitions per set increases, and rest periods between sets become shorter [22]. This can result in local muscle lactate accumulation even after a single set. Where multiple sets are performed, longer sets and shorter rest periods between sets are associated with greater increases in blood lactate (which can reduce muscle contractility) and declines in muscle glycogen [23,24].

## Metabolic and hormonal effects of exercise in diabetes

### Type 1 diabetes

Higher amounts of habitual physical activity are associated with decreased incidence of diabetes-related complications and reduced mortality in individuals with type 1 diabetes mellitus (T1DM) [25]. In a prospective study, 548 patients with T1DM were followed for 7 years to ascertain the prevalence of complications and mortality [25]. The risk of microvascular complications varied inversely with self-reported activity levels at baseline. Sedentary male patients were three times more likely to die than

**Figure 23.2** Proportion of men who died during a 7-year follow-up period among 548 patients with type 1 diabetes, stratified according to the physical activity quintile. Quintile cut-offs were <398; 398–1000; 1000–2230; 2230–4228 and >4228 kcal/week. The difference among groups is highly significant. Data from Moy *et al.* [25].

the active ones after adjusting for age, body mass index, smoking and diabetic complications (Figure 23.2) [25]. A similar, although statistically non-significant, relationship was also seen in females.

Studies have also shown an inverse association between physical activity and the severity of several complications in T1DM [26–29]. A longitudinal study of 1680 individuals with T1DM showed that self-reported leisure time physical activity levels were inversely correlated with measures of glycemic control and insulin sensitivity [29]. Women with diabetes in the study with low levels of leisure time physical activity tended to have poor glycemic control when compared with those with higher activity levels. Estimates of insulin sensitivity were also higher among more active men and women [29]. A follow-up study involving 1945 individuals with T1DM reported that those involved in either little leisure time physical activity or low intensity activity were more likely to have impaired renal function, a higher degree of proteinuria, as well as greater rates of retinopathy and cardiovascular disease when compared with more frequently and more vigorously active counterparts [28]. More recently, a randomized trial showed that the onset of diabetic peripheral neuropathy can be prevented and its progression delayed over a 4-year period by regular exercise [26].

### General metabolic considerations

The intensity and duration of exercise, the patient's level of blood glucose control, the type, dose and site of pre-exercise insulin

**Figure 23.3** Plasma insulin levels may vary widely during exercise in patients with insulin-treated diabetes, whereas healthy subjects (as well as patients with type 2 diabetes) show a steady decline during moderate intensity aerobic exercise. Hyperinsulinemia and hypoglycemia may occur when the peak action of a short-acting insulin analog (1), conventional soluble (regular) insulin (2) or intermediate-acting insulin (3) occurs during exercise, or if exercise itself accelerates the absorption from the injection site (4). Steady-state but elevated plasma insulin concentrations may occur if intermediate or long-acting insulin has been injected a few hours before exercise, or if the patient is using an insulin pump (5). Declining levels (6) or hypoinsulinemia (7) occur when the previous injection depots are exhausted.

injections, and the timing of the previous insulin injection and meal relative to the exercise can all affect the response of an individual with diabetes to physical activity (Figure 23.3). Accordingly, blood glucose concentrations can decline (the most common response in moderate aerobic exercise), increase (particularly in very intense exercise) or remain unchanged (Table 23.2). Whereas insulin secretion declines during moderate intensity aerobic exercise in individuals without diabetes, compensating for exercise-induced increased muscle insulin sensitivity, this physiologic decline in insulinemia cannot occur in T1DM because all insulin is exogenous. Insulin attenuates the appropriate rise in hepatic glucose production and further accelerates the exercise-induced stimulation of glucose uptake into the contracting muscle.

Hyperinsulinemia may occur for several reasons (Figure 23.4). Regular insulin injected a few hours previously may exert its peak action during exercise. This effect is exaggerated if the previously injected limb is exercised, as insulin absorption is accelerated by exercise [30]. Moreover, the use of intermediate or long-acting insulin generally produces higher peripheral insulin levels than would be found in an individual without diabetes of similar body composition. The result is often hypoglycemia, unless the insulin dose prior to exercise is decreased or extra carbohydrate is consumed. Hyperinsulinemia can also prevent the normal increase in lipid mobilization during exercise, leading to reduced availability of non-esterified fatty acids as a fuel.

Conversely, if insulin levels are too low, the inhibitory effect of insulin on hepatic glucose production and its stimulatory effect on glucose uptake are both reduced. In addition, the counter-regulatory response (catecholamines, glucagon, growth hormone, cortisol) to exercise is higher than normal under conditions of insulin deficiency [30]. The overall result is markedly increased hepatic glucose production and diminished glucose utilization by the exercising muscle, thus leading to hyperglycemia.

**Table 23.2** Factors determining the glycemic response to acute exercise in people with type 1 diabetes.

**Blood glucose tends to decrease if:**

- Hyperinsulinemia exists during moderate intensity aerobic exercise
- Exercise is prolonged (>30–60 minutes)
- No extra snacks are taken before or during moderate intensity exercise

**Blood glucose generally remains unchanged if:**

- Exercise is brief and mild to moderate in intensity
- Appropriate snacks are taken before and during moderate intensity exercise

**Blood glucose tends to increase if:**

- Hypoinsulinemia exists during exercise
- Exercise is very intense
- Excessive carbohydrate is taken before or during exercise

### Aerobic exercise in type 1 diabetes

#### *Effects of regular aerobic exercise training in type 1 diabetes*

Insulin sensitivity is reduced to varying degrees in patients who have had T1DM for several years [31]. Participation in a regular exercise training program improves whole-body insulin sensitivity in these patients, as it does in those without diabetes, which may help to induce and prolong remission in newly presenting T1DM [32]. It has been difficult to ascertain whether or not regular aerobic exercise improves glycemic control in T1DM, as outcomes of exercise intervention have been inconsistent. While some studies have demonstrated improvements, albeit not statistically significant, in blood glucose control as measured by decreases in HbA<sub>1c</sub> [33,34], most studies have either not shown any changes [35] or have produced increases in HbA<sub>1c</sub> [36]. The main reason for this is probably excessive reductions of insulin dose or disproportionate carbohydrate consumption before exercise in an effort to avoid hypoglycemia. It is important to note

**Figure 23.4** Insulin concentrations during exercise depend on the type of insulin and the time interval between the injection and exercise. Serum insulin concentrations during early exercise are higher after injection of the lispro (Humalog) insulin analog (A) than after conventional soluble insulin (S), whereas the opposite situation applies during delayed exercise. Soluble insulin was injected 30-min and lispro insulin 5-min after breakfast, and exercise was started either 40-min (early) or 180-min (late) after breakfast. \* $P < 0.05$ . Data from Tuominen *et al.* [163].

that participants in several studies still experienced many exercise-related benefits including lower body fat percentage [34], improved muscle mass [37], increased aerobic capacity [34,36,37], improved lipid profiles [34,36,37] and greater insulin sensitivity (with a consequent lower need for exogenous insulin) [36].

**Fuel metabolism during aerobic activity**

Under ideal conditions of low insulin and euglycemia, fuel selection during mild to moderate exercise can be very similar in people with T1DM as those without diabetes, with a gradual shift towards lipid oxidation with increasing exercise duration [38]. Conversely, if the levels of circulating insulin are too high, muscle, adipose and hepatic cells will continue to take up glucose for

storage rather than leaving it available for working muscles. While glucagon can still be produced in individuals with T1DM [39], the glucagon:insulin molar ratio at the portal vein may not reach the level necessary for adequate levels of hepatic glucose production to occur. Compared with individuals without diabetes, those with T1DM may demonstrate a lower reliance on hepatic glycogen stores during low intensity aerobic activity [40]. If the rate of glucose appearance in the system is not high enough to supply the demand, blood glucose levels will drop, thereby increasing the potential for hypoglycemia [39].

Levels of insulinemia and glycemia will also affect the fuels used during aerobic activity. Hyperinsulinemia can lead to a greater reliance on exogenous glucose utilization during moderate aerobic exercise, without sparing glycogen stores [41]. In a study where insulinemia was kept constant, the contribution of carbohydrates to overall energy metabolism during exercise was greater in hyperglycemia than in euglycemia [38]. The shift towards greater carbohydrate metabolism during exercise in hyperglycemia was accompanied by a blunted cortisol and growth hormone response. Insulin, glucagon and catecholamine levels were comparable between conditions [38]. Overall, individuals with T1DM seem to have a greater reliance on muscle glycogenolysis and gluconeogenesis to produce fuel during physical activity than their non-diabetic counterparts [40,42].

Despite the complexities of glucoregulation, well-motivated people with T1DM can successfully undertake several hours of exhaustive aerobic exercise if appropriate insulin and dietary adjustments are made [43–45]. After prolonged exercise, patients may be prone to hypoglycemia for many hours, even extending overnight and to the following day. This can be explained by persistently enhanced glucose uptake by the exercised muscles to replenish the depleted glycogen stores [43]; however, after certain types of prolonged exercise, such as a marathon run, increased lipid oxidation can persist, as occurs in healthy individuals [44]. In this case, the use of glucose as a fuel and insulin sensitivity are reduced after exercise, thereby decreasing the risk of post-exercise hypoglycemia [44]. It should also be noted that individuals who experience frequent bouts of hypoglycemia (whether exercise-related or not), may have further blunting of counter-regulatory responses to exercise, potentially creating a vicious cycle of hypoglycemic events [46–50].

**Effects of regular anaerobic exercise training in type 1 diabetes**

There is currently a gap in the literature as to how physical and metabolic adaptations to regular anaerobic training in individuals with T1DM differ from those of non-diabetic individuals. People with T1DM who participate in competitive sports may find that their glycemic control worsens, probably secondary to an irregular schedule of very vigorous exercise, insulin dose reduction and high carbohydrate consumption [51]. In spite of the elevation in physical fitness and  $\dot{V}O_{2max}$ , these individuals may not have increased insulin sensitivity, but instead show enhanced use of non-esterified fatty acids as a fuel [51]. It is likely that many individuals with T1DM will have to compromise some tightness

of control to be able to participate effectively in competitive sports and high intensity activities, to avoid the fear of hypoglycemia during exercise. Whether or not this affects their physical and metabolic adaptations to these types of activities requires further research. More details on carbohydrate and insulin adjustments for exercise can be found later in this chapter.

#### **Fuel selection during high intensity exercise**

Extremely strenuous acute exercise may cause hyperglycemia even in the presence of normal or high insulin levels. High counter-regulatory hormone action (especially catecholamines) can stimulate glucose production beyond the limits of peripheral utilization [52–56]. In addition, in T1DM the normal physiologic doubling of insulin concentration after cessation of such intense exercise cannot occur, resulting in more prolonged hyperglycemia [52,55,56]. Augmented lipid mobilization and ketogenesis in the liver increase blood ketone-body concentrations; the hypoinsulinemic individuals may thus become hyperketonemic and ketonuric after exercise.

Several recent studies have shown that such high intensity exercise is effective in increasing blood glucose levels and thereby delaying or preventing hypoglycemia related to moderate exercise even when performed in extremely short bouts [57–61]. Bussau *et al.* [57,58] showed that a 10-second sprint performed either prior to [58] or at the completion of [57] 20 minutes of low intensity cycling significantly attenuated post-exercise drops in blood glucose, when compared with exercise sessions where no sprint was performed. Similar results were found by Guelfi *et al.* [59,60] where post-exercise blood glucose levels remained higher after cycling exercise sessions where 4-second sprints were performed every 2 minutes versus those where the participants cycled continuously at constant moderate intensity (Figure 23.5). The post-exercise window in these studies, however, was limited to 120 minutes. One small study using continuous glucose monitoring systems (CGMS) found a trend towards late onset post-exercise hypoglycemia after high intensity activity [62]; however,

further studies with larger sample sizes will be necessary to confirm this.

#### **Resistance exercise**

##### ***Effects of regular resistance exercise training in type 1 diabetes***

There is a paucity of information regarding the outcomes of training programs consisting of only resistance exercise in individuals with T1DM. The one study completed to date involved a cross-over design with 10 weeks of heavy resistance exercise three times a week followed by a 6-week period with no resistance training, or vice versa [63]. Mean HbA<sub>1c</sub> was  $6.9 \pm 1.4\%$  ( $52 \pm 15$  mmol/mol) at the end of the non-resistance exercise period and  $5.8 \pm 0.9\%$  ( $40 \pm 10$  mmol/mol) at the end of the 10-week resistance exercise training period. Serum cholesterol and self-monitored glucose levels were also lower at the end of the resistance training period.

One study has compared the effects of 12 weeks of resistance training with those of a comparable period of aerobic training in individuals with T1DM [64]. While both groups showed decreases in waist circumference, reduced insulin dosage and lower self-monitored blood glucose after the training period, these variables only reached significance in the aerobically trained group. However, HbA<sub>1c</sub> levels showed a statistically significant increase in the aerobic training group (from  $8.7 \pm 1.6$  to  $9.8 \pm 1.8\%$ ; 72–84 mmol/mol), while a non-significant decrease (from  $8.2 \pm 2.9$  to  $7.6 \pm 1.6\%$ ; 60–66 mmol/mol) was found in the resistance training group.

A handful of pre–post studies have also examined the effects of combined aerobic and resistance training programs in individuals with T1DM [65–67]. Outcomes of these studies were generally positive, with benefits including lower HbA<sub>1c</sub> [65,67], decreased blood pressure [65,66], improved nerve conduction [65], higher cardiorespiratory fitness [67], greater muscular strength [67], higher lean body mass [65,67] and improvements in lipid profiles [67]. Nevertheless, it should be noted that the interpretation of these studies is limited by their lack of

**Figure 23.5** Effect of 30 min of intermittent high intensity exercise (IHE) or moderate continuous exercise (MOD) on normalized blood glucose levels. Data from Guelfi *et al.* [59].

**Table 23.3** Clinical trials involving resistance exercise with people with type 1 diabetes mellitus.

Source	No. of participants (n)	Sessions/week, no of weeks	No. of exercises	No. of sets, rest interval and intensity of exercise	HbA <sub>1c</sub> [mean (SD)]
<b>Type 1 diabetes – resistance training only</b>					
Durak <i>et al.</i> (1990) [63]	n = 8 (T1DM)	3 sessions/week; 10 weeks Training sessions after 5:00 PM Lunch time injections and food intake completed no later than 12:00 PM	5 lower body and 10 upper body exercises	3–7 sets (varied with exercise; 30 s to 2 min rest interval between sets, pyramid-type training routine used with 12 RM used for set 1, decreased with subsequent sets with addition of weight	6.9 (1.4) after 6 weeks with no resistance training and 5.8 (0.9)* after 10 weeks of resistance exercise training (cross-over design)

concurrent diabetic control groups. All studies involving resistance exercise interventions in individuals with T1DM (alone or in combination with aerobic exercise) published by March 1, 2009 are outlined in Table 23.3.

#### Fuel selection during resistance exercise

Very little is known about the acute hormonal and resulting blood glucose responses to resistance exercise in individuals with T1DM. Resistance exercise in individuals without diabetes produces elevated epinephrine levels, which enhance hepatic glucose production, resulting in an increase in blood glucose levels [68]. As studies involving high intensity exercise demonstrate that catecholamine responses are similar in young fit individuals with and without T1DM [55,57,59], it is likely that resistance-type activities are associated with increases in blood glucose during and after exercise. However, the authors are unaware of any published research examining the glycemic response during and after this type of exercise in people with T1DM.

## Type 2 diabetes

### Exercise and type 2 diabetes prevention

In large prospective cohort studies, higher levels of physical activity and/or cardiorespiratory fitness have consistently been associated with reduced risk of developing T2DM [69–81]. After adjustment for confounding variables, participants who exercised the most had a 25–60% lower risk of subsequent diabetes compared to those who were most sedentary. This was true regardless of the presence or absence of additional risk factors for diabetes such as hypertension, parental history of diabetes and obesity in most studies. Comparable magnitudes of risk reduction are seen with walking compared to more vigorous activity when total energy expenditures are similar [77].

Several clinical trials have demonstrated that supervised structured physical activity programs, with or without concomitant dietary interventions, reduce the risk of developing T2DM in individuals with impaired glucose tolerance (IGT) [82–85]. In the non-randomized Malmö trial [82,86,87], 260 men aged 47–49

years with IGT were identified through population screening and were offered a 6–12-month intervention including supervised exercise programs and dietary counseling. Among those attending a 5-year follow-up examination, 21% of the control participants (those who had declined the intervention) had developed diabetes, compared to only 11% of those receiving the intervention. Over 12 years, mortality among the controls was 14.0 per 1000 person-years, but only 6.5 per 1000 person-years in the intervention group [87].

In the Da Qing IGT and Diabetes Study [83], 577 people with IGT from 33 clinics were cluster-randomized by clinic to diet only, exercise only, diet and exercise or control, and followed for 6 years. The cumulative incidence of T2DM was 68% in controls, but only 44%, 41% and 46% in the diet, exercise, and diet and exercise groups, respectively. Li *et al.* [88] recently published a follow-up paper to the Da Qing Study [83] assessing the long-term effect of the 6-year intervention on the risk of diabetes. They found that, 14 years after the end of the trial, incidence of diabetes remained significantly lower in those originally randomized to one of the intervention groups versus controls.

In the Finnish Diabetes Prevention Study [89], 523 Finnish adults with IGT were randomized to an exercise and diet intervention or control. Patients in the control group had one meeting per year with a physician and dietitian, at which they received standard advice on diet and exercise. The intervention group received individualized exercise plans, thrice-weekly supervised facility-based aerobic and resistance exercise, and seven 1-hour meetings with a dietitian focusing on weight reduction, reduced fat intake and reduced total caloric intake. At 4 years, 22% of the control group and only 10% of the intervention group had developed diabetes – a 58% risk reduction. Three years after the end of the study, participants originally randomized to the intervention group continued to have much higher levels of physical activity than those originally in the control group [90]. Incidence of diabetes in the individuals who were previously in the intervention group remained 43% lower than in those who were previously in the control group [90].

In the US-based Diabetes Prevention Program [85], 3234 American men and women with IGT were randomly assigned to placebo, metformin or a lifestyle modification program. The goals of the lifestyle modification program included a 7% weight loss and at least 150 minutes of exercise per week. The lifestyle intervention included 16 lessons in the first 24 weeks, covering diet, exercise and behavior modification (delivered one-on-one by a case manager). A minimum of two supervised exercise sessions per week and at least monthly contact with the study personnel were maintained thereafter. The study was ended after a mean of 2.8 years of follow-up, 1 year earlier than originally planned, because of clear-cut superiority of the lifestyle arm. Cumulative incidences of T2DM were 11.0 per 100 person-years in the placebo group, 7.8 per 100 person-years in the metformin group and only 4.8 per 100 person-years in the intensive lifestyle group. The risk of T2DM was 58% lower in the lifestyle group than in the placebo group, and 39% lower than in the metformin

group. An epidemiologic analysis of the data by Hamman *et al.* determined that, after adjusting for changes in self-reported diet and physical activity, there was a 16% reduction in diabetes risk for every kilogram of weight loss among the lifestyle intervention participants [169]. Increased physical activity was a significant predictor of weight loss and had an important role in weight maintenance. In addition, participants who met the goal of more than 150 minutes of moderate exercise per week had a 46% reduction in diabetes risk.

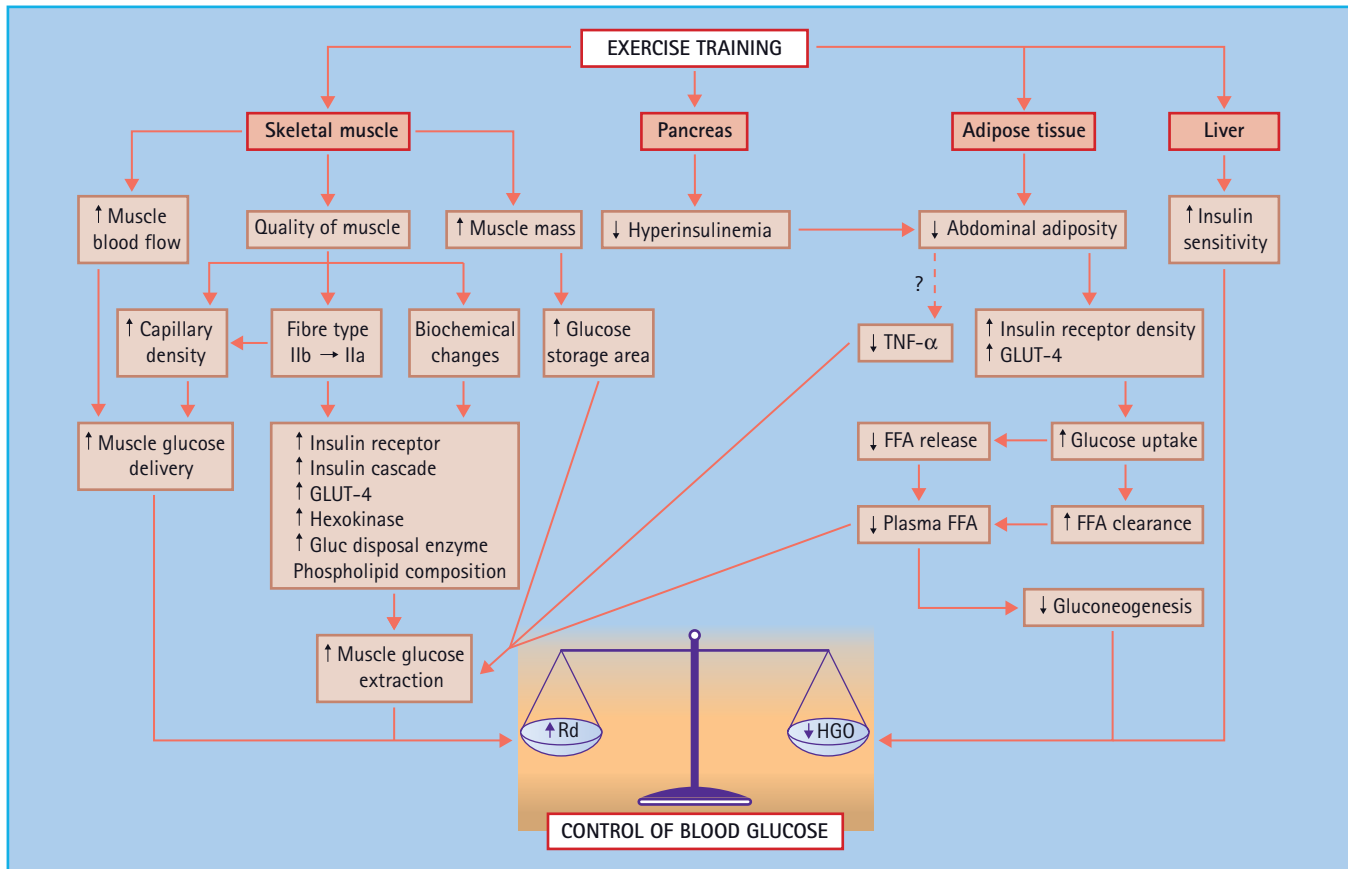

### **Aerobic exercise in type 2 diabetes**

Regular exercise is associated with reduced morbidity and mortality in T2DM. A 10-year follow-up of a large prospective cohort study including 347 individuals with diabetes and 1317 individuals without diabetes) found that the lowest aged-adjusted all-cause death rate was among those with diabetes who walked a mile or more daily [91]. Similarly, a prospective study of 1263 men with diabetes followed over 12 years found that, compared with the least fit men (bottom 20% as determined by maximal treadmill testing), those with moderate cardiorespiratory fitness had a 60% lower risk of cardiovascular and overall mortality [79]. The effect of fitness on mortality was considerably greater than the effect of body mass index. Further follow-up of this cohort confirmed these findings [92,93]. Greater habitual exercise was also associated with a lower subsequent risk of cardiovascular disease among women in the Nurses Health Study [94].

### **Effects of regular aerobic exercise training in type 2 diabetes**

Exercise-induced stimulation of glucose uptake may involve many factors (Figure 23.6), as reviewed by Ivy *et al.* [95]. They include increased post-receptor insulin signaling [96], increased glucose transporter protein and mRNA [97], increased activity of glycogen synthase [98] and hexokinase [99], decreased release and increased clearance of free fatty acids [95], increased muscle glucose delivery as a result of increased muscle capillary density [99–101], changes in muscle composition favoring increased glucose disposal [99,102,103] and changes in adipose tissue mass and distribution [104]. Decreases in visceral fat result in decreased concentrations of tumor necrosis factor  $\alpha$  [105] and free fatty acids [106], leading to decreased insulin resistance.

Inflammatory markers present in the bloodstream predict the onset of cardiovascular disease and related complications. Regular aerobic exercise training is generally associated with improvements in metabolic profile and results in anti-inflammatory effects in individuals with T2DM [107,108]. Exercise training in individuals with T2DM has been reported to produce anti-atherogenic blood lipid changes and to reduce other risk factors for coronary heart disease (hypertension, obesity, coagulation abnormalities) in some but not in all studies [109–115]. For instance, in elderly patients with relatively advanced atherosclerosis, exercise training may be less effective in retarding atherogenesis [113]. The prophylactic value of exercise against atherosclerosis might be greater in younger healthier individuals who have not yet developed disease.

**Figure 23.6** Mechanisms by which exercise training may improve insulin action and the control of blood glucose in type 2 diabetes. FFA, free fatty acid; GLUT, glucose transporter; HGO, hepatic glucose output; Rd, glucose uptake; TNF- $\alpha$ , tumour necrosis factor- $\alpha$ . Reproduced from Ivy et al. [95], with permission from Lippincott Williams & Wilkins.

**Fuel metabolism during aerobic activity**

Individuals with T2DM are characterized by both hepatic and peripheral insulin resistance and by hyperinsulinemia in the fasting state. During moderate intensity exercise, peripheral glucose uptake usually rises more than hepatic glucose production, and the blood glucose concentration tends to decline [116]. At the same time, plasma insulin levels fall, and the risk of exercise-induced hypoglycemia in individuals with T2DM not taking exogenous insulin is relatively small, even during prolonged exercise [117]. It has been shown that moderate intensity exercise decreases glycogen content similarly in individuals with and without diabetes [118]; however, glycogen and plasma glucose decreases more in obese individuals with diabetes compared with those without diabetes whether obese or lean [118]. The effects of moderate exercise on glucose tolerance and insulin sensitivity are similar whether the activity is performed in single versus multiple bouts of the same total duration [119]. Moderate aerobic exercise has also been shown to attenuate the increase in circulating triglyceride levels following ingestion of a high fat meal [120].

**Anaerobic exercise in type 2 diabetes**

**Fuel metabolism during high intensity activity**

If individuals with T2DM perform strenuous glycogen-depleting exercise, both peripheral and hepatic insulin sensitivity are increased and remain so for 12–16 hours thereafter [121]. Following maximal aerobic exercise (>85%  $\dot{V}O_{2max}$ ), sedentary individuals with T2DM demonstrate higher levels of blood glucose compared with sedentary individuals without diabetes and active individuals with diabetes [122].

**Resistance exercise**

**Effects of regular resistance exercise training in type 2 diabetes**

The age-related decline of muscle mass may cause reduced insulin sensitivity. Resistance training can potentially counteract the age-associated decrease in muscle mass, and therefore warrants important consideration as an effective intervention in managing T2DM [95,123]. Resistance training has been shown to improve insulin sensitivity and glucose metabolism in both men and women [124–130] and has also been associated with modest improvements in lipid profiles [63,67,128]. In longitudinal

studies involving healthy untrained adults, insulin responses to an oral glucose challenge are lower in both healthy younger [124,131] and older [131,132] individuals after resistance training. Resistance exercise, and its resulting increase in lean body mass, has also been associated with greater resting energy expenditure in older adults [133]. Whether or not this occurs in T2DM is still uncertain [134].

Studies published by Dunstan *et al.* [135] and Castaneda *et al.* [136], involving high intensity resistance training resulted in decreases in HbA<sub>1c</sub> of 1.2% (13 mmol/mol) with a 26-week program, accompanied by a moderate energy restriction diet [135] and 1.0% (11 mmol/mol) with a 16-week program [136], respectively. Meta-analyses have confirmed that resistance training exercise effectively reduces HbA<sub>1c</sub> in individuals with T2DM [137,138]. In a meta-analysis of clinical trials examining the effect of aerobic and resistance exercise interventions on glycemic control and body mass in T2DM (Figure 23.7), Boulé *et al.* [138] found no difference in HbA<sub>1c</sub> between aerobic and resistance exercise. Overall, participants in exercise intervention groups had HbA<sub>1c</sub> levels that were 0.66% (7 mmol/mol) lower post-intervention than those in control groups. Post-intervention body weight did not differ between exercise and control participants, suggesting that exercise is beneficial in its own right, not merely as an avenue to reduce body weight. Snowling & Hopkins [137] found in a more recent meta-analysis that the two types of exercise had similar effects on glucose control. An overview of clinical trials involving resistance exercise (both on its own and when combined with aerobic exercise training) in T2DM is provided in Table 23.4.

#### **Fuel metabolism during resistance exercise in type 2 diabetes**

The authors were unable to find any published research on fuel metabolism during resistance exercise in T2DM.

#### **Combined aerobic and resistance exercise training**

Snowling & Hopkins [137] reviewed controlled studies published in May 2006 or earlier that assessed the effects of aerobic training, resistance training or combined training on glucose control in T2DM. All three exercise modalities showed clinically significant reductions in HbA<sub>1c</sub>, while the combined training showed an additive and large beneficial effect on insulin sensitivity. The HbA<sub>1c</sub> meta-analyzed mean decreased by 0.8% (9 mmol/mol) in the combined exercise training studies compared to 0.7% (8 mmol/mol) and 0.5% (5 mmol/mol) for the aerobic and resistance training groups, respectively.

Three recent studies have investigated the combination of aerobic training and resistance training exercise on glycemic control [19,139,140] and one other study has examined the combined exercise effect on cardiac function in T2DM [114,115]. Study outcomes have been consistent, showing increases in aerobic fitness and muscular fitness [114,115,134] as well as improvements in body composition [139,140] and cardiovascular disease risk profile [19,114,115,139,140].

Balducci *et al.* [139] assessed the effects of a supervised facility-based combined aerobic and resistance exercise training program

on glycemic control, cardiovascular disease (CVD) risk factors and body composition in previously sedentary individuals with T2DM. Participants (aged 60–70 years) were randomized into an exercising intervention group (three times per week) or a non-exercising control group for 1 year. The exercise group showed a significant decrease in body mass index, fasting glucose, HbA<sub>1c</sub> and improved lipid profile. In addition, those in the exercise group using medication showed a decreasing trend in medication use whereas the control group showed an increasing trend. A study of shorter duration by Cauza *et al.* [140] also found improvements in HbA<sub>1c</sub> and lipid profiles in a combined aerobic and resistance exercise intervention group in comparison to a sedentary control group.

In the Diabetes Aerobic and Resistance Exercise (DARE) trial [19], 251 previously sedentary individuals with T2DM were randomized into four arms: aerobic exercise training; resistance exercise training; combined aerobic and resistance exercise training; or a non-exercising control group. Intervention groups performed exercise three times per week for 6 months in community facilities, supervised by personal trainers. Improvements in glycemic control were found in all exercise groups, and the improvements in the combined aerobic and resistance exercise group were significantly greater than with either aerobic training or resistance training alone. In contrast to this, a smaller study with participants randomized to combined exercise, aerobic exercise or non-exercise control did not find significant differences between the two exercising groups [141]. In this smaller study, there was no provision to keep dietary intake and/or medication use the same among groups, and statistical power was far more limited than in the DARE trial.

In the Italian Diabetes and Exercise Study [142], 606 individuals with T2DM from 22 clinics in Italy were randomized to a full year of either exercise counseling alone or supervised facility-based combined aerobic and resistance exercise training twice weekly plus exercise counseling. The group receiving the combined aerobic and resistance exercise training had significantly more favorable results for glycemic control, lipids, body composition, blood pressure and estimated cardiovascular risk than the group receiving exercise counseling alone. This study provides compelling evidence for incremental benefits of supervised structured exercise over exercise counseling alone for people with T2DM.

---

## **Recommendations for exercise in diabetes**

Most types of exercise can be recommended to both individuals with T1DM and T2DM. Exercise does not need to be strenuous, and even regular walking has beneficial effects [79,94]. Specific recommendations and guidelines for exercise in individuals with diabetes have been published by the American Diabetes Association [143,144] and the American College of Sports Medicine [145]. These and other guidelines are summarized in Tables 23.5–23.7. Advice should be tailored to individuals, taking

**Figure 23.7** Meta-analysis of exercise interventions in type 2 diabetes and the effect of glycemic control, as measured by HbA<sub>1c</sub>. CI, confidence interval; WMD, weighted mean difference. Studies are placed in ascending order of the intensity of the exercise intervention and represent the mean difference and the 95% CI for baseline and post-intervention measurements. Exercise vs. non-exercise control: baseline values, the chi-squared test for heterogeneity was 4.78 ( $P = 0.91$ ) and the z score for overall effect was 0.45 ( $P = 0.65$ ); post-intervention values, the chi-squared test for heterogeneity was 9.76 ( $P = 0.46$ ) and the z score for overall effect was 4.01 ( $P < 0.001$ ). Exercise and diet vs. control: baseline values, the chi-squared test for heterogeneity was 6.77 ( $P = 0.03$ ) and the z score for overall effect was 0.60 ( $P = 0.55$ ); post-intervention values, the chi-squared test for heterogeneity was 0.74 ( $P = 0.69$ ) and the z score for overall effect was 2.66 ( $P = 0.008$ ). The following equation should be used to convert HbA<sub>1c</sub> to IFCC Units: DCCT result (%) = (0.0915 × IFCC result in mmol/mol) + 2.15. Data from Boulé *et al.* [138].

**Table 23.5** Exercise recommendations.

Aerobic training				Resistance training		
Reference	Frequency	Intensity	Duration	Frequency	No. of exercises	Sets/Repetitions
<b>Healthy/sedentary adults</b>						
2008 CDC Guidelines [1]	At least 3 days/week	Moderate/vigorous	Accumulate 150 min/week of continuous moderate activity or 75 min/week of intense activity	At least 2 days/week	Involve all major muscle groups	At least 1 set of 8–12 reps, 2–3 sets preferable
2007 ACSM/AHA [146]	3–5 days/wk	Moderate/vigorous Start at lower intensity if initially unfit or sedentary	30–60 min of moderate aerobic activities or 20–30 min vigorous aerobic activity. Can be accumulated in bouts lasting >10 min	2 days/week (non-consecutive)	8–10 exercises involving major muscle groups	1 set, 8–12 reps
<b>Elderly persons (65 or older)</b>						
2007 ACSM/AHA Physical Activity Guidelines [147]	3–5 days/week	Moderate/vigorous	30–60 min of moderate aerobic activities or 20–30 minutes of vigorous aerobic activity Can be accumulated in bouts lasting >10 min	2 days/week (non-consecutive)	8–10 exercises involving major muscle groups	1 set, 10–15 reps
<b>Cardiac patients</b>						
1995 AHA Exercise Standards [167]	Minimum 3–5 days/week	50–60% $\dot{V}O_{2max}$ or HRR	Minimum of 30 min of continuous physical activity	2–3 days/week	8–10 exercises involving major muscle groups	1 set, 10–15 reps
2006 AACVPR [168]	3–5 days/week	50–60% $\dot{V}O_{2max}$ or HRR	30–45 min of continuous or intermittent aerobic activity	2–3 days/week	Incorporate all major muscle groups	1 set, 10–15 reps
<b>Individuals with type 2 diabetes</b>						
2006 ADA Consensus Statement on Physical Activity/Exercise and Type 2 Diabetes [144]	3–5 days/week No more than 2 consecutive days without exercise	50–70% $HR_{max}$ (moderate) or >70% $HR_{max}$ (vigorous)	at least 150 min/week of moderate aerobic exercise and/or at least 90 min/week of vigorous aerobic exercise	3 days/week	Targeting all major muscle groups	Progressing to 3 sets of 8–10 reps

**Table 23.6** Precautions and advice regarding exercise in diabetes.**Relative contraindications**

- If receiving insulin treatment: sports in which hypoglycemia would be dangerous (e.g. diving, climbing, single-handed sailing, motor racing). Individuals participating in this type of sport must test the capillary blood glucose concentration very frequently and take strict measures to avoid hypoglycemia. Whenever possible, another person should be close by and able to assist when needed. Note that the Amateur International Boxing Association prohibits people with insulin-requiring diabetes from participating in boxing
- With untreated proliferative retinopathy: very strenuous exercise, because of the risk of hemorrhage. However, a patient whose retinopathy has been adequately treated with laser therapy and is regularly followed by a retinal specialist can probably undertake strenuous exercise without undue risk

**Cautions**

Cardiovascular disease: there is a high prevalence of this in middle-aged and older people with diabetes. Middle aged and older individuals with diabetes wishing to undertake exercise more vigorous than brisk walking should probably first have a maximal exercise stress test with continuous electrocardiography monitoring. Patients with abnormal stress test results should be referred for additional cardiac investigations

**Table 23.7** Guidelines for exercise diabetes mellitus.**General guidelines**

- Exercise used to reduce weight should be combined with dietary measures
- Moderate intensity aerobic exercise should be part of the daily schedule if possible, accumulating 150 minutes each week. More vigorous exercise ( $\geq 70\%$  of  $\dot{V}O_{2max}$ ) undertaken 3–5 times per week will provide additional health benefits. Previously sedentary patients may have to build up exercise volume gradually, starting with as little as 5–10 min/day
- Multiple shorter exercise sessions lasting at least 10 min each in the course of a day are probably as useful as a single longer session of equivalent length and intensity
- Include low intensity warm-up and cool-down periods especially if vigorous exercise is undertaken
- Exercise should be appropriate to the person's general physical condition and lifestyle
- Resistance exercise performed 2–3 times per week will provide benefits over and above those of aerobic training. The studies reporting greatest impact of resistance exercise on  $HbA_{1c}$  have had subjects progress to 3 sets of approximately 8 resistance type exercises at relatively high intensity (8 repetitions performed at the maximum weight that can be lifted 8 times)
- Use proper footwear and, if appropriate, other protective equipment
- Avoid exercise in extreme heat or cold
- Inspect feet before and after exercise

**Specific considerations for exercise in type 1 diabetes**

Avoid hypoglycemia during exercise by:

- Avoiding heavy exercise during peak insulin action
- Using non-exercising sites for insulin injection
- If using multiple daily injections reducing pre-exercise insulin dosages by 20–50% or more if necessary. If using an insulin pump, decrease basal rate and/or amount of last bolus before exercise. These reductions should be individualized and based on blood glucose monitoring; not all individuals will require an insulin dose reduction
- Monitor glycemia before, during and after exercise as necessary
- Taking extra carbohydrate before and hourly during exercise. This amount should be individualized and based on blood glucose monitoring
- After prolonged exercise, monitor glycemia and take extra carbohydrate to avoid delayed hypoglycemia. The quantity required can be estimated using the semi-quantitative technique (1 g CHO/kg body weight/hour of activity) or by consulting tables of energy requirements for particular activities
- Use extra caution in monitoring glycemia if exercise is being performed within 24 hours of a hypoglycemic episode

**Specific considerations for exercise in type 2 diabetes**

- Hypoglycemia is less common during exercise than in type 1 diabetes, and extra carbohydrate is therefore usually unnecessary
- Patients taking insulin or sulfonylureas may need to reduce the doses of these medications during days when they exercise. Such adjustments should be guided by glucose monitoring

into account their interests, personal goals, levels of fitness, possible contraindications and available resources. If the patient is interested in sports or is even a professional athlete, diabetes should not interfere with his or her athletic career, and treatment should be adjusted according to the demands of the activity. For

activities and competitions considered to be higher risk for individuals with insulin-treated diabetes (e.g. car racing, flying, boxing), individual governing bodies should be consulted regarding restrictions in competition. It is also important to note that insulin is considered a banned substance by the World Anti-Doping Agency, and that elite level athletes with diabetes will be required to apply for a Therapeutic Use Exemption certificate prior to competition.

**Aerobic training**

It is generally recommended that all individuals accumulate at least 150 minutes of moderate aerobic activity, and/or at least 90 minutes of vigorous aerobic exercise every week, and that this activity be spread over at least 3–5 days [143,146,147]. A day's activity need not occur in a single session, but may be accumulated in bouts of 10 or more minutes at a time, performed throughout the day. Performing progressively greater amounts of moderate activity (in excess of the minimum 150 minutes) is associated with progressively greater benefits. Studies have also shown that group exercise environments can provide motivation, social support and enjoyment for individuals starting and maintaining exercise training programs [148].

**Resistance training**

A recent meta-analysis showed that resistance exercise can be safe and effective even for vulnerable cardiac patients [149]. High intensity weightlifting in healthy older men (mean age 64 years) caused less circulatory stress than walking up 192 stairs [150]. Weightlifting was not associated with increased proliferative retinopathy risk in the Wisconsin Epidemiologic Study of Diabetic Retinopathy, although the statistical power of the study was limited [151]. When properly performed, resistance training can be safe and enjoyable while at the same time producing significant health benefits.

Resistance training programs should be progressive in nature. Previously sedentary individuals should always start with a low intensity workload. It is important that individuals receive proper instruction on lifting and breathing techniques used during resistance training in order to maximize the benefits of the exercise, while at the same time minimizing the risk of injury. The authors recommend that beginners use weight machines in the initial stages of a training program, before moving on to free-weight exercise once sufficient strength has been gained and appropriate lifting techniques have been mastered [21]. Warming up before each training session with low intensity aerobic activity or light sets of selected exercises is also thought to help minimize the risk of injury [21]. When multiple exercises are performed in a workout, exercises involving the use of large muscle groups (e.g. lunges or pull-downs) should be performed before exercises requiring the use of smaller muscle groups (e.g. calf raises or bicep curls). Multiple joint exercises such as squats, chest press or seated row should precede single joint exercises such as leg extensions or tricep extensions [21]. Although one set of each exercise may be sufficient to increase muscle strength [152], the

resistance exercise studies with the greatest HbA<sub>1c</sub> reductions [63,153,154] have used three or more sets of each exercise. The authors therefore suggest that three sets of each exercise be performed on three non-consecutive days per week (assuming the same muscle groups are being targeted) to ensure the best possible metabolic benefits [1,143,146,147].

### Special considerations in people with long-term complications of diabetes

Some advanced long-term complications of diabetes may limit individuals' ability to perform certain types of exercise safely, but should not prevent them from becoming active at all. Where proliferative or severe non-proliferative retinopathy is present, it has been suggested that individuals may want to avoid vigorous activity (both aerobic and resistance) because of the possible increased risk of triggering vitreous hemorrhage or retinal detachment [155]. Mild to moderate activity can still be encouraged for these individuals. In individuals with peripheral neuropathy, weight-bearing activity could, in theory, increase the risk of skin breakdown and infection as well as Charcot joint destruction [156,157]; however, a recent study showed that the incidence of foot ulcers was no greater in individuals with diabetic neuropathy than in individuals without neuropathy after a 6-month walking intervention [158]. As exercise training is important in delaying the progression of peripheral neuropathy [26], it can be recommended that these individuals stay active by walking, swimming or bicycling. Before changing or adding activities for individuals with autonomic neuropathy, it is generally recommended that these individuals undergo cardiac investigation [159,160], as the risk of CVD in such individuals is high. Decreased cardiac responsiveness to exercise, postural hypotension, unpredictable carbohydrate delivery increasing the risk of hypoglycemia where gastroparesis is present and impaired thermoregulation have all been associated with autonomic neuropathy, warranting caution in the practice of certain activities in this population [157]. The authors know of no evidence justifying any specific exercise restrictions in nephropathy.

### Insulin and oral hypoglycemic agent adjustments for exercise

In individuals with T1DM or T2DM treated with multiple insulin injections, the dosage of short-acting insulin taken before exercise can be reduced instead of using dietary adjustment. The amount of such reduction, if required, should be tailored to each individual, based on blood glucose monitoring results before, during and after exercise, at least until the pattern of glucose response to exercise for that individual is known. Depending on the intensity and duration of exercise, the reduction required can be as much as 75% of the usual dose [30], although dose reductions of 20–50% are more typical. The insulin formulation (short- or intermediate-acting) to be reduced is that which has its maximal action at the time of exercise. For brief, very intense exercise such as competitive hockey, weightlifting or sprinting, there may be no need to reduce insulin dose. If the blood glucose concentra-

tion increases during exercise, the insulin dosage may need to be slightly increased or the injection schedule changed in order to achieve higher plasma insulin concentrations during exercise. Use of an insulin pump may be advantageous for many physically active individuals, as circulating insulin levels can be more easily adjusted to accommodate meals, snacks and exercise [161]. The variability of glucose absorption is also generally decreased, lowering the risk of hypoglycemia [161]. Decreases in insulin for pump users may or may not need to be accompanied by carbohydrate supplementation [161].

In individuals with T2DM, exercise does not usually cause hypoglycemia, and in obese individuals it can be a valuable tool to improve glycemic control and assist with weight maintenance. For these reasons, carbohydrate supplementation is usually unnecessary with exercise (Table 23.7). If blood glucose declines rapidly during exercise, as may occur in individuals taking oral hypoglycemic agents or insulin, the dosage of the drug should be reduced or the drug withheld on exercising days.

### Carbohydrate supplementation

There are few controlled studies regarding the appropriate type and amount of carbohydrates to be taken with exercise in people with T1DM. A reasonable starting point is to take approximately 15 g carbohydrate before and 15–40 g at 30–60-minute intervals during longer exercise sessions. Supplementation should be advised if pre-exercise blood glucose levels are <5.6 mmol/L. The amount of carbohydrate consumed should be adjusted according to blood glucose monitoring results; some individuals will not require any carbohydrate supplementation whereas some will require large amounts. During strenuous exercise, at least part of this can be taken as a sucrose-containing beverage. If exercise is performed post-prandially, there is less need for carbohydrate supplementation, whereas larger snacks should be taken if some hours have elapsed since the last meal. Also, the risk of hypoglycemia and subsequent need for exogenous carbohydrate supplementation decreases as the amount of time since the last insulin injection increases [162,163].

A recent review by Perkins & Riddell [161] describes several methods of carbohydrate supplementation. The goal is for the patient to consume a quantity of oral carbohydrate that matches the amount of glucose being used by the working muscles during activity. This can involve either a basic approach (where 15–30 g of carbohydrate is consumed for every 30–60 minutes of exercise), a semi-quantitative approach (consuming approximately 1 g glucose/kg body weight/hour of activity) or a quantitative method, based on standardized tables of energy requirements for specific activities, intensities and individual body weights [161]. The latter is referred to as “excarbs” (extra carbohydrates for exercise), developed originally by Walsh & Roberts [164]. However, it should be noted that only a finite amount of carbohydrate (40–60 g/hour) can be absorbed while the body is moderately or vigorously active [165], requiring that a certain amount of the carbohydrate be consumed prior to exercise or during recovery. Regular glucose monitoring is still recommended, espe-

cially where the participant is experimenting with new types, intensities or durations of exercise training.

## Acknowledgments

The authors are grateful for the contributions of Veiko Koivisto to this chapter in previous editions of this textbook. Jane Yardley was supported by a Doctoral Student Award from the Canadian Diabetes Association and funds from the Ottawa Hospital Research Institute Research Chair in Lifestyle Research. Glen Kenny holds a University Research Chair from the University of Ottawa. Ronald Sigal is a Senior Health Scholar of the Alberta Heritage Foundation for Medical Research.

## Social Aspects of Diabetes

**Brian M. Frier<sup>1</sup> & Mark W.J. Strachan<sup>2</sup>**

<sup>1</sup>Department of Diabetes, Royal Infirmary of Edinburgh, Edinburgh

<sup>2</sup>Metabolic Unit, Western General Hospital, Edinburgh

### Keypoints

#### Driving

- Potential hazards facing the driver with diabetes include hypoglycemia, visual impairment, and disability from severe neuropathy or leg amputation.
- Hypoglycemia can severely disrupt driving skills by causing cognitive dysfunction and mood changes. Motor skills and judgment can become impaired when blood glucose falls below 3.8 mmol/L, often without inducing hypoglycemic symptoms. Impaired awareness of hypoglycemia is a relative contraindication to driving. Drivers with diabetes must take precautions to avoid hypoglycemia and know how to treat it if it occurs while driving.
- Corrected visual acuity that is worse than 6/12 in the better eye precludes driving in the general population. People with diabetes may fulfill this criterion, but still have significant visual impairment (e.g. field loss, poor night vision and perception of movement) secondary to retinopathy, laser treatment or cataracts.
- In many countries, drivers with diabetes are legally required to declare the diagnosis for their driving license and motor insurance. Failure to do this will invalidate insurance claims.
- Driving licenses are often issued for fixed terms and only renewed following satisfactory medical review. In many countries, insulin-treated drivers are barred from driving passenger-carrying vehicles and large goods vehicles.

#### Employment

- Diabetes is not a bar to most occupations, and people with diabetes are protected in many countries by legislation against discrimination on the grounds of disability.
- People with insulin-treated diabetes are barred from certain occupations because of the risk of hypoglycemia. These include the armed forces, emergency services, commercial pilots, prison and security services, and jobs in potentially dangerous areas (e.g. at heights, underwater and offshore).
- Severe hypoglycemia in the workplace is uncommon and shift work seldom compromises glycemic control. Depressive illness and poor glycemic control are associated with higher unemployment and sickness absence in people with diabetes.

#### Prison and custody

- Glycemic control may be suboptimal in prison because of restrictions in diet, exercise and blood glucose monitoring. Intercurrent illness and metabolic abnormalities may not be recognized or treated promptly.
- Input from a diabetes specialist may improve the quality of care. Knowledge of diabetes among prison officers and staff of short-term custodial units is often limited and may be improved by liaising with local diabetes specialist services.

#### Insurance

- Diabetes should be declared to insurers, who may impose higher premiums or limited coverage. Many insurers' decisions are based on outdated actuarial data or misconceptions about the current prognosis of diabetes. National diabetes organizations can provide details of insurance brokers who do not weight policies against people with diabetes.
- Life expectancy in type 1 diabetes can be modeled from age, sex and the presence of proliferative retinopathy and nephropathy. As the latter is a major determinant of survival, life insurance premiums should be reduced for all those who reach the age of 50 years without renal impairment.

#### Alcohol

- The association between excessive alcohol consumption, chronic pancreatitis and secondary diabetes is well established. Alcohol excess is also associated with central obesity and poor compliance with medication; both could increase the risk of type 2 diabetes and compromise control of established diabetes. Most epidemiologic studies, however, have demonstrated a U-shaped relationship between alcohol consumption and diabetes, with moderate intake being associated with a lower risk of diabetes.
- In type 2 diabetes, moderate alcohol consumption is associated with a 35% reduction in total mortality and lower risk of cardiovascular disease compared to abstinence. Excessive alcohol consumption is associated with hypertriglyceridemia and resistant hypertension; affected individuals have an increased vascular risk.

- Ethanol inhibits hepatic gluconeogenesis and increases the risk, severity and duration of hypoglycemia. Alcohol obscures the ability, both of the individual and of observers, to recognize and treat hypoglycemia, and intoxication can simulate hypoglycemia.

#### Recreational drugs

- Approximately one-third of young people with diabetes use recreational drugs at some time. The most common class of drug taken is cannabis, but amphetamine-type stimulants (including 'ecstasy'), cocaine and opiates are also used.
- Recreational drug use is associated with a sixfold higher risk of death from acute metabolic complications of diabetes. Intravenous drug use is uncommon but is dangerous and is associated with omission of insulin therapy, frequent hospital admissions (usually with diabetic ketoacidosis) and high mortality.
- Cocaine and amphetamine-type stimulants can have profound hemodynamic effects through sympatho-adrenal activation. In addition to an increased risk of cardiac arrhythmias and myocardial ischemia, the sympathetic activation antagonizes the action of insulin and can precipitate diabetic ketoacidosis.

#### Travel

- Diabetes is not a bar to traveling, but changes in meals, physical activity and antidiabetic drug treatment *en route* and after arrival all need careful consideration. Important issues include travel insurance, medical identification, supplies and storage of medication and monitoring equipment and immunizations.
- During long flights, blood glucose should be monitored frequently and glycemic control relaxed to avoid hypoglycemia. Insulin injection schedules may require in-flight adjustment, especially if the time-shift exceeds 4 hours.

#### Leaving home

- In the Diabetes UK Cohort Study, "living alone" was associated with a more than fourfold increase in risk of death from acute metabolic complications of diabetes.
- Leaving home is potentially a period of high risk for young people with diabetes; particular concern has been expressed about the welfare of university students with type 1 diabetes.

Diabetes influences many aspects of daily life, principally through the effects of treatment and its potential side effects, particularly hypoglycemia. The development of diabetic complications, such as neuropathy and retinopathy, can also affect everyday activities, particularly when these are severe with clinical manifestations, or require time-consuming treatment such as dialysis for chronic renal failure.

## Driving

Driving is an everyday activity that demands complex psychomotor skills, visuospatial coordination, vigilance and satisfactory judgment. Although motor accidents are common, medical disabilities are seldom responsible. Diabetes is designated a "prospective disability" for driving because of its potential to progress and cause complications, while side effects of treatment (principally hypoglycemia) can affect driving performance. In most countries, the duration of the license of a driver with diabetes is period-restricted by law, and its renewal is subject to review of medical fitness to drive. The problems associated with diabetes and driving and the limitations of relevant research data have been reviewed [1,2].

The main problems for the driver with diabetes are hypoglycemia and visual impairment resulting from cataract or retinopathy. Rarely, peripheral neuropathy, peripheral vascular disease and lower limb amputation can present mechanical difficulties with driving (Table 24.1), but these problems may be overcome by adapting the vehicle and using automatic transmission systems.

Despite these challenges, drivers with diabetes do not appear to be involved in more accidents than their non-diabetic coun-

**Table 24.1** Reasons for drivers with diabetes to cease driving.

Newly diagnosed people with diabetes, especially insulin-treated, should not drive until glycemic control and vision are stable
Recurrent daytime hypoglycemia (particularly if severe)
Impaired awareness of hypoglycemia, if disabling
Reduced visual acuity in <i>both</i> eyes (worse than 6/12 on Snellen chart) – note use of mydriatics for eye examination will affect visual acuity
Severe sensorimotor peripheral neuropathy, especially with loss of proprioception
Severe peripheral vascular disease
Lower limb amputation

terparts [3]. Population studies have shown no excess in accident rates among drivers with diabetes in Northern Ireland [4], Scotland [5], England [6], Germany [7], Iceland [8] or Pittsburgh in the USA [9], while a large survey of over 30 000 drivers in Wisconsin, USA found only a modest increase [10]. In most surveys, however, incidents were self-reported and probably underestimated, while fatal accidents (in which a diabetes-related cause, such as hypoglycemia, could have had a role) were excluded. Accident rates may also have been lowered by regulatory authorities barring high-risk drivers and by drivers with advancing diabetic complications who voluntarily stop driving [4,5]. Practical advice for drivers with diabetes is given in Table 24.2.

#### Hypoglycemia

Drivers with insulin-treated diabetes often experience hypoglycemia while driving [4,5,11] and this can interfere with driving

**Table 24.2** Advice for drivers with diabetes.

Inform licensing authority* (statutory requirement) and motor insurer of diabetes and its treatment
Do not drive if eyesight deteriorates suddenly
Check blood glucose before driving (even on short journeys) and at intervals on longer journeys
Take frequent rests with snacks or meals; avoid alcohol
Keep a supply of fast-acting and longer-acting carbohydrate in the vehicle for emergency use
Carry personal identification to indicate that you have diabetes (and are prone to hypoglycemia)
If hypoglycemia develops, stop driving, switch off engine, leave the driver's seat and then treat
Do not resume driving for 45 minutes after blood glucose has returned to normal (delayed cognitive recovery)

\* In the UK, the licensing authority is the Driver and Vehicle Licensing Agency (DVLA), Swansea, SA99 1TU, UK.

skills by causing cognitive dysfunction, even during relatively mild hypoglycemia that does not induce symptoms. Studies of subjects with type 1 diabetes (T1DM) using a driving simulator showed that driving performance often became impaired at blood glucose concentrations of 3.4–3.8 mmol/L, and deteriorated further at lower levels [12]. Problems included poor road positioning, driving too fast, inappropriate braking and causing “crashes” by stopping suddenly. Alarmingly, most did not experience hypoglycemic symptoms or doubt their competence to drive; only one-third treated the hypoglycemia, and only when blood glucose had fallen below 2.8 mmol/L [12]. In the UK, the Driver and Vehicle Licensing Agency (DVLA) does not distinguish between type of diabetes, and the restrictions are based on the use of insulin as therapy, as this can cause hypoglycemia in any person using this treatment. The risk of hypoglycemia in insulin-treated type 2 diabetes (T2DM) rises with duration of insulin therapy.

Judgement and insight become impaired during hypoglycemia, and some drivers with diabetes describe episodes of irrational and compulsive behavior while at the wheel [12]. Hypoglycemia also causes potentially dangerous mood changes, including irritability and anger [13]. In addition, asymptomatic hypoglycemia impairs visual information processing and contrast sensitivity, particularly in poor visibility [14,15], which may diminish driving performance.

Poor perception of hypoglycemia is also potentially dangerous. Many drivers with diabetes subjectively overestimate their current blood glucose level and feel competent to drive when they are actually hypoglycemic [16]. Impaired awareness of hypoglycemia, often associated with more frequent severe episodes, is particularly hazardous and is a common reason for revocation of the driving license. It is not an absolute contraindication to driving if it can be demonstrated, by frequent self-monitoring, that there is prolonged freedom from hypoglycemia [17].

Hypoglycemia is a recognized cause of road traffic accidents, but its true frequency and causal relationship to an accident are often difficult to ascertain. Blood glucose is seldom estimated immediately after a crash, and evidence for preceding hypoglycemia is often circumstantial. Hypoglycemia was the main cause of non-fatal motor accidents in the Diabetes Control and Complications Trial (DCCT); hypoglycemia was three times more common in the intensively treated patients, but the rate of major accidents was no higher, perhaps because of better precautionary advice [18]. Other studies found that the frequency of hypoglycemic episodes during driving correlates with the total number of accidents [4,5,19]. The frequency of hypoglycemia-related accidents is substantially lower than those caused by alcohol and drugs.

### Avoiding and treating hypoglycemia while driving

General measures to avoid hypoglycemia are discussed in Chapter 33. All drivers with insulin-treated diabetes should keep some fast-acting carbohydrate in the vehicle: disturbingly, some do not [20,21]. Each car journey, no matter how short, should be planned in advance to anticipate possible risks for hypoglycemia, such as traffic delays. It is advisable to check blood glucose before and during long journeys, and to take frequent rest and meals. Unfortunately, this is seldom undertaken [22]. Driving expends energy and – as with other forms of exercise – prophylactic carbohydrate should be taken if the blood glucose is <5.0 mmol/L [23].

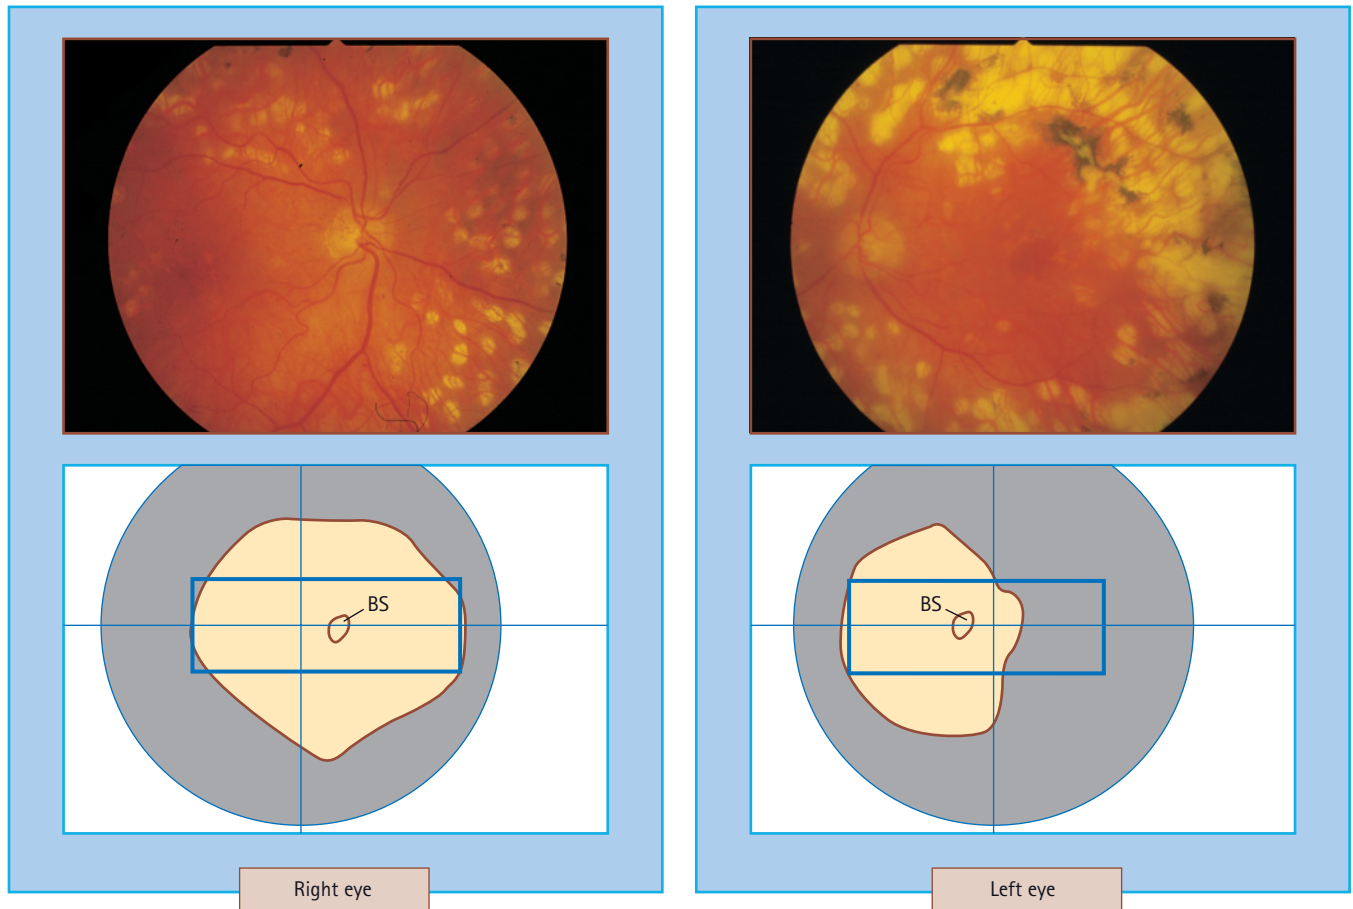

If hypoglycemia occurs during driving, the car should be stopped in a safe place, and the engine switched off before consuming some glucose. In the UK, the patient should vacate the driver's seat and remove the keys from the ignition, as a charge can be brought for driving while under the influence of a drug (insulin) even if the car is stationary. Driving should not be resumed for at least 45 minutes after blood glucose has returned to normal, because cognitive function is slow to recover after hypoglycemia [13].

Many features of hypoglycemia resemble alcohol intoxication, and semi-conscious hypoglycemic diabetic drivers are sometimes arrested on the assumption that they are drunk. Drivers with insulin-treated diabetes should therefore carry a card or identity bracelet stating the diagnosis. Individuals with newly diagnosed insulin-treated diabetes may have to stop driving temporarily until their glycaemic control is stable.

Sulfonylureas is the only group of oral antidiabetic drugs that may cause hypoglycemia while driving, and people treated with these agents should be informed of this possibility. While GLP-1 agonists alone are not associated with a risk of hypoglycemia, this may be a problem when used in combination with a sulfonylurea. Blood glucose testing in relation to driving is not a requisite for drivers with group 1 licenses (see below), but may be required for holders of group 2 licenses who are taking this treatment combination.

### Visual impairment

In the UK, monocular vision is accepted for driving, provided that the person meets the minimum legal requirement, i.e. is able

**Figure 24.1** Visual field loss caused by photocoagulation. This 60-year-old man with diabetes needed heavy laser photocoagulation to the temporal retina of the left eye, causing nasal visual field loss which caused this eye to fail the standard test for driving. The right eye required less intensive laser treatment and the visual field was adequate for driving. BS, blind spot. Blue rectangle: minimum area recommended for safe driving. Courtesy of D. Flanagan, Addenbrooke's Hospital, Cambridge, UK.

to read a number plate with letters 8.9 cm (3.5 inches) high at a distance of 30 m (75 feet), wearing spectacles if necessary. This corresponds to a distance visual acuity of approximately 6/10 on the Snellen chart. The number plate test has deficiencies: it is poorly reproducible under clinical conditions and does not assess visual fields, night vision or the ability to see moving objects. All of these may be severely reduced by retinal ischemia in proliferative retinopathy [24], while visual field loss can be caused by extensive laser photocoagulation for diabetic retinopathy [25,26] or macular edema (Figure 24.1) [27]; careful containment of laser burns may help to preserve vision [28]. Cataracts often accentuate glare from headlights, and in such cases driving in the dark should be avoided.

Previous surveys have identified very few drivers with diabetes who would fail the standard eyesight test. Impaired vision is an uncommon reason for the driving license to be refused or revoked [29], although many people stop driving voluntarily because their eyesight is deteriorating. Worsening vision from diabetic (or other) eye disease should be reported by the individual to the licensing authority.

Eye screening is a crucial part of assessing medical fitness to drive. Pupillary dilatation for funduscopy or retinal photography temporarily reduces visual acuity, particularly if the usual binocular visual acuity is 6/9 or worse [30]. Patients should be told not to drive for at least 2 hours after the use of mydriatics. The driving regulatory authority may request perimetry to assess visual fields (Figure 24.1).

### Statutory requirements for drivers with diabetes

In most developed countries, drivers with diabetes are required by law to declare their diabetes to the relevant regulatory authority (in the UK this is the DVLA). The statutory requirements for ordinary and vocational (professional) driving licenses vary considerably around the world; the national licensing authority should be contacted for details.

#### European driving licenses

##### *Ordinary driving licenses (group 1)*

The European Union (EU) States all use the same classification for driving licenses but this is not applicable to other areas. In the

UK, the DVLA must be informed when a person with diabetes applies for a driving license, or if diabetes develops subsequently. Failure to do this constitutes “concealment of a material fact,” which can incur a fine [29], and can invalidate a claim to the motor insurers; professed ignorance of the law is not accepted as an excuse. The onus to declare rests with the individual driver, and doctors who provide diabetic care, including general practitioners, have a responsibility to inform patients of this legal requirement, and should offer practical advice (Table 24.2). Drivers with diabetes who are treated with diet alone or with antidiabetic medications do not have to notify the DVLA unless they have visual impairment or other diabetes-related problems that could affect medical fitness to drive. In the UK, a driving license is usually issued for a maximum of 3 years, and is renewed after completion of a medical questionnaire. The DVLA request further medical reports in a few cases, and always when an applicant reports a medical problem that may seriously affect driving (e.g. recurrent hypoglycemia). GLP-1 agonists (given by injection) can be used without restriction, other than when used in combination with a sulfonylurea for drivers with group 2 (vocational) licenses, when this must be notified to the DVLA and requires assessment of medical fitness to drive.

Although the member states of the EU have an agreed policy on restrictions on driving licenses for people with insulin-treated diabetes, considerable variations in policy and practical application exist between countries with respect to the implementation of the recommended regulations and how these are reviewed.

#### **Vocational driving licenses (group 2)**

It is extremely difficult to estimate the risk and likely outcome of a motor accident. In the absence of scientific evidence, risk and hazard are gauged by the size of vehicle being driven, which is perhaps not unreasonable, given the potential consequences of a hypoglycemic person losing control of a vehicle weighing several tons.

Most European countries restrict vocational (group 2) driving licenses for people with insulin-treated diabetes. These include category C licenses for large goods vehicles (LGV; previously called heavy goods vehicles) weighing over 7500 kg, and category D licenses for passenger-carrying vehicles (PCV; previously called public service vehicles), or those with more than 17 seats (including the driver's). In 1991, the then European Community (now the European Union) extended group 2 licenses to include small lorries and vans weighing 3500–7500 kg (category C1) and minibuses with 9–16 seats (category D1). Although all EU member states agreed to this policy (2nd European Council Directive on Driving Licences, 91/439/EEC), and presumably enacted appropriate legislation, considerable variations exist in the interpretation and imposition of these restrictions, and in some countries the EU Directive is openly disregarded. A few countries, such as the UK, Sweden and Spain, have robust systems in place to review medical fitness to drive at regular intervals. In the UK, C1 (but not D1) licenses are issued to drivers with insulin-treated diabetes as “exceptional cases” provided specific medical criteria are satisfied. A recent EU directive on driving has recommended individual assessment of

all insulin-treated drivers with diabetes who apply for a Group 2 license, so medical fitness criteria will be modified in 2010.

Oral antidiabetic medication is not a bar to vocational driving licenses in the UK. In practice, however, many public transport companies restrict the employment of drivers with T2DM who take sulfonylureas; metformin or exenatide treatment is not a contraindication, but medical assessment is usually necessary. Progression to insulin therapy will terminate the employment of bus and train drivers. Taxi and ambulance drivers are not covered by the statutory regulations. In the UK, taxi licenses are issued by local authorities, which vary considerably in the assessment of medical fitness to drive [32,33], although many have now adopted group 2 licensing standards.

The European approach to vocational licensing has been criticized as being draconian and discriminatory against drivers with diabetes, showing how difficult it can be to balance the civil rights of the person with diabetes against the need to safeguard public safety.

#### **Driving outside Europe**

Outside Europe, the regulations in different countries range from a complete ban to no restriction other than a medical examination for prospective or current drivers who require insulin [31]. Differences in approach between countries are influenced by the level of economic development and the prevalence of insulin-treated diabetes; many low and middle income countries impose no restriction on vocational driving licenses for people with insulin-treated diabetes [31]. In the USA, the Federal Highway Administration (FHWA) prohibits drivers with insulin-treated diabetes from driving commercial motor vehicles across state borders [35]. Within most states, drivers with insulin-treated diabetes can drive commercial vehicles except for lorries transporting hazardous materials and passenger-carrying buses.

In most other countries, insulin treatment alone is targeted by legislation, even though hypoglycemia can occur with other diabetic drugs. Interestingly, a Canadian survey of crashes involving truck and commercial vehicle drivers with diabetes revealed an increased risk for drivers with T2DM treated with sulfonylureas [34], the presumption being that unsuspected hypoglycemia is a causal factor.

#### **Aircraft pilot licenses**

The UK Civil Aviation Authority does not allow individuals with diabetes treated with insulin or sulfonylureas to fly commercial aircraft or to work as air traffic controllers. Private pilot licenses can be issued to individuals with diabetes taking sulfonylureas (provided that they have a safety license endorsement), but not insulin. The EU has discussed introducing common airworthiness regulations for pilots with medical disorders.

---

## **Employment**

With a few provisos, people with diabetes can successfully undertake a wide range of employment. There remains some prejudice

against people with diabetes, but employment prospects in the UK and many other countries have improved with the introduction of legislation that makes it unlawful to treat a disabled person less favorably.

The main concern when considering people with diabetes for employment is the risk to safety associated with the condition or its treatment. Employers often fail to make the crucial distinction between a “hazard” (something with the potential to cause harm) and a “risk” (the likelihood that such harm will occur). The potential problems of diabetes relevant to employment are the hazards of acute hypoglycemia related to insulin and sulfonylureas, poor control of diabetes and the development of serious diabetic complications that may affect ability to work or interfere with performance at work.

Employment is generally restricted where hypoglycemia could be hazardous to the worker with diabetes, their colleagues or the general public. Employment-related issues, however, are not confined to people with T1DM. The rising prevalence of T2DM in the population of working age, along with the increasing use of insulin, has become an issue for occupational health assessment. Access to employment may be limited through discriminatory employment practices and restrictions posed by companies (rather than by legislation) because of perceived problems associated with diabetes or to job-sensitive issues related to the potential risks of hypoglycemia or to visual impairment. Diabetes can also affect employment through increased sick leave and absenteeism and by adversely influencing productivity. Diabetes in general has a negative long-term influence on the economic productivity of the individual; health-related disabilities can cause work limitations, especially in older employees in whom early retirement is more common on medical grounds.

A prospective survey in Edinburgh of 243 people with insulin-treated diabetes in full-time employment found that hypoglycemia occurred uncommonly at work (14% of all severe episodes) and had few adverse effects [36]. The study cohort, however, may have been subject to selection bias in terms of occupational diversity and many had suboptimal glycemic control; surprisingly few participants had impaired awareness of hypoglycemia. For some occupations (e.g. commercial airline pilots or train drivers) any risk of hypoglycemia is obviously unacceptable. Elsewhere, the case for employment restrictions may be less clear-cut.

Jobs that restrict the employment of workers with insulin-treated diabetes are listed in Table 24.3. People treated with insulin are not usually permitted to work alone in isolated or dangerous areas, or at unprotected heights. Shift-work is not necessarily a contraindication: one study in a car assembly plant found no difference in glycemic control between day and night-shift workers with diabetes, although control deteriorated if shift rotas were changed frequently [37].

In one British survey, the prevalence of diabetes in the workforce was 7.5 per 1000, including a lower-than-anticipated rate of 2.6 per 1000 for people treated with insulin [38]. Employment is generally disbarred in the armed forces, emergency work such as fire-fighting, civil aviation, jobs in the off-shore oil industry and in many forms of commercial driving [38]. Workers with diabe-

**Table 24.3** Forms of employment from which insulin-treated people with diabetes are generally excluded in the UK. Data from Waclawski [38] and Waclawski & Gill [56].

#### **Vocational driving**

Large goods vehicles (LGV)  
Passenger-carrying vehicles (PCV)  
Locomotives and underground trains  
Professional drivers (chauffeurs)  
Taxi drivers (variable; depends on local authority)

#### **Civil aviation**

Commercial pilots and flight engineers  
Aircrew  
Air-traffic controllers

#### **National and emergency services**

Armed forces (army, navy, air force)  
Police force  
Fire brigade or rescue services  
Merchant navy  
Prison and security services

#### **Dangerous areas for work**

Offshore: oil-rigs, gas platforms  
Moving machinery  
Incinerators and hot-metal areas  
Work on railway tracks  
Coal mining  
Heights: overhead lines, cranes, scaffolding

tes seldom conceal their medical condition from their employers, and any blanket policy that disbars workers with diabetes from a specific occupation may be inappropriate or even discriminatory. Individual assessment is crucial, as employment regulations may not differentiate between different types and treatments of diabetes. Some bureaucratic regulations have been successfully challenged on medical grounds: for example, active fire fighters in the UK and a US air traffic controller were reinstated following appeals against dismissal.

In some cases, entering or persevering with a specific occupation may not always be in the individual’s long-term interests (e.g. with the advance of disabling complications). This is clearly a difficult issue, which may require sympathetic medical counseling because of possible repercussions on the individual’s income, self-esteem, future quality of life and the financial support of dependants.

### **Unemployment, sickness and diabetes**

According to a British survey, employers do not generally believe that diabetes *per se* limits employment prospects, because most workers with diabetes have few medical problems and can tackle a wide range of occupations [39]. Discrimination by employers, however, may affect hiring practices; a US study reported that job applicants who told prospective employers of their diabetes were more likely to be refused than their non-diabetic siblings or individuals who did not declare that they had diabetes [40].

Some British and Dutch surveys reported no apparent excess of unemployment among people with diabetes as compared with the general population [41–44], but other studies in the UK [45,46] found that relatively more people with diabetes were not earning because of inability to work, intercurrent illness, early retirement or by being housewives. Although in many cases there was no apparent reason why an individual with diabetes could not obtain employment [46], depressive illness is strongly associated with unemployment and difficulties with work performance [47]. Adolescents with diabetes appear more likely than their non-diabetic peers to lose jobs, or to fail to follow their desired occupation or cope with shift-work [48]. Reduced employment and income in workers with diabetes in North America have been related to disability, which was seven times more common than among a sibling control group, was mainly related to diabetic complications [49,50] and was associated with lower employment income [51,52]. Sickness absence rates among employees with diabetes are reportedly either similar to, or 1.5- to twofold higher than in non-diabetic workers [40,53–55]. Workers with insulin-treated diabetes and good glycemic control had fewer sickness absences than those with poor control [56]; poor control itself (86 mmol/mol [ $\text{HbA}_{1c} > 10\%$ ]) is associated with a high rate of sickness absence [57].

---

## Prison and custody

Imprisonment and short-term custody are unusual but troublesome life situations that can interfere with the management of diabetes. Hypoglycemia can occur if food is withheld after arrest, and may be confused with intoxication by alcohol or drugs. Diabetes is generally managed badly in prison because of the unsuitability of prison diets, lack of exercise and the practical difficulty of using some insulin regimens (e.g. basal bolus); also, self-monitoring may be prohibited, and glucose to treat hypoglycemia may be unavailable during long “lock-up” periods. Most prison medical personnel have no specialist knowledge of diabetes and there may be no access to specialist supervision during custody.

Some prisoners with diabetes deliberately manipulate their treatment (e.g. by omitting insulin to induce ketoacidosis to have themselves removed to hospital which arguably offers a more amenable environment [59]). By contrast, treatment of intercurrent illness may be delayed by prison staff, who think that the prisoner is “misbehaving.”

In some cases, withdrawal of alcohol, better dietary compliance and weight loss may actually improve glycemic control while in prison, and structured diabetic care can be provided effectively by an attending specialist physician [60,61]. Facilities for people with diabetes in police custody are generally limited, with an inability to measure blood glucose, treat diabetic emergencies or to provide insulin and appropriate meals [62]. A Scottish liaison initiative between a specialist diabetes department and the local police force identified and successfully addressed deficiencies in

their custody facilities, including the provision of glucose monitoring equipment and the training of police staff [62]; this has been assisted by the development of a forensic nursing service.

---

## Insurance

In many societies, insurance is viewed as essential to protect individuals and their families from the financial risk of unexpected events or illness, and insurance is often necessary to secure a financial loan, as for house purchase. People with diabetes are sometimes refused insurance or have to accept higher premiums and limited coverage, because the disorder is associated with reduced life expectancy, the risk of complications and greater use of health care services. Several factors are important for insurance underwriting, including the severity and duration of the diabetes, the extent of diabetic complications and other concurrent medical disorders. It is reasonable for an insurer to be cautious in dealing with applicants who have poorly controlled long-standing diabetes and established complications.

There is wide variation in insurance terms and premiums among different European countries [63], in the USA [64] and even within the UK [65], which suggests that insurers work from assumptions about diabetes rather than using scientific evidence from actuarial studies. The presence of T1DM may be the only factor considered by insurers [64], and many still base potentially discriminatory decisions on outdated information that reflects the poor outcome of diabetes diagnosed and treated decades ago. There are no standardized guidelines, nor is there any uniformity in the approach to diabetes and insurance [65], although risk classifications for life insurance have been published [66]. Some companies do not accept applicants with diabetes, while others do so without financial penalty. People with diabetes seeking insurance cover should therefore request quotations from several companies, and should be supported by a medical assessment from a physician who is competent in the specialty. Many national patient organizations have negotiated favorable terms with insurance brokers and will provide details on request.

The prognosis of people with diabetes (particularly T1DM) has improved considerably during the last 50 years, and the impact of this on life insurance for people with T1DM has been analyzed in Scandinavia [67]. In the last 30–40 years, median life expectancy has increased by over 15 years, largely because of substantial reductions in diabetic nephropathy. It has therefore been suggested that life insurance in T1DM should focus entirely on the risk of developing diabetic nephropathy [68], and a model to calculate insurance terms has been proposed, based on current age, age at diagnosis, sex, presence of nephropathy or proliferative retinopathy and other pre-existing disease [67]. As the risk of nephropathy falls after 25 years of diabetes, all people who reach the age of 50 without nephropathy should have their insurance premium reduced. This approach has been adopted by most insurance companies in the Nordic countries, and by some in other European countries. To avoid penalizing people with dia-

betes, there must be regular updating of mortality and life expectancy data, and this information must be transmitted to actuarial advisers and insurance underwriters.

People with diabetes also face higher premiums for accident insurance, which is unjustified because there is no evidence that they have more accidents or permanent disability than the general population [69]. Neither is there any rationale for higher motor insurance premiums [64,65,70], particularly for those not treated with insulin, because no excess in road traffic accidents has been demonstrated (see above). A US study of the insurance cost of employees with diabetes showed that while health care expenditure was three times higher than all health care consumers, it was not more expensive than other chronic illnesses such as heart disease, asthma and cancer [71].

Diabetes must always be disclosed to the insurer: concealing the diagnosis constitutes the withholding of a material fact, which nullifies the contract with the insurer and thus the insurer's liability in the event of a claim.

## Alcohol

Many people enjoy drinking alcohol and diabetes should not be a barrier to social drinking. Accumulating data suggest that moderate alcohol consumption not only reduces the risks of developing T2DM but improves metabolic control and restricts diabetic complications. By contrast, alcohol can promote hypoglycemia and chronic excessive consumption may be deleterious both to long-term diabetes management and general health.

### Alcohol consumption and risk of diabetes

Chronic high consumption of alcohol can predispose to the development of secondary diabetes. Alcohol has a direct toxic effect on the pancreas resulting in both acute and chronic pancreatitis. Diabetes complicates about 45% of cases of chronic pancreatitis (see Chapter 18). Insulin treatment is usually required to control hyperglycemia in patients with chronic pancreatitis, although diabetic ketoacidosis is rare. This may be because the pancreatic damage also destroys the  $\alpha$ -cells that secrete glucagon, which is an essential factor in ketogenesis (see Chapters 13 and 34). A heavy alcoholic binge, with concomitant low food intake, can result in alcoholic ketoacidosis.

By contrast, modest alcohol consumption appears to protect against T2DM, reducing risk by up to 30% [72,73]. A U-shaped relationship has been observed between alcohol consumption and risk of diabetes, such that heavier drinkers and those who abstain from alcohol share a similar risk of developing T2DM (Figure 24.2). In epidemiologic and clamp studies, moderate alcohol consumption is associated with enhanced insulin sensitivity, which in part may be a consequence of reduced central adiposity [74]. Such epidemiologic data, however, may not provide an accurate assessment of risk for very heavy drinkers who tend to be underrepresented in such studies.

**Figure 24.2** Pooled relative risk estimates for development of type 2 diabetes (with 95% confidence intervals) for five alcohol consumption categories (demarcated by the vertical lines) from 15 prospective studies. The categories are:  $\leq 6$  g/day; 6–12 g/day; 12–24 g/day; 24–48 g/day and  $\geq 48$  g/day. Reproduced from Koppes *et al.* [73], with permission from American Diabetes Association.

## Alcohol and glycemic control

### Hypoglycemia

Ethanol has marked metabolic effects on the liver, which metabolizes over 90% of an alcohol load. Gluconeogenesis is suppressed, even at blood alcohol levels that are not usually associated with intoxication [75–77], while the processes of recycling carbon as glucose and lactate between hepatic gluconeogenesis and muscle glycolysis [76] and fatty acid oxidation are also inhibited by alcohol. Thus, alcohol has the potential both to predispose to hypoglycemia and to inhibit glucose recovery. In non-diabetic individuals, total hepatic glucose production is not reduced by alcohol, despite the inhibition of gluconeogenesis [77], and alcohol-induced hypoglycemia only occurs if hepatic glycogen stores are already depleted; for example, by fasting for at least 36 hours [78].

In people with diabetes, alcohol consumption may impede recovery from insulin-induced hypoglycemia. This effect is often delayed, occurring up to 24 hours after alcohol ingestion and may occur during the night or the following day [79]. Those with a deficient glucagon response to hypoglycemia (see Chapter 33) may be at greater risk, because they are unable to increase hepatic gluconeogenesis. The signs of hypoglycemia may be missed or mistaken for those of alcohol intoxication by the individual or by observers and even moderate alcohol consumption increases the cognitive impairment that occurs during hypoglycemia [80]. People with insulin-treated diabetes should be advised not to drink *any* alcohol before driving.

Overall, alcohol is an important contributory factor to many episodes of hypoglycemia in people with diabetes – an estimated 20% in one study [81]. Hypoglycemia-induced brain damage is rare, but when it occurs, it is often preceded by excessive alcohol consumption, which presumably promotes protracted neuroglycopenia. Severe hypoglycemia caused permanent neurologic damage after binge drinking in five alcoholic patients with insulin-treated diabetes, two of whom died [82].

**Hyperglycemia**

Excessive alcohol consumption is associated with central obesity [83], which may be a consequence of the adverse lifestyle factors that tend to accompany high alcohol intake. It should also be noted that alcohol provides 7kcal energy per gram (1 unit = 10g alcohol) in an easily consumable form and can therefore provide a substantial caloric intake, particularly as beer and lager. This is a commonly overlooked source of calories in obese, middle-aged males with T2DM, who are having difficulty in achieving weight loss by dietary means. The caloric content of spirits is much lower but may be augmented by adding sugar-rich mixers to drinks. Low-carbohydrate beers and lagers (such as Pilsner) have been marketed as being suitable for patients with diabetes but should not be recommended because of their high alcohol content.

Heavy drinking has also been linked with poorer compliance with medications, outpatient follow-up and self blood glucose

monitoring [84,85]. Despite this, and the association with increased central obesity, excessive alcohol consumption does not appear to be associated with poorer glycemic control. Indeed, in one large registry study, a linear inverse relationship was found between glycemic control and alcohol consumption [86]; however, the same caveat applies to these data with respect to very heavy consumption.

**Alcohol and diabetic complications**

Moderate alcohol consumption in people with T2DM is associated with a 35% reduction in total mortality compared with non-drinkers (i.e. a similar magnitude to the effect of moderate alcohol on the risk of developing T2DM) [87]. High alcohol consumption (more than 18g/day) is not associated with any excess mortality, and indeed cardiovascular mortality and incident coronary heart disease are lower than in non-drinkers (Figure 24.3). These favorable effects of alcohol consumption

**Figure 24.3** Pooled relative risk estimates (with 95% confidence intervals) of: (a) total mortality; (b) coronary heart disease mortality; and (c) coronary heart disease incidence for three alcohol consumption categories, with non-drinkers as the reference. Reproduced from Koppes *et al.* [87], with permission from Springer-Verlag.

may be a consequence of enhanced insulin sensitivity, lower blood pressure and favorable changes in lipids and hemostatic factors [74]. These observations do not include data on substantive numbers of very heavy drinkers and it is well established that excessive alcohol consumption increases serum triglyceride concentrations in susceptible individuals and raises blood pressure; excess alcohol consumption is an important cause of hypertension failing to respond to treatment (see Chapter 40). It might be anticipated in such individuals that cardiovascular risk would be higher [88].

With regard to microvascular complications, a U-shaped relationship is again observed between risk and alcohol consumption [89]. Moderate consumption (30–70 g/week) is associated with a 40% reduction in risk of proliferative retinopathy and neuropathy in T1DM, and over 60% reduction in risk for macroalbuminuria. Conversely, chronic excessive consumption of alcohol in people with diabetes is associated with peripheral neuropathy and exacerbation of neuropathic symptoms [90] and also with erectile dysfunction.

### Recommended alcohol intake

Diabetes UK recommends that women with diabetes should drink no more than 2 units of alcohol per day and men no more than 3 units. Guidelines issued by comparable organizations in other countries are broadly similar. Although these limits have been chosen arbitrarily for the non-diabetic population, it seems reasonable to apply them to people with diabetes as well. The general advice given to people with diabetes regarding alcohol is summarized in Table 24.4.

## Recreational drugs

Use of recreational (illicit) drugs is a serious problem in the general population, but can pose particular difficulties for people with diabetes [91]. The main classes of drugs involved are cannabis, amphetamine-type stimulants (including “ecstasy”), cocaine and opiates, with cannabis being the most commonly used drug by far.

### Regulation

In the UK, drugs that are associated with dependence or misuse are regulated under the Misuse of Drugs Act, 1971. This Act grades drugs according to harm associated with misuse and specifies controls over manufacture, supply and possession (Table 24.5). The Misuse of Drugs Regulations, 2001 define the classes of individuals who are authorized to supply and possess controlled drugs and lay down the conditions under which these activities may be carried out. Drugs are classified under five schedules, which specify the requirements governing import, export, production, supply, possession, prescribing and record keeping. Cannabis and lysergide (LSD) classified as Schedule 1 as they have no medicinal use, while opiates, cocaine and amphetamine are

**Table 24.4** General advice on alcohol for people with diabetes. Reproduced with permission from Diabetes UK.

Moderate amounts of alcohol can be drunk shortly before, during or soon after a meal without affecting short-term blood glucose control and can be beneficial for the heart
Alcohol should never be drunk on an empty stomach as the alcohol will be absorbed too quickly
Alcoholic drinks should not be substituted for usual meals or snacks as this may cause hypoglycemia
Severe hypoglycemia can occur with larger quantities of alcohol, particularly when taken by people treated with insulin and especially if insufficient carbohydrate has been eaten
Hypoglycemia may occur up to 16 hours after heavy drinking
Observers may be less aware of hypoglycemic symptoms when a person with insulin-treated diabetes has been drinking; some form of diabetes identification should be worn. A hypoglycemic episode can be confused with drunkenness
Continuous heavy drinking can lead to raised blood pressure
All types of alcoholic drinks contain calories and may contribute to weight gain or failed dietary effort
Drinking alcohol can worsen neuropathy and aggravate associated symptoms
Drinking low carbohydrate beers and cider offer no benefit because of their higher alcohol content
Low alcohol wines are often higher in sugar than ordinary ones, so intake should be restricted
Mixer drinks should be “diet” or “sugar-free” such as diet tonic water and diet cola
Drinking and driving should be avoided.

**Table 24.5** Classification of controlled drugs. Data from UK Misuse of Drugs Act 1971.

#### Class A includes:\*

Cocaine  
Diamorphine (heroin)  
Methadone  
Methylenedioxymethamphetamine (MDMA, “ecstasy”)  
Morphine  
Opium  
Pethidine

#### Class B includes:

Oral amfetamines  
Barbiturates  
Codeine  
Cannabis

#### Class C includes:

Most benzodiazepines  
Ketamine  
Zolpidem  
Androgenic and anabolic steroids

\* Includes Class B substances when prepared for injection.

classified as Schedule 2 and as such are subject to full controlled drug requirements.

### **Prevalence of recreational drug use**

On a global scale, approximately 5% of adults aged 15–64 years (208 million people) use recreational drugs on at least an annual basis and 2.6% (112 million people) use such drugs on at least a monthly basis [92]. In the UK, drug abuse is more common in men and in people under 25 years of age [93]. Approximately one-third of adults have used recreational drugs at least once in their lifetime and approximately 10% over the previous year [93]. Trends in recreational drug use have changed in recent years with a decline in the use of LSD and solvents and an increase in the use of amphetamine-type drugs and ketamine, particularly associated with the night-club and “rave” culture.

Data specifically about the use of recreational drugs by people with diabetes are sparse. Two uncontrolled questionnaire surveys of young adults with T1DM, one from the USA and one from the UK, have reported a similar prevalence and pattern of recreational drug use to that observed in the general population [94,95]. In the UK survey, approximately 30% of respondents had used recreational drugs, with cannabis (28.2% of respondents), amphetamine-type stimulants (13%) and cocaine (12%) being used most commonly [95]. Many (15% of respondents) used more than one drug. A report from Chile has suggested that use of recreational drugs was lower in school-aged adolescents with T1DM than in the general population (9.6% vs 22.2%), although this difference disappeared during later years at school [96]. The prevalence of recreational drug use in people with T2DM is low, which reflects the pattern in adults of similar age in the general population [97].

### **Impact of recreational drug use on diabetes**

In the Diabetes UK Cohort Study, acute metabolic complications (diabetic ketoacidosis and, to a lesser extent, severe hypoglycemia) were the most common causes of death in adults with T1DM under the age of 30 years, closely followed by accidents and violence [98]. In that study, a history of previous drug abuse was associated with a nearly sixfold increase risk of death from acute complications. Drug misuse has also been identified as a major cause of death in young people with T1DM [99]. Substance abuse co-occurring with mental illness is associated with a particularly high mortality [100].

### **Intravenous drug abuse**

Recreational drug use often disrupts normal lifestyle and a person with diabetes may abandon the daily routine of regular meals and insulin injections. Recreational drug use may also be only one aspect of a chaotic lifestyle associated with other high-risk behaviors. This can result from the use of any recreational drug, but intravenous drug abuse (particularly of opiates, but also amphetamines) is particularly damaging and is strongly associated with poor social support, criminality and mental illness. Intravenous drug use is uncommon in people with diabetes (as it is in the

general population), but is associated with omission of insulin therapy, frequent admissions to hospital and high mortality, both from diabetic ketoacidosis and deliberate or accidental opiate overdose [101]. Unsurprisingly, intravenous drug abusers with diabetes may also present with complications related to the route of drug administration: deep venous thrombosis and abscesses at groin or limb injection sites. Intravenous drug abusers often default from outpatient clinic attendance (this may be associated with imprisonment) and maintaining contact with such individuals is usually difficult.

### **Cocaine and amfetamines**

Cocaine and amphetamine-type stimulants can have dramatic effects on the cardiovascular system through activation of the sympathetic nervous system [102]. Cocaine is a sympathomimetic that inhibits reuptake of norepinephrine and dopamine at sympathetic nerve terminals. Amphetamine and ecstasy potentiate the release of norepinephrine, dopamine and serotonin from the central and autonomic nervous systems. Cocaine toxicity may be potentiated by cannabis, while amphetamine toxicity is enhanced by alcohol. Drug-induced sympathetic activation leads to tachycardia, vasoconstriction and hypertension. Myocardial ischemia and infarction, supraventricular and ventricular tachyarrhythmias, and severe hypotension can all occur. Prolonged use can result in a dilated cardiomyopathy. The sympathetic activation produced by these drugs antagonizes the action of insulin and cocaine use has been identified as an independent risk factor for diabetic ketoacidosis [103]. The risk of diabetic ketoacidosis may be increased by the omission of insulin before discos and parties to avoid the potential risk and embarrassment of hypoglycemia.

Ecstasy is also associated with severe hyponatremia, secondary to inappropriate secretion of antidiuretic hormone, which may complicate the management of diabetic ketoacidosis [95].

### **Cannabis**

Cannabis is not known to affect glucose metabolism but its effects on the central nervous system may increase appetite and impair recognition of hypoglycemia. Use of cannabis in low doses is associated with sympathetic activation and tachycardia; at high doses, parasympathetic activation may predominate, resulting in bradycardia and hypotension. In the absence of any structural heart disease, these effects are usually well tolerated.

### **Hypoglycemia**

While the association between recreational drug use and diabetic ketoacidosis is well established, there are few data suggesting any association with hypoglycemia. Such drugs, however, are often taken in conjunction with alcohol and may be associated with poor oral intake of carbohydrate both of which will increase the risk of hypoglycemia. Moreover, amphetamine-like stimulants can induce frenetic behavior at night clubs and raves which can induce hypoglycemia in people treated with insulin [104]. The

hallucinatory, or central nervous system, depressant effects of recreational drugs may impair an individual's ability to recognize and treat hypoglycemia. Furthermore, the sympathomimetic effects of cocaine and amphetamine-type stimulants may mimic the autonomic signs and symptoms of hypoglycemia.

### Advice on recreational drug use in diabetes

Illicit drugs cause significant morbidity and are hazardous for people with diabetes. Their dangers must be emphasized to people with T1DM (particularly teenagers and young adults), but advice must be given in a sensitive and non-judgmental manner. When exposed to recreational drugs and alcohol, modest reductions in insulin dosage and regular consumption of carbohydrate-based snacks or non-alcoholic sugary drinks are required, particularly if strenuous dancing is to be undertaken. In such situations, dehydration occurs and water should be drunk regularly.

---

## Travel

Diabetes must not be regarded as a bar to short or long-distance travel, although careful planning may be required to avoid metabolic disturbances and other problems of diabetes that could have particularly serious consequences away from home. Diet and an adequate fluid intake may be disrupted while traveling or staying abroad, and local differences in climate, food, endemic diseases and medical facilities may compromise diabetes control. Blood glucose levels should be monitored frequently during travel and holidays, and people with diabetes must be able to take a pragmatic approach to deal with contingencies (e.g. loss of insulin, delays during travel) that could perturb their diabetes. Occasionally, specific diabetic complications or other medical disorders such as uncontrolled hypertension or ischemic heart disease can jeopardize health and safety during travel and periods away from home.

### Preparation for travel

#### Personal identification

Travelers with diabetes should carry a doctor's letter stating the diagnosis and treatment, and ideally some other form of identification such as the "Medic Alert" bracelets or necklaces or "Medi-Tag" labels (these contain personalized medical information and are recognized worldwide). These should also allay the suspicions of airline security, immigration and customs officials who discover syringes and drugs in luggage. Many national diabetes associations provide an identification card that shows the patient's photograph, doctor's name and contact telephone number. Diabetes UK issues a card with the statement "I have type 1 diabetes" in five different languages.

If a prolonged stay abroad is intended, it is useful to carry a prescription letter listing all medications (with generic names, as brand names often vary between countries), insulin-injection devices and blood-testing items.

### Insurance and medical care abroad

Comprehensive medical insurance is essential to cover accidents and illness that require medical assistance, and loss of medical equipment and drugs. The insurance policy must cover diabetes and other pre-existing medical conditions, as claims relating to these may otherwise be rejected. Most travel policies contain exclusions, which frequently include diabetes; a person with diabetes may not be covered for conditions such as a stroke or myocardial infarction for which diabetes is a recognized risk factor. When appropriate, insurance must be adequate to cover any dangerous sporting activities (when hypoglycemia could be particularly hazardous), and the costs of emergency air transport home in the event of a serious accident or illness.

Most countries in the EU provide emergency medical attention free or at reduced rates to visitors from other member states, although immediate payment for treatment may be demanded in some countries, such as France. Travelers from the EU can obtain a form (E111) in their home country, which confirms their entitlement to this scheme, although full medical travel insurance is still recommended. Those planning to stay in an EU country for over 6 months will require an E112 form. Some non-EU countries (e.g. Australia and Russia) offer free or reduced-rate medical care for EU members. Details are given in leaflet SA30, obtainable from travel agents and government departments. In the USA, emergency medical treatment can be extremely expensive, and insurance premiums are correspondingly high. A list of insurers who do not load premiums against people with diabetes can be obtained from national diabetes associations.

Irrespective of medical insurance cover, it should be appreciated that emergency medical care available in some countries is suboptimal or even potentially dangerous for a diabetes-related emergency. In some parts of the world, insulin is not readily obtainable and intravenous fluids are in short supply. These considerations may influence the choice of holiday destination for people with diabetes.

### Drugs and equipment

Essential items for the diabetic traveller are listed in Table 24.6.

- *Immunization.* Routine recommendations should always be followed for the relevant destination. Occasionally, a severe reaction to a vaccine may cause a temporary rise in insulin requirements.
- *Medication.* Air travelers treated with insulin should carry an ample supply in their hand luggage. Preferably, another supply of medication should be carried by a relative or friend in case of loss or theft. When traveling by air, medication and blood monitoring equipment should not be consigned to the hold, because of the risk of losing luggage. During travel, insulin can be carried in an insulated cool bag or a pre-cooled vacuum flask. People on CSII should carry insulin pens as a back-up in case of pump failure and the contact details of the pump manufacturer so that a replacement can be ordered.

**Table 24.6** Checklist of essential items for travelers with insulin-treated diabetes.

**Documents**

Diabetes identity card/bracelet  
 Document stating diagnosis and treatment  
 Blood glucose monitoring diary

**Equipment**

Insulin vials or cartridges  
 Syringes and needles/pens and spare pen needles  
 Flask or cool bag for insulin storage  
 Blood glucose meter; spare meter and batteries  
 Finger pricker and spare lancets; container for used needles  
 Blood glucose strips (visual reading)

**Fluids**

Glucose free drinks (screw-top container)  
 Bottled water (plastic container)

**Hypoglycemia treatment**

Quick-acting carbohydrate:  
 • Glucose drinks (screw-top container)  
 • Glucose tablets/confectionery  
 Slow-acting carbohydrate:  
 • Biscuits or cereal bars

- *Blood glucose monitoring.* Extremes of temperature and high altitude can disable some blood glucose meters and affect the accuracy of blood glucose test strips, although the cabin pressure of passenger aircraft (equivalent to an altitude of up to 8000 feet) should not pose problems [105]. While on holiday, it is sensible to carry a spare meter and/or visually read glucose strips in case the meter fails.
- *Other considerations.* Those prone to motion sickness should take an anti-emetic to prevent nausea and vomiting from disrupting glycemic control. Antidiarrhoeal agents and a broad-spectrum antibiotic should be carried, particularly if traveling to regions with a high risk of acquiring gastroenteritis. People with peripheral sensory neuropathy should take comfortable and appropriate footwear for travel and for holiday use, as foot ulceration may be caused by wearing ill-fitting sandals or walking barefoot across rocks or even hot sand.

**Long flights and crossing time zones**

These pose several potential problems, ranging from the timing and composition of airline meals to ensuring that insulin dosages will cover the flight and adjust to local time on arrival.

**Meals**

Times of serving in-flight meals after take-off can usually be obtained from the airline. Meals can either be regarded as snacks or as main meals, depending on the travel schedule. Some airlines provide so-called “diabetic” meals but these are mainly intended

for people with T2DM and are small and low in carbohydrate [106], thus increasing the risk of hypoglycemia. Vegetarian meals may be more suitable for people with T1DM, as they often contain pasta-based dishes or rice. In-flight meals can be supplemented with the patient’s own supply of suitable carbohydrate, but it is impractical to carry large quantities, not least because of the limits of what foods may be imported into many countries. Allowance may have to be made for delayed flights or long intervals between meals, while fatigue or travel sickness may blunt appetite.

**Alcohol**

Drinking alcohol before and during air travel is best avoided because of the risk of hypoglycemia; also, the diuretic effects of alcohol favor dehydration, which has been implicated in deep venous thrombosis and pulmonary embolism during long-haul flights (although diabetes does not appear to confer greater risk) [107]. Water or non-alcoholic sugar-free drinks should be drunk liberally.

**Blood glucose**

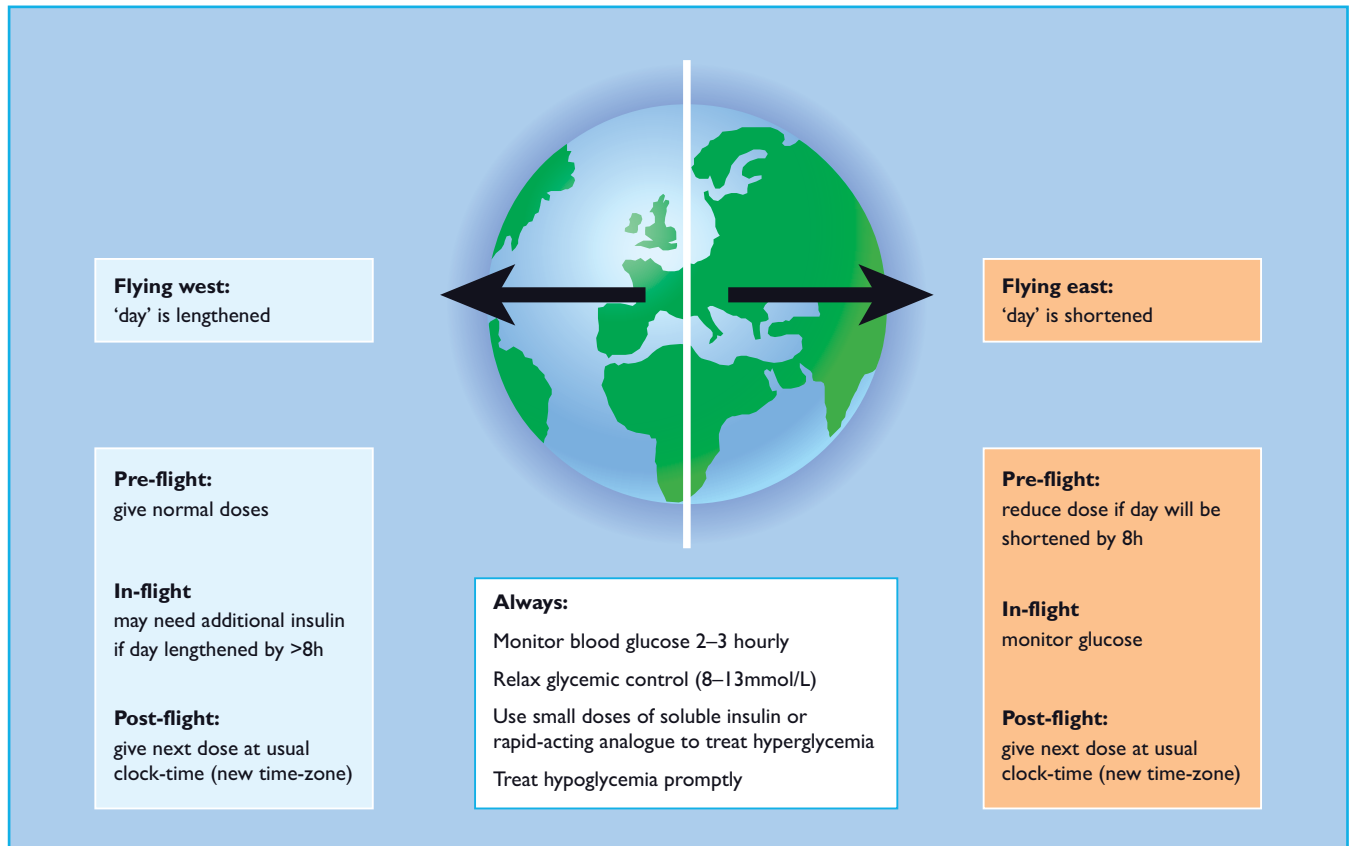

Blood glucose levels should be monitored frequently while in transit and when changing time zones. It is often safer to allow in-flight blood glucose values to be slightly higher than usual to avoid the risk of hypoglycemia.

**Insulin treatment**

There is no evidence-based information on how to adjust insulin dosages during flights that cross several time zones, and this probably accounts for the variability in the advice that is given [108]. Each case should be discussed individually with the patient, taking into account the duration of the flight and the change in time zone, the usual insulin preparations and dosages, the size and timing of meals, and the results of glucose monitoring. Some general guidelines are suggested in Table 24.7 and Fig. 24.4.

Guiding principles are:

- Do not aim for strict blood glucose control while flying. A few hours of mild or moderate hyperglycemia (e.g. 10–13 mmol/L) will do no harm and, as long as glucose levels are monitored regularly, it is safer to reduce usual insulin dose and use small additional insulin dosages rather than risk hypoglycemia.
- Blood glucose levels should be checked every 2–3 hours.
- Time changes of less than 4 hours in either direction usually need no major adjustment of the usual insulin schedule: simply give the next dose of insulin at its usual clock time, using the destination’s time zone.
- Westward flights lengthen the “day.” Give the next dose of delayed-acting or premixed insulin at its usual clock time (using the destination’s time zone) or adjust the insulin infusion rate using an insulin pump. If this injection is delayed by more than 12 hours, then additional insulin with food will be needed in the interim. The most convenient way to do this is with small doses (usually a few units) of soluble insulin or a rapid-acting analogue,

**Figure 24.4** Scheme for adjusting insulin dosages during flights that cross time zones.

**Table 24.7** Management of diabetes during long-distance air travel.

<p>Obtain advice from the diabetes clinic before traveling</p> <p>Obtain essential information, including the local time of departure, flight duration and local time of arrival</p> <p>Inform the airline that you have diabetes, especially if treated with insulin</p> <p>Carry extra supplies of carbohydrate</p> <p>Anticipate that delays may occur</p> <p>Time zone travel may necessitate two consecutive morning or evening insulin doses, before and after the flight</p> <p>Ensure that you can monitor your blood glucose frequently during travel</p> <p>Do not strive for meticulous control of blood glucose while traveling</p> <p>Adjust insulin doses if necessary</p>
--

injected every 4 hours or so on the basis of blood glucose measurements.

- Eastward flights shorten the “day.” The next dose of delayed-acting or premixed insulin should again be given at its usual clock time (destination time zone), but because this injection will effectively be earlier than usual, the previous dose of delayed-action insulin should be reduced if the interval between the injections is less than 12 hours.

- Extremely long flights with a time shift of 12 hours or more may require two “morning” or two “evening” insulin dosages to be injected consecutively, before and after the flight.
- Any additional insulin needed to fill in long gaps between delayed-action injections or to correct hyperglycemia is best given as small doses of soluble or a rapid-acting analogue, ideally using a pen injection device.

#### Oral antidiabetic agents

Additional doses are not usually required to cover an extended day.

#### Insulin treatment in hot climates

A patient’s insulin requirements may change markedly in different countries, the main factors being differences in diet and daily physical activity. Subcutaneous insulin absorption can be accelerated by high ambient temperatures, such as in a sauna (see Chapter 27), and this effect has variable clinical significance in very hot climates.

Modern formulations are quite stable, but sometimes denature if exposed to high temperatures and shaken; in this case, discolored particles or a granular appearance (distinct from the normal cloudiness of delayed-action preparations) may be seen
